When earth faults occur on a system the normal symmetry of the currents in a 3-phase feeder is upset, and in effect a single-phase current equal in value to the fault current flows through all feeders, sound and faulty, to the fault. This single-phase current induces voltages in all pilot wires lying near to the feeders. In one instance of which the authors have a record, this voltage amounted to 0·13 volt per ampere of fault current per mile. Where the pilots terminate in protective transformers having considerable capacity to earth, the voltages consequent upon a heavy earth fault may easily cause currents of sufficient magnitude to operate relays. It must be remembered, also, that the magnitude of these currents will be increased where fault currents have components of higher frequencies, because the voltages will be increased and the capacity reactances will be diminished.

Fig. 19.—" Translay " relay element.

In cases of earth fault, the returning fault current flows to a great extent along all metallic paths lying in the direction of the fault, and this includes all cable sheaths and armourings as well as pilot wires if these are earthed at one or both ends. For this reason it is necessary at both ends of the feeder to insulate from earth the secondary windings of balanced-voltage transformers. Even an earth connection at one end of the pilot wires may lead to wrong operation of relays, the path of the vagabond currents being completed through pilot-core capacity to earth. Here again the trouble is aggravated where higher-frequency components exist in the fault current. Safety can be assured and this trouble minimized by earthing one or both ends through spark-gaps either air- or paper-insulated, but care must be taken so to adjust the gaps that they do not break down at the maximum induced voltages met with in practice, which may attain high values during through-faults.

When a high-voltage cable is energized, as well as when a fault is cleared on the system, heavy charging currents flow momentarily and may assume abnormal values due to the distortion of the voltage wave-form. This is particularly the case at times of fault on the system due to the serious voltage fluctuation, and is equivalent to currents of frequencies higher than the normal. Unless steps are taken to prevent it, the resultant secondary currents may cause relay operation. This can be avoided by shunting the inductive winding of the relays by a non-inductive resistance which will tend to shunt a larger proportion of higher-frequency currents. Where these transient charging currents reach very large values, it may be necessary to use condensers also in shunt with the relay windings. The use of condensers without resistances is not to be recommended, owing to the danger of breakdown of the condenser insulation. Immunity from wrong operation due to this cause can also be obtained by the use of relays tuned electrically or mechanically to respond to the fundamental frequency only.

It will be seen from the foregoing that difficulties are met with in the application of balanced-voltage pilot-wire protective gear to high-voltage feeders, particularly where these feeders form part of extensive systems, and, with these difficulties in view, several new forms of balanced feeder protection have recently been developed. Two of these systems which are typical and which have been successfully tried out in practice will be briefly described. Both systems make use of ordinary current transformers without air-gaps, and, while one introduces a biasing arrangement to take care of variations in the current transformers, the other relies upon the current transformers having exactly similar characteristics to give stability on through-fault conditions.

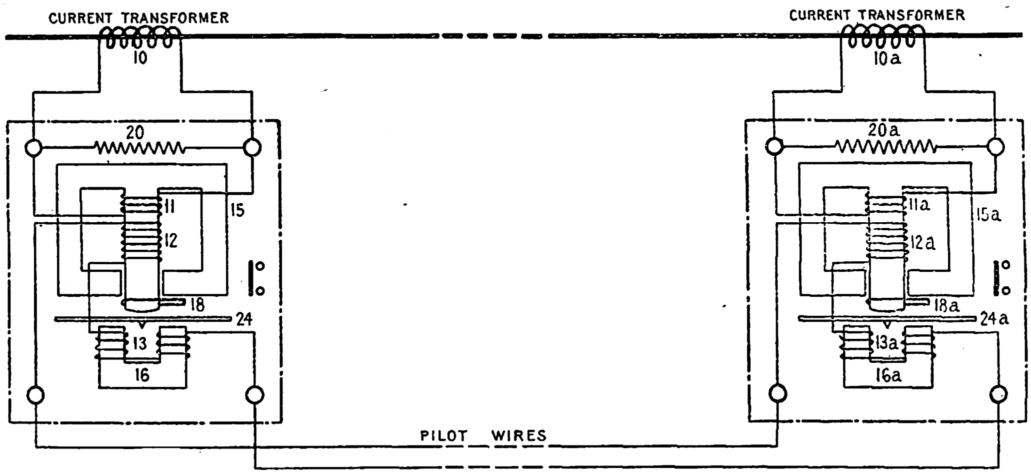

FIG. 20.—" Translay " protection for single-phase feeder.

" Translay " System.—The first of the two systems to be described has many novel features which are confined chiefly to the design of the relay. This is of the induction type instead of the electromagnetic type usually employed in pilot-wire schemes (see Fig. 19). The arrangement can be best explained by illustrating its application to a single-phase feeder as shown in Fig. 20. The relay primary winding is energized from the secondary of a current transformer, and in addition to setting up a leakage flux which, in conjunction with a suitable flux from the lower magnet, will cause the non-magnetic metal disc to rotate, it acts also as the primary of an air-gap transformer, causing a voltage to be generated in the secondary winding. The value of this secondary voltage depends upon the current flowing in the primary winding, and as the secondary windings of the relays at opposite ends of the feeder are connected in opposition through the pilot wires no current will flow in this circuit under normal operating conditions. If, however, owing to a fault on the feeder there is a discrepancy between the currents flowing at the two ends, the resultant difference between the secondary voltages will cause a current to flow in this circuit. This current will set up a flux which, by interaction with the leakage flux from the primary winding, will cause the relays to operate.

Several important advantages follow from this simple arrangement. In the first place, the necessary interaction between the fluxes only causes forward torque on the disc when their relative phase displacement lies between certain limits. An adjusting device is provided by which the phase of the leakage flux can be so adjusted that forward torque is only produced when the pilot current is in phase with or lagging behind the pilot voltage. Consequently any current flowing through the capacity of the pilot cables, which will lead the pilot voltage, can only exert backward torque on the disc. The necessity for pilot sheaths is thus avoided. Also, since the pilot current has to supply only a small portion of the energy necessary for relay operation, the pilot currents are only small, and heavy pilot wires are not necessary. A third advantage is that the insulation of the pilot circuit from the current-transformer secondary circuit permits the earthing of the current-transformer secondary windings at both ends of the feeder without danger of untoward operation. Further, owing to the small pilot currents the voltages set up in the secondary winding need only be small, with important resultant economy in pilot-cable insulation.

Since in many cases it may be necessary to employ current transformers of slightly different characteristics at the two ends of the line, it has been deemed advisable to incorporate a bias device in the relay. The bias is obtained by an asymmetrical arrangement of the adjusting winding. This sets up a backward torque on the disc, this torque being the greatest when the flux in the electromagnet is large, which is the condition of through fault, and this is sufficient to overcome any small forward torque due to slight out-of-balance between the transformers at the two ends. In case of fault, however, the resultant secondary back ampere-turns on the electromagnet reduce the main flux and consequently the bias, leaving the relays free to be operated by the out-of-balance secondary current.

As a further precaution against operation under transient conditions the relay is given a slight inverse-time characteristic, which rapidly approaches 0·1 sec. for faults exceeding three times the setting; also the provision of non-inductive shunts across the primary and secondary windings renders the relay less sensitive for currents of frequencies higher than the normal. Where special circumstances make it desirable, a frequency filter circuit can be added which renders the relays inoperative at 80 cycles and above.

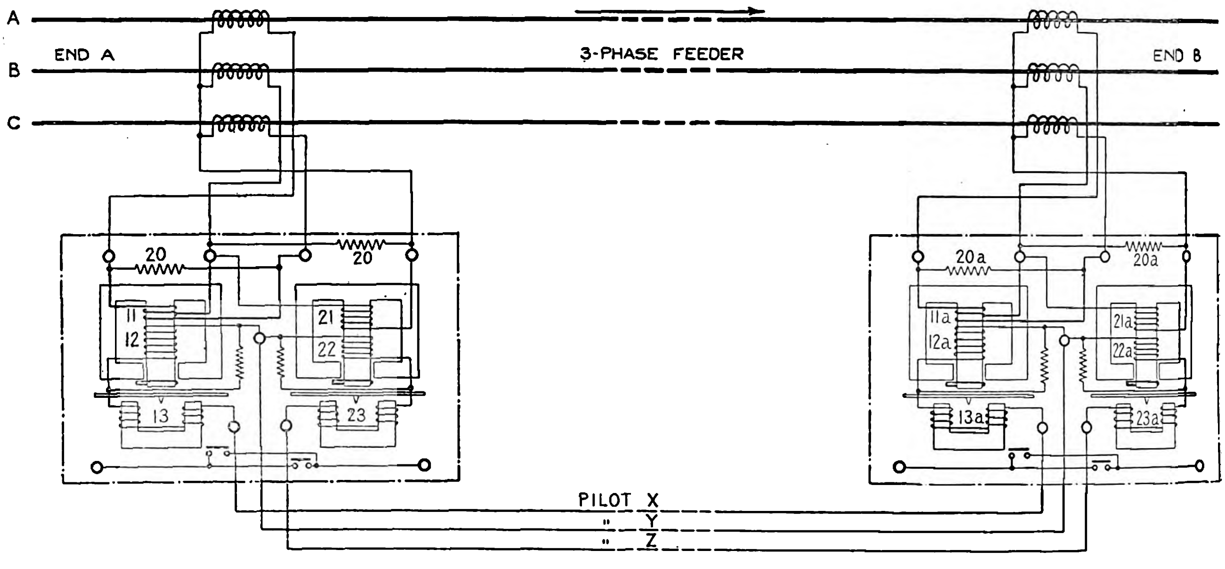

Fig. 21.—Three-phase protection—" Translay " system.

When applying this type of gear to 3-phase feeders, protection against earth faults can be obtained by the use of a single relay element, as already described, at each end, the operating coils being energized from the residual current of the current transformers (see Fig. 21).

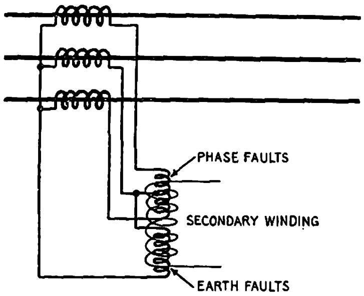

Fig. 22.—Diagram illustrating summation of 3-phase currents for protective relays.

For protection against phase faults, the phase currents at each end are summed in a second element. The two earth-fault elements and the two phase-fault elements are separately balanced through the medium of three pilot wires, one of these being common to the two pairs of elements.

In the choice of a method of obtaining an energizing current for the phase-fault elements, many methods have been considered, and that adopted is shown in greater detail in Fig. 22. Under normal conditions a small effective magnetizing current built up from the red and blue phases flows, but under fault conditions this is completely swamped by the fault current. This arrangement has the advantages that the variation in sensitiveness for faults in the various phases is never more than 2 : 1, that under no conditions do the magnetizing currents cancel one another out, and also that the secondary burden on the current transformers can be kept low. For a fault between outer phases the whole coil is energized, whilst for a phase fault between either outer phase and the centre phase one of the half coils will be energized. A symmetrical 3-phase fault produces an effect between these two.

It has been found feasible to operate such relays with earth settings of 30 per cent of full load of the current transformers. Phase-fault settings should preferably be higher, and these can be chosen to suit conditions. The actual fault settings obtainable vary slightly with the resistance of the pilot wires. Throughout the normal range of pilot loop resistance, say up to 500 ohms, the variation of minimum setting is only 30 to 50 per cent. The setting is, as already described, a function of the normal full load of the feeder, and, subject to the usual limitations of current transformers, settings can be made proportionately smaller on small feeders. These settings compare very favourably indeed with the settings obtainable with older types of gear.

An alternative arrangement employs one relay element at each end and a pilot cable having two cores only. In this case the earth-fault coil is wound on the same core as the phase-fault windings, and consists of a larger number of turns than either of the latter. Sensitive earth-fault settings are thus afforded in addition to phase-fault protection by means of two pilot wires only and one single-element relay at each end of a 3-phase feeder. The limitations to this arrangement are that the setting for earth faults cannot be varied independently of the phase-fault settings, and in general less sensitive settings are obtained. The arrangement is shown in Fig. 19.

Self-compensated System.—This method also employs pilot wires but is a circulating-current system and not a balanced-voltage system, and the general arrangement is illustrated in Fig. 23. The current transformers at either end of the feeder are employed to energize a summation transformer which has primary windings arranged on the principle already described (see Fig. 22). The iron circuits of the current transformers and summation-transformer are liberally designed so that saturation will not be reached with the burden due to the impedance of the pilots up to the maximum through-current anticipated. As a result of this a circulating current will flow through the two outer pilots, this being of the order of 0·3 ampere at full load. The two single-pole relays situated one at each end of the feeder are connected in series with each other through the third pilot core between two equipotential points on the circulating-current system.

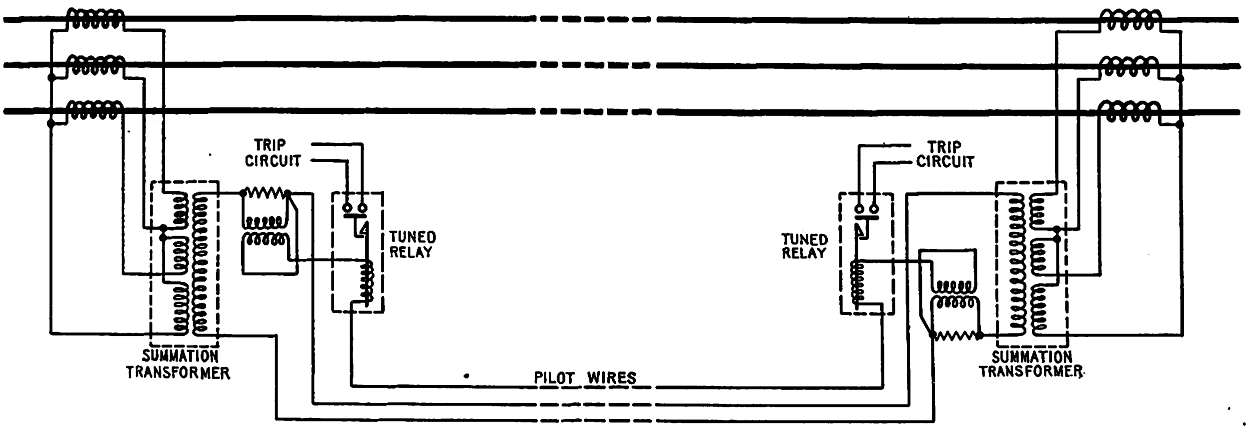

FIG. 23.—Theoretical diagram of self-compensated feeder protective gear.

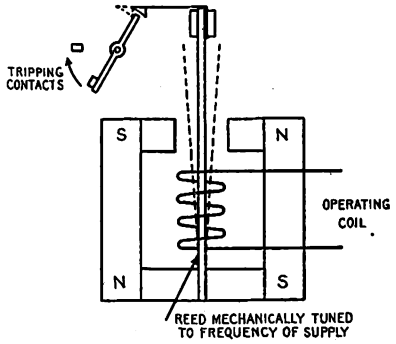

FIG. 24.—Principle of tuned-reed relay.

This simple arrangement requires two modifications to guard against incorrect operation due to capacity currents in the pilot wires and to high-frequency transient currents. The first consists of a device to maintain the potential of the relay pilot core always midway between those of the outer cores. This is done by the inclusion of a resistor in series with one of the circulating-current pilot wires and having a resistance a predetermined fraction of the pilot resistance. The voltage-drop across the resistance is multiplied by a small voltage transformer to represent the voltage-drop in half one pilot and is then applied to the relay pilot core. The two ends of the centre core are thus held at the potential of the centre points of the outer pilots, and the capacity charging currents flowing to and from the relay pilot core will neutralize each other.

To render this gear immune from operation consequent upon high-frequency disturbances, a special relay is used which, by mechanical tuning, is rendered comparatively insensitive to currents of frequencies other than the fundamental frequency of the system.

Details of the relay can be followed by reference to Fig. 24. The magnetic reed is so designed that its natural frequency of vibration is the same as the system frequency. It is polarized by a permanent magnet, and when currents of the correct frequency energize the two operating coils the reed responds and releases a catch which permits the contacts to close. The response of the relay to frequencies other than the normal is shown in Fig. 25. After operation the relay must be reset by hand before the circuit breaker can be reclosed.

D.C. Pilot-Wire Methods.

As an alternative to balanced systems, there are now several systems which employ pilot wires to operate, by direct current, relays for locking or tripping. These systems have the advantages that balancing of the protective apparatus at the two ends of a feeder is not necessary, and if suitable relays are used it is also possible in some cases to use an earth return and so save a pilot conductor. Alternatively, the fact that pilots carry only direct current permits the use of standard pairs in telephone cables without any possibility of interference taking place.

PHASE FAULT ELEMENTS
EARTH FAULT ELEMENT

Fig. 29.—Combined phase- and earth-fault relay for d.c. pilot-wire balance system.

One of the earliest of these systems was due to Mr. C. E. Longfield and belongs to the "locking" class. In effect the system as applied, for instance, to a radial feeder comprises an overload relay at each switch in the sequence, which operates to energize a pilot circuit instantaneously and the tripping circuit of the switch after a short time-interval. The pilot circuit operates a locking relay at the preceding substation nearer the power source to prevent the completion of the tripping function at that point (see Fig. 26). The only relay able to complete the tripping function is therefore the relay nearest the fault, which is cleared after a delay not exceeding 0·1 sec., wherever the fault may be upon the system. The time-lag need only be long enough to allow for the operation of the very rapid locking relay before the tripping contacts close.

The design of a relay suitable for use on a ring main or in any other situation where a directional relay is necessary, is illustrated in Fig. 27. The method of combining the overload and directional features is similar to that already described for overcurrent directional relays, and the locking feature is obtained by the introduction of the normally closed contacts of the locking relay in series with the tripping contacts of the fault relay. The pilot-energizing contacts are normally held open by the resetting torque of the induction disc, and they close immediately this begins to move forward.

Another system of this kind operating on the tripping principle instead of the "locking" principle is illustrated in Fig. 28. In this instance the direct current is passed through the pilot wire and operates d.c. relays whenever the flow of fault power at the two ends of the feeder is in opposite directions, or whenever fault power flows in at one end only. Directional overcurrent a.c. relays are, of course, necessary to indicate the direction of fault power, and if a single pilot circuit is used in protecting a 3-phase feeder these relays must be of special design because it is necessary that the relay should sum up the 3-phase power at each end and operate a single contact. It is not permissible to connect the contacts of separate phase relays in parallel as this might result in the relays in healthy phases operating in the reverse direction to those in the faulty phase. A special directional relay (see Fig. 29) is therefore required for this purpose. It will be seen that the relay consists of three wattmeter elements, the moving portions of which are mounted on a common shaft which also carries the moving contact. The two upper elements are connected in the well-known two-wattmeter method and the bottom element is connected as a directional leakage relay, but is wound to produce a higher torque for a given current than the two upper elements. The upper elements will therefore indicate the flow of power on short-circuits between phases, and the lower element will indicate the flow of power for faults between any phase and earth.

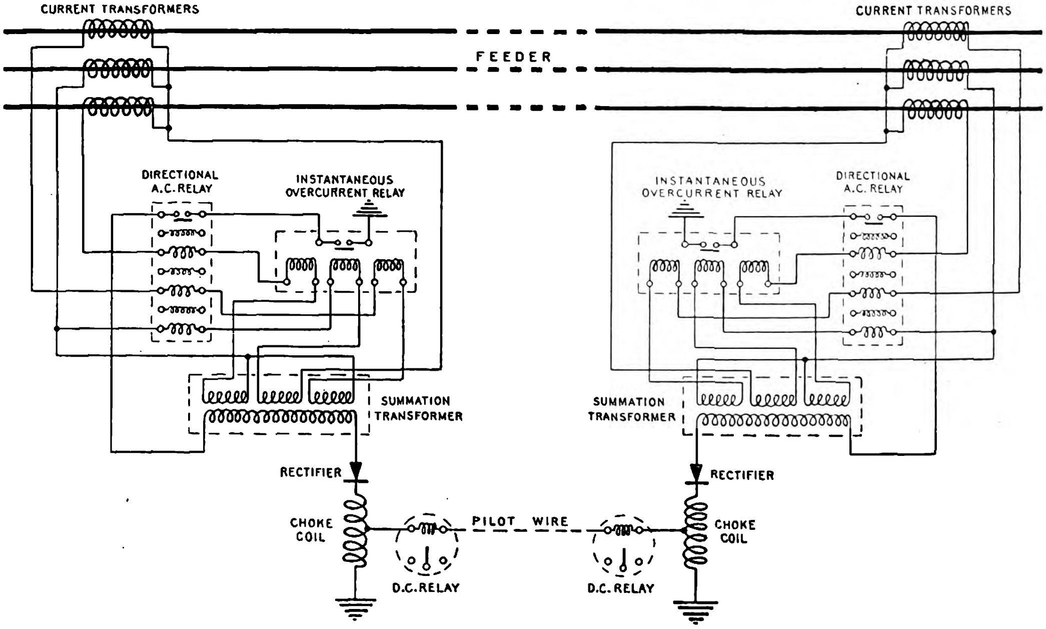

FIG. 30.—Theoretical diagram of d.c. pilot-wire balance scheme.

The application of this relay to the protective scheme may be followed from Fig. 28, from which it will be seen that its contacts are so arranged that when closed they complete a circuit from a suitable battery through a choke coil, the mid-point of which is connected to the pilot wire and one end of which is connected to earth. The choke coils are necessary to prevent excessive alternating current flowing through the pilot relay due to any difference in potential between the earth connections at each end during heavy earth faults. Such currents, although they would not operate the d.c. relays, might damage them by excessive heating.

The operation of the scheme is as follows: Through faults in a direction to close the contacts of both directional relays would result in both batteries—which must have approximately equal voltages—being connected in opposition through the choke coils and pilot wire. This would result in little or no current flowing through the pilot wire and pilot relays, and the latter would remain inoperative, whereas faults on the feeder would cause one of the directional a.c. relays to close its contacts and the other a.c. relay to open its contacts, which condition would allow direct current to flow through the pilot circuit and operate both pilot relays, to trip both circuit breakers.

A further development of the scheme is to use rectifiers to provide the direct current for operating the pilot relays. This has the advantage that batteries of equal voltage are no longer necessary, because the direct current for the pilot circuit is supplied from the protective transformers through the rectifiers. The connections for a feeder are shown in Fig. 30, from which it will be seen that a small summation transformer, so arranged that there will always be a secondary voltage derived from the fault current on any phase, is used to obtain the a.c. voltage for the rectifier. This transformer is designed to saturate at about four times the minimum fault-setting, which assures that the d.c. voltages at each end of the feeder will always be approximately equal, even when the protective current transformers have dissimilar characteristics.

The rectifier must be of a type which starts to rectify immediately the a.c. supply is applied to it. Such a rectifier is the copper-oxide type, which has proved to be very reliable in service and is largely used for railway signal purposes. The saturated summation transformer prevents an over-voltage being applied which might break down the rectifying copper-oxide film, and, moreover, as the rectifiers are connected to the supply only during fault conditions, they will be practically everlasting.

Little operating experience has yet been obtained with interlocking schemes such as these, but several experimental installations have been made. It is possible that in the future there will be a wide field of application, especially on long lines or feeders, for schemes of this general type, and further developments are to be anticipated.

Balanced Protection for Parallel Feeders.

Whenever two or more similar feeders are connected to a common busbar at each end, it is possible to employ an instantaneous unit protective equipment of the balanced type without pilot wires. This form of protection has many advantages and well deserves the consideration of supply authorities.

An equipment comprises differential relays connected to current transformers associated with corresponding phases of two feeders, the principle being the simple comparison of the currents in the feeders. The relay remains inoperative until the balance of currents is disturbed by a fault on either feeder, when the difference is effective to energize the relay to cut off the faulty feeder.

In the case of two dead-ended parallel feeders, the fault current passing to a fault in the immediate neighbourhood of the "receiving" substation may have two paths of nearly equal impedance, so that the difference in the feeder currents is insufficient to cause relay operation at the outgoing end. At the receiving end, however, the fault power flows in opposite directions in the two feeders, and, by using relays with a sensitive directional element at that end, advantage can be taken of this condition to trip the circuit breaker at the receiving end immediately a fault occurs, thus leaving only a single path through the faulty feeder for the fault current. The difference is then a maximum at the outgoing end, and operation of the relay follows immediately on the clearing of the receiving end. If directional relays are arranged for overload and sensitive earth leakage, the potential coil of the leakage relay must be energized according to one of the methods already described for directional leakage relays.

What may be classed as a limitation of this form of protection is that its satisfactory operation involves vigilance on the part of station operators to ensure that the circuit breakers at both ends are opened whenever a feeder is taken out of commission. The reason for this is that auxiliary switches on the oil circuit-breakers are generally used to disconnect the differential relays when the balance is disturbed owing to one of the associated feeders being unloaded; and to leave a circuit breaker closed at one end may result in wrong operation of the

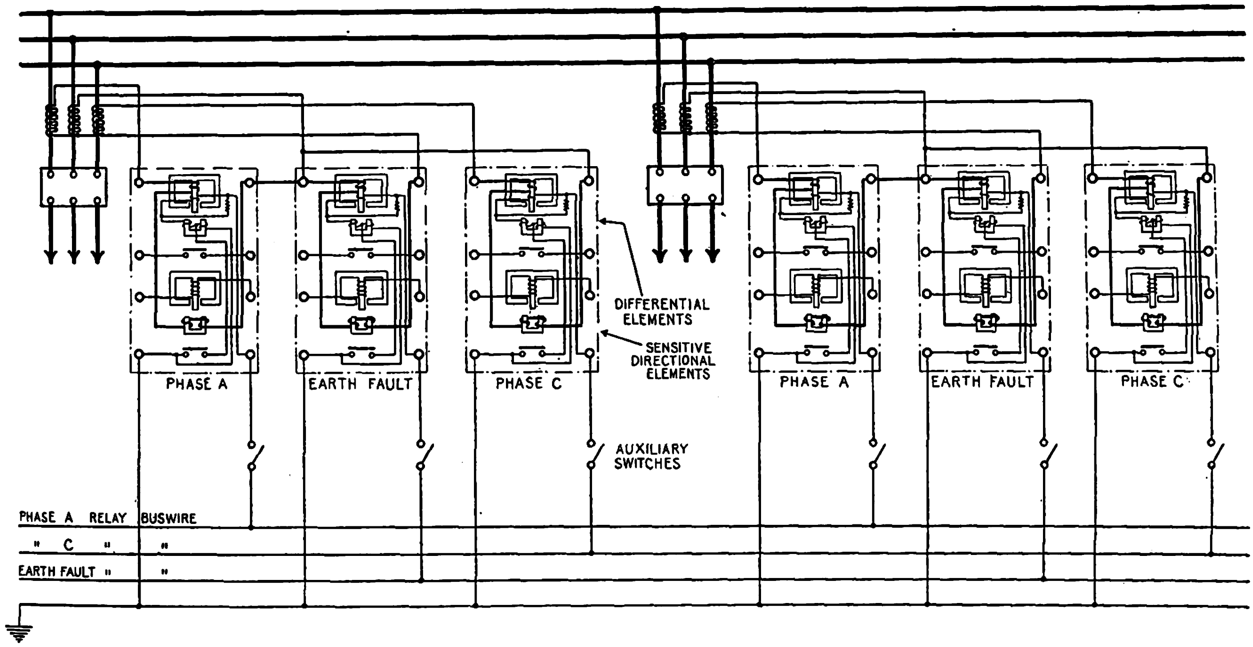

Fig. 31.—"Translay" parallel-feeder protection for phase and earth faults.

relays, with consequent tripping of the healthy feeder at times of fault on other sections of the system.

In the event of settings equivalent to full load or less being necessary, they can be obtained for earth faults only, by connecting one pole of the balanced relay to be operated by the residual currents of the current transformers in the feeders. Any convenient settings for earth faults can then be chosen. With such an arrangement it is possible to carry out switching operations without danger of incorrectly tripping loaded feeders under normal load conditions, since although the phase-fault relays tend to operate before the incoming feeder picks up its load the high setting would prevent the contacts from closing; whilst the earth-fault relay with a lower setting will remain stable because no current will flow through either of its coils under healthy conditions.

In applying such protective gear to parallel feeders it has been the custom to group feeders in sets of two or three. A recent development has made it possible to employ larger groups, with considerable gain in flexibility. This is illustrated in Fig. 31, which shows the application of differential directional relays to a group of similar feeders, the relays being arranged for phase-fault and sensitive earth-fault protection.

The differential elements of the relays are similar in type to the Translay relays already described for pilot-wire feeder protection, but the secondary voltages of all the relays associated with similar phases of the various feeders are connected to a common wire, and the two coils of the operating magnet are connected in opposition. So long as equal primary currents flow in the various feeders, equal voltages will be generated in all the secondary windings and the relays will remain stable. During through faults the stability of the relays will be assisted by the biasing arrangement just as in the case of Translay pilot-wire feeder relays. Owing to the arrangement of the operating magnet coils, no relay can operate under any conditions unless power flows into the feeder, thus causing the contacts of the directional element to short-circuit one of the two opposing coils.

In the case of a fault on one feeder when the group is carrying load away from the busbars, the secondary voltage of the corresponding relay will be increased and the resultant secondary current will cause that relay to trip. The same current returns through the secondary windings of relays on other feeders and will give a stabilizing torque to those relays. In the event of a fault on one feeder when all are carrying load towards the busbars, the reversal of the secondary voltage of one relay would tend to operate all relays, but since the lower operating coils of all relays of healthy feeders can produce no flux (the two coils of each relay being in opposition) only the relay of the faulty feeder, in which one of the coils is short-circuited by the directional element contacts, can operate, so that the faulty feeder will be correctly isolated.

In conclusion, the authors would emphasize that it is possible, by a correct choice from the various systems described in this paper and others of generally similar types, to obtain stable and discriminative protection of feeders even under the most difficult conditions obtaining to-day, so that the art of protection may truly be said to have overtaken the present demands made upon it. In the future new requirements, some already envisaged, will no doubt arise, and the limits of application of even these methods may be reached, but we may safely anticipate that any new requirements can again be met as they arise, and that protective problems will not constitute a limiting factor in the development of transmission systems.

The authors wish to acknowledge assistance received from colleagues, and their indebtedness to the Metropolitan-Vickers Electrical Co., Ltd., for permission to publish details of apparatus of their manufacture, and to the British Thomson-Houston Co. for details of self-compensated gear.

APPENDIX.

(*Received* 6*th June*, 1930.)

As there is a difference of opinion as to the effect of arc resistance upon the performance of impedance relays it will no doubt be of interest to engineers to include, in the form of an Appendix, extracts from a description of a recent research on this subject. The research was carried out at the instigation of the authors and the results indicate that the resistance of an arc is so low that, for all practical purposes, its effect on the behaviour of impedance relays may be neglected.

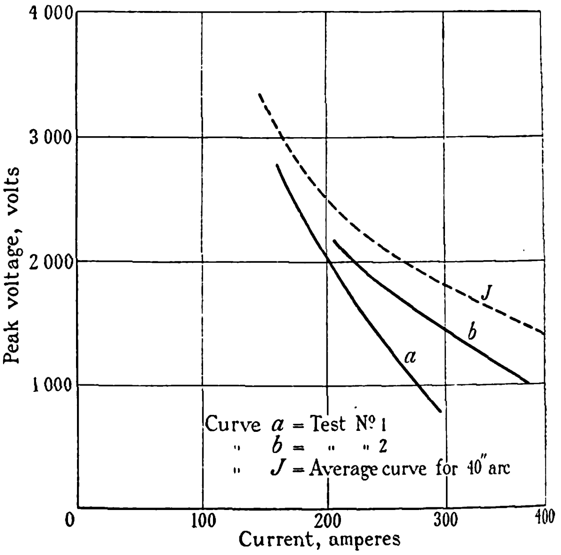

FIG. 32.—Curves for 15-in. arc; also average curve for 40-in. arc.

In order that the results of the tests should be as comprehensive as possible, arcs were struck across a pin-type insulator suitable for 33-kV lines and also across a string of insulators as used on 132-kV lines. In the latter case the insulators were fitted with arcing tips and galvanized-iron rings, and tests were made with the strings mounted (*a*) horizontally and (*b*) vertically.

The approximate length of the arc in the case of the pin-type insulators was 15 in. and 40 in. in the case of the 132-kV type.

Seven different tests were carried out with varying conditions, particulars of which are given in the table. The curves in Figs. 32 and 33 have been plotted to indicate the results, and the values from which the curves are plotted are the instantaneous values of voltage and current obtained from oscillograms. It should be noted that each curve represents the average of a series of values recorded for a particular condition. There is actually a dispersion of about ± 30 per cent about the mean curve, although the majority of the points were within 10 per cent of the mean.

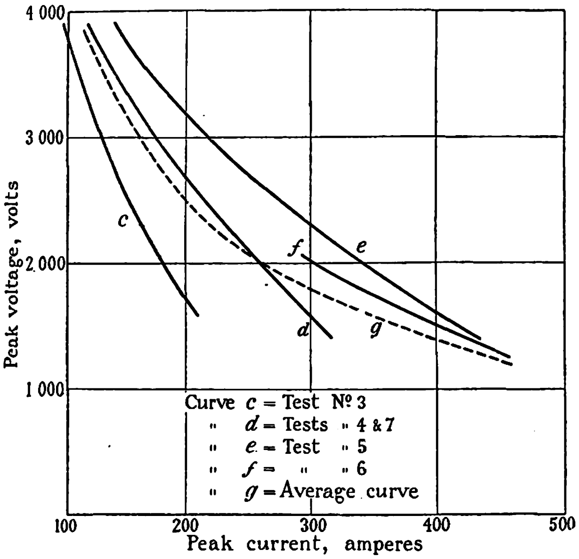

FIG. 33.—Curves for 40-in. arc.

The current was supplied by an alternator of 2 500 kW capacity through a 3 000-kVA transformer giving a secondary voltage of 6 000 volts. An adjustable resistance, connected in series with the arc, limited the current to a convenient value.

Table giving particulars of the Tests.

Test No.	R.M.S. line voltage	Value of limiting resistance	Length of arc	Position of insulator
	volts	ohms	in.	
1	3 230	15·2	15	Vertical
2	4 480	15·2	15	Vertical
3	4 700	20·3	40	Horizontal
4	5 200	20·3	40	Horizontal
5	5 470	15·2	40	Horizontal
6	5 470	15·2	40	Vertical
7	3 520	15·2	40	Vertical

On analysis the oscillograms show fairly smooth curves of peak voltage against peak current. It will be seen from the general shape that the voltage-drop across the arc is in inverse ratio to the arc current, and that for the larger values of current the resistance is comparatively low and will therefore have a negligible effect upon the impedance of the line.

A comparison of the values for the 15-in. arc with those for the 40-in. shows that there is no great variation of resistance with arc length.

The authors wish to express their thanks to Messrs. Metropolitan-Vickers Electrical Co., Ltd., for permission to publish these results.

DISCUSSION BEFORE THE INSTITUTION, 9TH JANUARY, 1930.

Lieut.-Col. K. Edgcumbe: I am glad to see that the authors emphasize the value of the "distance" relay. I am sure that this form of protection has a great future before it, particularly for overhead lines where the cost of pilots is usually prohibitive. I agree with the authors in their preference for the impedance as opposed to the reactance principle, for such relays. The idea underlying the use of reactance relays is that the high-voltage arc behaves as a true ohmic resistance, so that the fault current flows through the reactance of the line in series with the resistance of the arc. Consequently, a relay sensitive to reactance only should be able to pick out the reactance component due to the line, whilst taking no account of the resistance component due to the arc. Unfortunately, experience shows that whilst the resistance of the high-voltage arc is negligible for currents exceeding 200 or 300 amperes, it may amount to as much as 100 to 200 ohms at currents of 100 amperes or less. It must be remembered that the impedance of the line is possibly less than 10 ohms, and it would tax the capabilities of even a sensitive laboratory wattmeter to pick out an inductance "swamped" by an ohmic resistance of more than 20 times its value. It is clearly impossible for a robust protective relay to do so. In my view, therefore, the effect of the resistance of the arc can be neglected at all fault currents likely to be met with in practice, and for abnormally low fault currents no form of distance relay, whether of the impedance or reactance type, can be relied upon. Consequently, the extra complication and delicacy of the reactance pattern is certainly not justified. It may further be pointed out that where the fault is close to the relay the arc resistance tends to keep up the voltage, a fact which is of considerable advantage in the case of the impedance relay but is of no value in that of the reactance relay, which suffers accordingly. The authors' suggested method of compensating for arc resistance is not clear to me. As I understand it, their proposal amounts to deducting, at all currents, an almost constant resistance from that of the line. But the resistance of the arc increases rapidly, as I have said, at small currents. It would, in fact, seem more logical to deduct a constant voltage rather than a constant resistance. This could well be done, in the case of the relay shown in Fig. 11, by giving the attracted iron armature a definite bias away from the poles by means of a spring, for example. In my view, however, no such precautions are necessary and the arc resistance can be neglected. The authors express the opinion that the most satisfactory form of time-lag overload relay is one with an inverse time-characteristic tending to a definite minimum value at high currents. As to the necessity for a definite minimum, I am in agreement with them, but it is, I think, doubtful whether under modern conditions the inverse characteristic is of any value. The old idea that a small overload should be allowed a longer time than a heavier one in which to clear itself seems to me to be out-of-date. Fault currents do not behave in this convenient way and in 99 cases out of 100 they almost instantly reach such a high value that the sooner they are cleared the better. Consequently, the relay should operate within a definite time, the exact value of which has been predetermined to meet the special requirements of the system. In this respect, very much closer accuracy is attainable with the definite time-lag relay than with one of the combined inverse and definite minimum time-lag type; an accuracy of timing of 2 per cent is quite easily obtained with the definite time-lag pattern.

Major A. M. Taylor: My remarks will apply to underground cables rather than to overhead lines. Consideration must be given to the protection of long super-tension underground trunks, such, for example, as the 10-mile main underground trunks which are connected to the Hams Hall station, Birmingham. On such lines freedom from interruption due to surges, high-frequency charging currents and magnetizing currents demands attention. The question of freedom from operation by the 3rd and 9th harmonics, etc., is also very important. In my opinion, the arrangement shown in Fig. 21 would fail to distinguish high-frequency and triple-frequency charging currents in the trunk line from fault currents. Such currents are produced when something unforeseen occurs at a generating station at one end. It is possible that a generator may be put in without a field, so that oscillations of great force and rapidly varying frequency are set up in the line. The practice of having a current transformer at either end of the transmission line, and balancing the one against the other, cannot take account of the capacitance currents. In the case of a 6-phase system or of two 3-phase feeders with one of the phases reversed, it is possible, by means of a suitable arrangement,* to balance *everything* except the fault current. When the transformers are thus suitably connected the relays can be set to very close limits; pilot wires and their troubles are eliminated, and the earth fault is the only point which requires attention. In Birmingham, leakage protective gear has been installed at either end; it was thought that the system would be satisfactory, particularly because S.L.-type cables were being used. There is no doubt, however, that charging currents and harmonics are capable of operating the relay. I know of no relay at present on the market which would give the desired security and allow of the fault setting being reduced to, say, 5 per cent. A device which will remove the fault on a single-core cable immediately it occurs, and before it burns through sufficiently to heat the next cable, is urgently needed.

Mr. F. J. Lane: This paper describes, under the section dealing with pilot-wire protective gear, three different methods of attacking the problem of the provision of balanced protection by means of current transformers. The first is the Merz-Price or balanced-voltage system, the second is the Translay system and the third the self-compensated pilot-wire system. In considering this subject it is important to remember that the ampere-turns input of a current transformer is equal to the sum of the ampere-turns output and the ampere-turns used for magnetization. Thus, if the burden is increased and the input remains constant, the output decreases because more ampere-turns are required for magnetization purposes. In the balanced-voltage system the current transformers are being used entirely to produce voltage; in other words the ampere-turns are completely absorbed as magnetization ampere-turns. It is consequently essential that the magnetic characteristics of the transformers concerned in the balance should follow each other very closely. The curves and the illustration of the opposed-voltage transformer which have been shown have emphasized the precautions necessary. These precautions include very careful design, a multi-gap arrangement to prevent interference from external iron, special methods of assembly and, finally, very accurate balancing in the laboratory. Thus, in the opposed-voltage system, the magnetizing characteristics are the criteria of balance. The Translay system also makes use of the opposed-voltage principle. It is so arranged that it is permissible, within certain limits, to take any pair of current transformers and to employ them at opposite ends of the balanced circuit, since the bias feature will prevent any instability arising from small inherent differences. This system is an important advance in that it permits the use of the ring-core type of current transformer without air-gaps, thereby reducing the magnitude of the magnetization quantities. Such quantities are still important, however, for without the feature of bias accurate balance would still be necessary to ensure stability. If the magnetization quantities can be reduced so that they are not in themselves of sufficient magnitude to produce operation of the protective relays, differences between these quantities are of negligible importance; the difficulties met with in providing special balanced transformers or a biased form of relay then disappear. One of the essential features of the self-compensated pilot-wire arrangement is that it comprises a circulating-current circuit in which the magnetizing losses have been reduced to quantities of the second order of magnitude. The current transformers are of the ring-core type. Pilot currents, iron circuits, and primary ampere-turns have been so chosen that the magnetizing characteristics are negligible with respect to the relay-operating current. Thus, even with considerable variations in the iron or the secondary burden, no unstable operation is experienced. In the systems described there are, therefore, three different methods of dealing with the magnetization quantities. Balanced-voltage systems require very careful design and accurate balance. The Translay system reduces the magnitude of the quantities, but depends on the bias feature as an alternative to balancing. The self-compensated pilot-wire system reduces the quantities to a negligible order of magnitude so that differences between them cannot disturb the stability.

Mr. H. W. Clothier: I am in agreement with the authors upon the main issues of their paper. Whilst overload, parallel feeder and time-limit systems of protection are satisfactory, up to a point, for the protection of small plant, unimportant feeders and connections, the necessities of maximum efficiency in the maintenance of continuity of supply on the present-day large networks and all-ring mains involve the use of one of the reliable pilot-wire systems of protection. Where, however, the cost of pilot wires is excessive (as for long overhead lines), the improved British designs of pilotless time-distance protection provide a good substitute. The Merz-Price balanced system will always hold the preference because of its simplicity, absence of potential element, and short time-characteristic or so-called instantaneous operation, although in this last respect the performance of the pilotless system now approaches very nearly to that of the Merz-Price type over the major length of the feeder protected. It may not be generally realized that it is now 25 years since the original Merz-Price voltage-balance feeder and current-balance transformer types of protection were put into practical operation. The plans for the British grid, which have been under consideration by so many authorities, have recently had an important effect upon the designs of relays; many new ideas, as well as revivals of earlier ones, have been given serious attention. The paper is very complete in its description of some of these, but three systems which are established in production and are at least of equal importance have been omitted. These are (1) the Split pilot, (2) Interlock and (3) Ratio balance systems.* The first is purely a Merz-Price current-balance feeder system and it retains the ideal of easily-measured current values in balance. Stability on through faults is secured by the known principles of split-conductor and self-balance protection. It is used with the ordinary 3-core pilot cable. The second requires only the momentary use of an ordinary telephone pair. It is a unit system which combines the use of directional relays with time-limit overload relays at each end, and uses the lock-out principle to prevent operation on through overload current, the lock-out being effected by the d.c. current signals. The third is the time-distance type of protection in which the time function is regulated by separate clockwork mechanism. The relays are of the reactive type, when used on overhead lines, so that the resistance of the arc does not affect the correct measurement of the distance of the fault. The selection of one or other of these three systems satisfies any conditions and provides, in each case, a comprehensive unit protection—that is to say a faulty line is isolated without interference with sound lines under all the conditions of service which have yet been experienced. I agree with the authors regarding the design of transformers of the multi-air-gap type, as shown in Fig. 16, although such equipment can hardly claim, at this stage, a place among recent developments. The voltage characteristic and general design correspond to the 4-gap transformers of which there are many thousands in use, and presumably the new 8-gap transformer will balance reasonably well against the old standards, which have a similar (Fig. 17) straight-line characteristic up to 10 000 amperes, or thereabouts. The wattmeter-type relay used in pilot-wire protection was also tried many years ago because in theory it was not operated by pilot-wire capacity currents, but it never came into extensive use in practice. In Translay protection the special air-gap transformer is eliminated in favour of solid-core instruments, compensation for the resultant poor balance being provided by the old method of increasing fault setting on the bias principle. There is no mention in the paper of how the difficulties which led to the abandonment of wattmeter-type relays have been overcome in the present Translay protection. Apart from the details, there is the main difficulty of discriminating by phase-angle displacements and even of measuring the latter, particularly when in service. The original basis of Merz-Price protection lay solely in the balance of easily-measured current values, and the alternative split-pilot system, because it retains this feature and the other ideal features of Merz-Price protection, seems to satisfy in a better form the authors' plea for stability. The split-pilot system is one of self-balance and it incorporates the ideal characteristics of split conductor and self-balance protection. Would the authors find any difficulty in protecting a line with a T-connection, on the Translay plan? The modern call is for the use of telephone pairs, and assuming that this is theoretically possible on the Translay system because of the small amount of energy necessary for operation over the pilot wire, is it practicable on Post Office lines under the existing Post Office Regulations, and, seeing that the pilot is in constant service, is it reliable? If, on the other hand, a special pilot is installed, has it much advantage in cost over the ordinary pilot wires as used in the past for other types of Merz-Price protection? Where the use of telephone pairs is the predominating demand, the system of interlock protection is an alternative of some merit. For example, it is free from the limitation of the non-unit type of protection shown in Fig. 26, and has the universal unit application of a Merz-Price system with a qualification in respect of time function only. The d.c. pilot-wire system shown in Fig. 28 might be used with telephone pairs, but it seems to be defective in that it will only operate with fault current fed in one direction. The earthing of the pilot at both ends might render it liable to inadvertent operation from d.c. vagabond currents, as, for example, when it is used in the vicinity of tramway systems. With regard to time-distance protection, the curve [Fig. 12(*b*)] is on the right lines. So far as instantaneous tripping over the major length of the line is concerned, it corresponds to the ratio balance system, but the latter provides an improved characteristic in respect to the "back-up" part of the protection. This is due to the clockwork timing-device, which enables the shape of characteristic best suited to the length and relative positions of the feeders to be incorporated. Moreover, on this system the relays measure the reactive voltage rather than the impedance voltage, when used on overhead lines. This feature, as the authors suggest, renders the system independent of the resistance of the arc constituting the fault and of variation in earth-plate resistance. Thus the compensation suggested in Figs. 13 and 14 is superfluous: it is, at best, based upon a rough estimate only of the resistance of the arc in any particular fault. This quantity cannot be predicted with the necessary degree of accuracy. The distance of the fault selected by the impedance relay with arc resistance in circuit may cause isolation of the wrong feeder, but with reactance relays the arc resistance does not affect the correct measurement of the distance of the fault, and hence, irrespective of the amount of arc resistance, it gives correct discrimination. In the case of cables, where the reactive loop is much less than for overhead lines, the measurement of distance by impedance voltage is preferable, but there is more scope here for the Merz-Price system as pilot wires and cable can be laid at the same time.

* British Patent No. 200194, 1922.

---

* Also see written communication by Messrs. H. W. Clothier and B. H. Leeson on page 827.

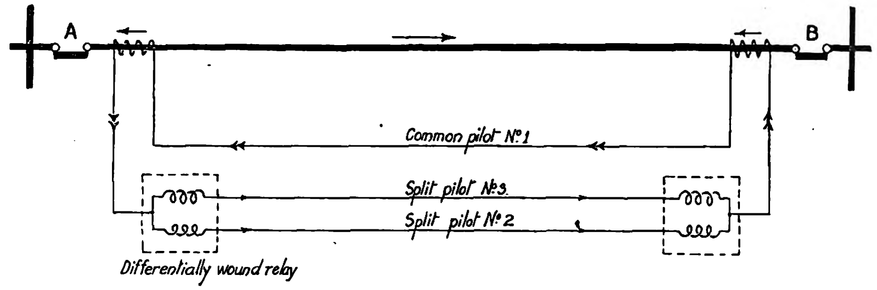
Mr. J. R. Beard: So far as this country is concerned, the real starting point of the striking developments in high-voltage feeder protective equipment dates from the years 1900 to 1905 when Charles H. Merz was engaged in developing the Tyneside district as our first extensive power supply area. He soon realized the economy resulting from the use of ring mains for high-voltage distribution. The operating difficulties, however, proved considerable. Attempts to solve these by graded overload and inverse power relays demonstrated that the protective problem was an essential feature in the design of high-voltage networks. Bernard Price solved the problem, as it then existed, by putting forward the fundamental idea of balancing the input and output currents to each section of network. This —at that time revolutionary—idea abolished all time-limits and enabled faulty lines to be disconnected almost instantaneously. It was certainly the greatest advance in protective gear ever made. Price has since devoted his life to work in South Africa and one sometimes wonders whether his outstanding contributions to electrical engineering are sufficiently appreciated in this country. Another name which should be associated with early development is that of E. B. Wedmore who, I believe, worked independently of Price on very similar lines. Why is mains protection so important in electrical work? I think the reason is the same as that which gives electricity its chief advantage; that is, its ease of transmission. This makes it necessary to regard every leakage as a serious fault and equivalent to a burst gas-main or water-main. Protective systems have proved a peculiarly attractive field to amateurs, as may be seen from the Patent Office files. To each beginner his scheme seems infallible, but those who have been through the mill hesitate to admit finality and are always suspicious that methods claimed to be improvements may introduce old difficulties. I just remember the first Merz-Price tests in 1905. The balancing was arranged to cover not only the high-voltage feeders but also the complete substation apparatus—transformers, switches and busbars. This was tested in the most vigorous manner by artificial faults, such as bullets fired into the cables, and everything worked perfectly. Shortly afterwards, due to delay in the completion of the cable tunnel under the Tyne, some high-voltage cables were laid in the bed of the river and protected by the new method. One of these was parted when dragged up by a ship's anchor and the protective gear disconnected it, very surprisingly as it then seemed, without shock to the system. At that time the protective problem seemed to have been permanently solved. However, the growth of systems to cover larger areas, to carry bigger loads and to operate at higher voltages has introduced further difficulties. The start due to Price and the fact that British conditions necessarily involve congested areas and cable networks have combined to keep this country in the forefront of balanced protection schemes. Each technical problem has been solved as it arose, and I recently had striking confirmation of the efficiency of one of the solutions with which I have been associated. The 33-kV network in Sydney is protected by the compensated-pilot method and this network has of recent years had a considerable number of cable failures. Mr. Forbes MacKay has, however, recently told me that in the course of 63 faults in no case did the protective gear fail to operate correctly. I believe Manchester has had a similar satisfactory experience with the same method. Pilot protection is, I think, universally admitted to be a complete technical solution of feeder protection problems. The chief difficulty is that of capital cost. While this is not of great importance on cable systems, where the pilots can be laid at the same time as the cables, it is very important on overhead lines. On wood-pole lines it is possible to suspend the pilot from a catenary carried on the poles, but the cost is rather high and for steel-tower lines with long spans the cost of suspension becomes considerable. In fact, in many instances it is preferable, if pilots are essential, to lay these underground in a separate trench along the route of the lines. Several methods have been devised with the object of overcoming the difficulty of capital cost. A number of these aim at reducing the number of cores to two or even one; others reduce the momentary voltages induced in the pilot under fault conditions and thus enable less insulation and, therefore, a lighter cable to be used. Kapp and Carrothers propose a system in which the pilot is embedded in the ordinary earth wire. Carrier-wave systems have also been employed, using the power wires themselves for pilot purposes. I believe one of the features of the Translay system described in the paper is that it reduces the size and number of the pilot conductors and also diminishes the peak voltages imposed upon them. I should like to ask the authors whether these can be reduced to such an extent that ordinary telephone pairs can safely be employed. Another promising means of reducing capital cost is the use of rectifiers to apply direct current to the pilot and I am glad to note the references to possible developments on these lines. In connection with the 132-kV lines of the grid, it has been necessary for economic reasons to abandon the general use of pilot protection, although this is still being used on the shorter sections. For the longer lines, pilotless arrangements of the impedance type such as have been developed in America and on the Continent are adopted. British experience in protective gear has, however, proved of great value in adapting and improving these forms of protection in the direction of giving greater discrimination and shorter time-settings. The paper describes one of these improved British methods and I believe there are at least two others which have been developed commercially. I look forward with great interest to practical experience of these methods over the next 2 or 3 years, as the grid system comes into commercial operation. I was surprised to note the omission from the paper of the problem of protecting feeders with direct-connected transformers. The use of such transformer-feeders is on the increase because of the endeavour to economize in the use of switchgear, and their satisfactory protection is, therefore, of great importance. A typical example of the difficulties which arise is that of ensuring that a fault on the lower-voltage winding will disconnect the transformer-feeder at the end remote from the transformer. Anything which the authors may be able to add regarding proposals for dealing with the protection of feeder-transformers will be useful.

Mr. R. O. Kapp: The paper contains references to several systems of directional relays; where these are to be employed for protection, certain difficulties arise. One of them is that a directional relay often depends on voltage for its correct operation. If the fault is near the relay, the voltage may be very low. Another difficulty is that, on systems with a high circuit impedance, for example on comparatively low voltages with a small generating plant or a source of supply through transformers, the fault currents are comparatively small. Some of the load current may be fed past the fault, thus swamping the effect of the load current towards it, and preventing correct operation of the relays. I should like to ask the authors whether they have used phase filters to overcome these troubles. Fortescue has shown that a 3-phase unbalanced system can be represented as three balanced superimposed systems, one of them a symmetrical 3-phase system with normal phase rotation, the second a symmetrical 3-phase system with reverse phase rotation, and the third a single-phase system. A phase filter picks out one of these systems, namely, that of the reverse phase rotation. This does not exist so long as the line is sound, so that the load currents do not contribute to it and the relays can be made very sensitive. The reverse-phase sequence voltage is a maximum near the fault, so that the phase filter lets through just those operating effects which have the greatest magnitude where they are most needed. There are, no doubt, certain difficulties attending their use, and it would be interesting to hear more of these. In the past, the necessary connections involved a phase displacement of 60 degrees, and to allow for this a combination of capacity and self-induction was necessary. But a system developed by Messrs. Iliovici and Dubusc, which has been successfully employed in France for about a year, transforms the 3-phase current on the secondary side of the current transformers into a 2-phase system. A 2-phase filter requires a displacement of 90 degrees; this can be provided by a suitable adjustment of resistance and capacity and it is stated that the system overcomes the practical difficulties. The principle of impedance protection has a limitation in connection with the length of the line to be protected. Impedance relays or reactance relays on a section must be supplied with a sufficient voltage to prevent them from operating incorrectly. If the sections are very short this may not be possible. The greater the fault current, the higher will be the voltage at the end of a section of given length. It is, therefore, rather easier to protect lines on high-power systems at very high voltage than lines of the same length on small systems where the fault currents are not so great. The arc resistance has been mentioned by several speakers, and in my opinion the authors exaggerate its importance. They suggest a means of compensating for it. In large power systems with high voltages the arc resistance is likely to be so low that any compensation will be excessive and should be omitted. For example, consider a system capable of carrying 2 500 amperes to the fault; such a case would occur on the Scottish grid at Dundee, and is typical of very large systems. It is possible to calculate the relationship between voltage, resistance, and fault current. Supposing the arc resistance were only 0·1 ohm, the arc would absorb 625 kW at 250 volts. If the arc resistance were only 3 ohms, then approximately 19 000 kW would be absorbed in the arc, and 7 750 volts would be required to sustain it. An arc is essentially unstable; as the current increases the resistance drops. If the resistance were high, the energy absorbed by the arc would be equal to that required for the lighting of a whole town, and it is clear that such intense illumination is not provided by an arc. The earth-return path is a more important factor, but some of the investigations of the Research Association in conjunction with the Post Office and Central Electricity Board have shown that, with a variation in earth resistance between 5 000 and 20 000 ohms per cm cube, the effect of the earth resistance on the apparent impedance of the British grid lines would be about 8 per cent. The effect of the earth resistance, therefore, is not very marked in this connection. Fig. 12(*a*) of the paper shows characteristic curves which are, in my opinion, misleading because they are far too flat for practical purposes. It should be observed that, in addition to the theoretical minimum times, allowance must be made for incorrect adjustment, so that the actual curves are considerably steeper. I agree that it is essential to cut off a short-circuit in the minimum possible time, and therefore the characteristic of the curve in Fig. 12(*b*) is desirable in spite of the slight complication.

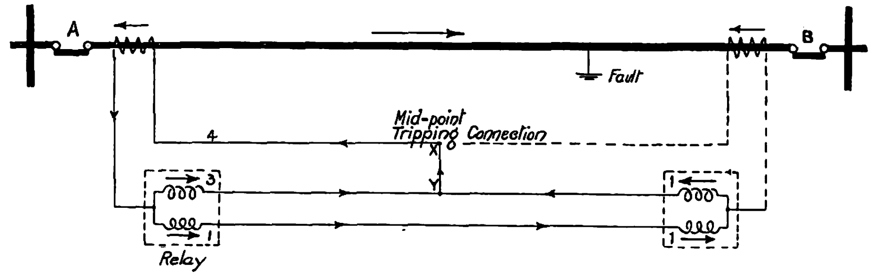
Messrs. H. W. Clothier and **B. H. Leeson** (*communicated*): The recent expansion of the demands made upon protective systems for 3-phase overhead transmission lines and cables, by reason of increased interlinking of power supply systems, has occasioned a revision of the methods used for discriminating protection which have been evolved during the preceding 20 years. The recent factors causing this expansion may be summarized as follows: (*a*) Transmission at higher voltages; (*b*) transmission over longer distances; (*c*) demands for more sensitive earth-fault settings; and (*d*) demand for displacement of pilot wires on the grounds of economy, particularly for long lines. A protective system, the stability of which is independent of protective systems or faults on other units, and the operation of which extends only over the unit it protects, is said to provide unit protection, and this is the chief feature of the Merz-Price pilot-wire type of protective system. Any new protective system is required to provide protection as nearly as possible equal to that of a Merz-Price pilot-wire system, and the three protective systems about to be described have been devised with this aim in view. These three protective systems are the "split-pilot," the "interlock," and the "ratio-balance."

"Split-Pilot" System.

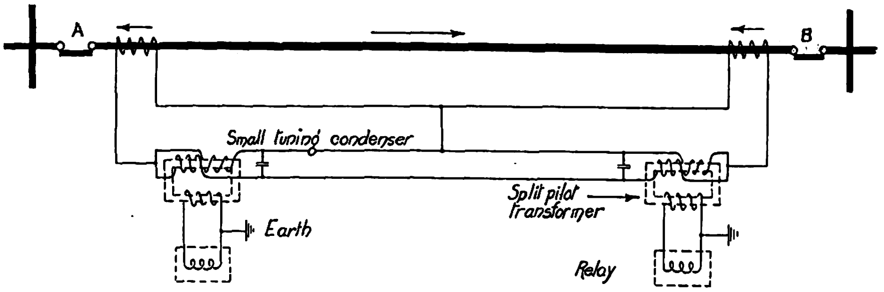
This is an evolution of the Merz-Price pilot-wire protective system with its instantaneous operation under fault conditions, and was designed upon the principle of devising first a scheme for obtaining stability of the relays under external fault conditions, and then a method of operating the relays under internal fault conditions. The system derives its name from the way it achieves this principle by using two of its three pilot wires on the split-conductor method so that pilot capacity currents are inherently self-balancing, and operation of the relays is effected by a tripping connection in the middle of the pilot cable which only disturbs the inherent balance in the split pilots when the feeder is faulty.



(a) Inherent Balance



(b) Operation



(c) Safety & Tuning

FIG. A.—Diagrams illustrating principle of inherent balance and tripping of "split-pilot" protective system.

The split-pilot system shown in Figs. B and C is of the current-balance type, and further features are the use of electrically-tuned relays only responsive to normal-frequency fault currents (and therefore immune from wrong operation by unbalanced oscillatory currents which flow in the feeder under straight-through fault conditions); the earthing of all relays on one pole for safety to operators; the current-transformer connections; and the adaptability of the system with a common tripping connection to protect tee'd feeders.

The evolution of the split-pilot system upon the lines just described is illustrated in Fig. A, the feeder and transformers being shown single-phase at this stage for simplicity. The 3-phase transformer connections are described later in conjunction with the practical applications shown in Figs. B and C.

From diagram (*a*) in Fig. A it will be seen that any current, capacity or other, flowing in the pilot circuit divides equally between the split pilots 2 and 3, thus producing no operating effect in the differentially-wound self-balanced relays at "A" and "B." Thus in this form the system has inherent stability for all fault currents, and it requires the addition of a means for operating the relays by the occurrence of faults on the feeder.

Diagram (*b*) shows how operation of the relays is obtained by what is termed a mid-point tripping connection. When the feeder is healthy and carrying a straight-through current of any value the points " X " and " Y " situated at the geographical centre of the pilot cable are equipotential points, and may therefore be connected together by the tripping connection without disturbing the self-balance of the system. The tripping connection, however, has the desired effect of disturbing the balance in the split pilots and operating both relays simultaneously when a fault occurs as shown at " F." With a fault fed from " A," and neglecting the portion of the pilot circuit shown dotted, the out-of-balance current divides in the two split pilots in the proportion of 3 : 1 as shown by the arrows, owing to this proportionality between the impedances of the two paths. This produces an operating effect on the relay at " A " of 3 minus 1, and a similar effect on the relay at " B " of 1 plus 1. Although the shunting

effect of the dotted path slightly alters the proportionality of the currents just described, the general principle that the difference between the two split-pilot currents at one end of the feeder is equal to the sum of the split-pilot currents at the other end is always true for any fault fed from one direction. For a fault fed from both directions the tripping effect is intensified but it is still equal in each relay at " A " and " B."

Diagram (*c*) shows how the substitution of a differentially-wound transformer for the differentially-wound relays enables standard low-voltage relays to be used and earthed on one pole to ensure safety to an operator. Owing to the mutual inductance between the two split windings of the split-pilot transformer a very small condenser will tune the circuit electrically, so that the relays respond to fault current only at the normal system frequency. Under normal and straight-through fault conditions the voltage across the small tuning condenser is negligible because of the current equality in the split pilots, and it is only during the period in which a faulty feeder is being isolated that a voltage exists across its terminals. Fig. D illustrates the electrical tuning characteristics obtained in this way, and it will be seen that the system is inherently stable for all frequencies which can occur above normal, including third-harmonic currents.

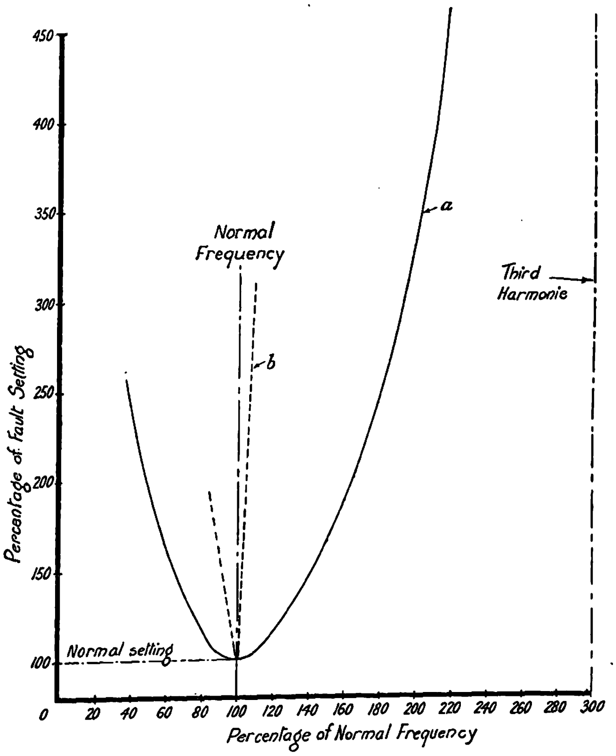

FIG. D.—Tuning characteristics of " split-pilot " protective system.

(*a*) With electrically-tuned relay.
(*b*) With mechanically-tuned relay.

When the tuning of protective systems by electrical or mechanical means was explored first,[*] mechanically-tuned relays using vibrating reeds were developed, and a typical characteristic is indicated by the dotted line (*b*) in Fig. D. Later, electrical tuning was adopted in view of the improved characteristic obtained, as shown by (*a*) in Fig. D, from which it will be seen that the fault setting is increased by only 5 per cent for a drop in network frequency of 10 per cent.

Figs. B and C illustrate practical applications of the split-pilot system to feeders up to 44 kV and 220 kV respectively, and in each system the transformers are connected up in " discriminating delta " or its equivalent. In Fig. B each transformer has a different turns ratio, in such proportions as 4, 5, and 6, which affords protection to the feeder for all types of fault, the earth-fault settings being more sensitive than those for phase faults. The use of distributed-air-gap transformers provides stability by nature of their straight-line characteristics, and the discriminating delta connection subjects the pilots to a minimum voltage for a given straight-through current and so reduces pilot capacity currents to a minimum.

Distributed-air-gap transformers have been used on voltages up to 66 kV, but for reasons of economy and interchangeability amongst various makers' products the split-pilot system as applied to the 132-kV British grid employs solid-core bushing-type current transformers of equal turns ratio, which are connected up in discriminating-delta to multi-air-gap summation transformers, the secondaries of which are connected to the pilot wires as shown in Fig. C. The two distributed-air-gap summation transformers are balanced by nature of their straight-line characteristics, but the solid-core current transformers are not self-balanced and may cause a small out-of-balance current to flow in the pilot wires, depending upon the value of the straight-through fault current. To nullify this out-of-balance current, a device called a " divertor reactor " is used, consisting of a small three-limbed iron core with an exciting winding on the centre limb in series with the pilots. The two outer limbs have divertor windings connected in series, so that the resultant inductive effect upon them from the exciting winding is zero. As the out-of-balance current in the pilots and exciting winding (due to the solid-core current transformers) increases, the flux density in the divertor-reactor core increases above saturation and therefore causes a diminution in the reactance of the divertor windings which shunt the relay terminals. This diverts or by-passes from the relay a current proportional to the out-of-balance current existing in the pilot circuit, and self-neutralizes any lack of inherent balance in the system caused by the solid-core bushing-type transformers.

Fig. E shows the split-pilot system applied to a tee'd feeder in which the 3-core pilot cable is tee'd off at the same place as the feeder. The mid-point tripping connection between " X " and " Y " is also made at the same place. With a tee'd feeder having three equal branches and a straight-through current fed from " A " towards " B " and " C " as shown by the arrows in Fig. E, it will be apparent that the voltage-drop in the pilots from " A " to the points " X," " Y," and " Z," is equal to the sum of the voltage-drops from " X," " Y," and " Z," to " B," and " X," " Y," and " Z," to " C." The points " X " and " Y " are therefore equipotential and the mid-point tripping connection between them functions in exactly the same manner as described for the plain feeder in diagram (*b*) of Fig. A, and this applies for any direction or distribution of current in the tee'd feeder. In practice, the three branches of a tee'd feeder are usually unequal, and such conditions are met by inserting a balancing resistance in the common pilot of one of the branches of the pilot cable so that they are artificially made electrically equal at the tee point.

FIG. F.—Key diagram illustrating principle of " interlock " protective system.

To summarize: The chief characteristics of the split-pilot system are its universal application, the unit protection it provides, inherent stability by self-balancing, and " instantaneous " tripping.

"*Interlock*" *System.*

This system protects a cable or overhead line on the unit principle without incurring the cost and continuous use of pilot wires, or employing graded time-delays to obtain discriminative operation.

The system obtains its discrimination under these conditions upon the following principle, which is illustrated in Fig. F. When a fault occurs on the feeder, as shown in diagram (*b*), the fault-currents flow in a direction away from the busbars and operate overcurrent and earth-leakage tripping-elements (denoted by the shaded squares), which isolate the feeder. When a fault occurs external to the feeder, as shown in diagram (*c*), the straight-through fault-current at the end of the feeder nearest to the fault flows in a direction towards the busbars, and this characteristic is utilized to operate a directional stabilizing-element (denoted by the shaded triangle), which interlocks the tripping-element at each end of the feeder and prevents it from being isolated.

FIG. G.—Diagram illustrating "interlock" protective system utilizing an existing pilot circuit.

While the external fault exists, the interlock of the tripping element at the distant end of the feeder "A" is performed by a signal transmitted over a pilot circuit. The latter is borrowed by the tripping elements, after which it is returned to its normal duty, as shown in diagram (*a*).

The interlock system is thus applicable to feeders wherever any form of pilot circuit or means of communication from one end of the feeder to the other may be borrowed momentarily to transmit a stabilizing signal. The interruption caused to the normal duty of the means of communication utilized in this way for feeder protection is negligible, because the interlock system borrows it on rare occasions only, and then for a period of something less than three-quarters of a second. Typical normal duties are telephony, remote indication, metering, and control, and such everyday use adds to the reliability of the protective system by indicating that the means of communication is in good condition.

A typical application of the interlock system to a 3-phase feeder of any voltage with existing telephonic communication between stations "A" and "B" is shown in Fig. G. The secondary current and voltage connections are omitted for simplicity, because they follow standard practice for overcurrent, earth-leakage and directional relays, and when applied to extra-high-voltage feeders the potential coils of the directional stabilizing elements may be energized by capacity currents obtained from the bushings of the circuit breakers.

When a fault occurs at "F," corresponding to key diagram (*b*), Fig. F, the overcurrent elements momentarily isolate the telephone circuit and instantaneously energize the tripping elements, which close the circuit breaker trip-circuit after a time-lag of 0·3 sec, thus isolating the faulty feeder. When a fault occurs external to the feeder at "B," corresponding to key diagram (*c*), Fig. F, the overcurrent elements instantaneously borrow the telephone circuit, and the stabilizing element at "B" similarly connects its battery to the pilot circuit at "B" to operate the interlock relay at "A." The instantaneous operation of these elements stabilizes the protective system by de-energizing the tripping elements with time-hesitation at "A" and "B" long before either has had time to operate, thus preventing the isolation of the healthy feeder. The time-hesitation of 0·3 sec., divided by the time required for the so-called instantaneous elements to operate, gives a minimum stability factor of 2.

To summarize: The chief characteristics of the interlock system are that it is universally applicable for protecting a network of feeders on the unit principle, that its small time-hesitation and its stability factor are uniform on all feeders, and that its momentary use of pilots either eliminates their cost or reduces it to a mere fraction by reason of the other services for which they may be used normally.

"*Ratio-Balance*" *System.*

This system belongs to the distance class of protective systems, which obtain their discrimination for operation and stability by automatically grading their time-settings in accordance with the voltage and current conditions produced in the network by the fault itself.

The system was designed to provide a pilotless protection having operating characteristics similar to those of the Merz-Price pilot-wire type. Although no system in the distance class of protection achieves this completely, the ratio-balance system approaches it closely because it provides instantaneous protection for faults over the major length of the feeder, and introduces a time-lag, of the order of 1 sec., for discrimination only when a fault occurs in the remaining length of the feeder.

FIG. H.—Diagrams illustrating principle of time-distance characteristics of " ratio-balance " protective system for securing stability and discrimination.

The time-distance characteristics for securing stability and discrimination are illustrated in Fig. H, and one feature of the system is that any desired characteristic can be provided to fulfil any particular condition to the best advantage.

Three conditions typical of service requirements are shown in the examples (*a*), (*b*), and (*c*), from which it will be seen that each time-distance characteristic is divided into three fundamental zones. The first is the instantaneous zone; the second is the time-discriminating zone; and the third is the overlap, or " back-up," zone. These three zones provide stability and discrimination under all conditions of fault as follows:—

With reference to the time-distance characteristics above the base line in Fig. H(*a*), a fault in the feeder AB occurring within the first zone is cleared instantaneously by the circuit breaker at station " A," and a fault on AB adjacent to station " B " in the second zone is cleared after a time-lag of approximately 1 sec. A fault in the feeder BC in the third zone, for example at " O," will not be cleared by the circuit breaker at station " A," because the time-lag of the relay at " A " will have increased to the value represented by OS, and the circuit breaker at station " B " will have cleared the fault in the time represented by OE, which is slightly longer than that of the relay characteristic OR, namely, by the time required for the circuit breaker to perform its opening duty. The stability factor is represented by the ratio OS/OE, the desirable value of which is an average of 2.

Two of the chief features of the time-distance characteristics shown in Fig. H are the flat portions of the characteristic in the first and second zones, and the flexibility of the characteristic, which can be altered at will to suit the different conditions of (*a*) two feeders of equal length; (*b*) a long feeder followed by a short feeder; and (*c*) a short feeder followed by a long feeder. Like other protective systems in its class, the ratio-balance system provides protection against busbar faults.

FIG. J.—Diagram illustrating principle of time-distance discriminating unit of the reactance-type "ratio-balance" protective system.

The most useful field of application for protective systems of the distance class is the protection of long overhead transmission lines, and many such systems adjust their time-lag by measuring the impedance of the faulty line on the assumption that it is proportional to the geographical distance of the fault from the relay.

In practice, the resistance of an arc in air forming a fault, together with the resistance of the earth connections, corresponds to a considerable length of transmission line, so that the impedance measured by a relay may represent not the real geographical distance of a fault from it but the increased distance of what may be called an apparent fault situated far beyond the real fault. In consequence, the relay may adjust its time-lag upon a false basis and discriminate wrongly. An alternative method, which eliminates the effect of arc and earth-plate resistance, is to measure the reactance of the faulty line and to adjust the time-lag accordingly.

The main innovation of the ratio-balance system is the time-distance discriminating unit shown in Fig. J, which measures the reactance of the line and adjusts the time-lag in accordance with the characteristics shown in Fig. H. The unit consists of two essential components, the distance-measuring element which measures the reactance, and the time-measuring element which measures the time-delay; and these two elements work in combination with one another by means of an electrical connection in the following manner: Normally, the induction movement of the distance-measuring element holds the contact-making member against the stop, and leaves the tripping circuit open. When a fault occurs, the voltage and current-coil circuits are energized by contacts (a) and (b) respectively by means of the starting elements and phase selectors referred to later on.

If the fault is in the first zone of the time-distance characteristics shown in Fig. H, the distance-measuring element, which is set to operate at or below a definite value of reactance, closes the tripping circuit instantaneously; if, however, the fault is outside the first or instantaneous zone the time-measuring element, which is also started up on the occurrence of the fault, gradually alters the setting of the distance-measuring element by inserting resistance in the circuit of its voltage coil. Thus, the time taken to complete the tripping circuit is equal to the time taken by the time-measuring element to insert sufficient resistance to cause the distance-measuring element to operate.

FIG. K.—Key diagram of elements forming "ratio-balance" protective system.

The torque on the induction movement is produced by the resultant flux caused by the current and voltage coils in the two magnetic systems, which are not provided with shaded poles, and hence it does not operate, as may be thought at first sight from Fig. J, by two mechanically balanced forces.

Fig. K shows a key diagram of the elements forming the ratio-balance system, and it will be seen that these are arranged fundamentally upon the well-known overload-and-earth-leakage principle. Thus, the elements divide into two groups, one dealing with phase faults and the other with earth faults. Both groups utilize the same time-measuring element, and for this reason the thick dotted lines with the arrows associate it with both the phase-fault distance-measuring elements and the earth-fault distance-measuring element. The operation of the elements in each group is identical in principle. On the occurrence of an earth fault, for example, the directional starting element and the phase selector on the faulty phase operate simultaneously and initiate the distance-measuring and time-measuring elements, as shown in Fig. J, and these two elements produce the time characteristics shown in Fig. H.

To summarize: The principal application of the ratio-balance protective system is to protect long overhead transmission lines, when, for reasons already described, it is required to measure reactance values. Its characteristics approach those of the Merz-Price system very closely, and it offers alternative protection when pilot wires cannot be provided.

Conclusion.

Each of the three protective systems described above has a distinct purpose, which may be briefly described as follows:—

The split-pilot system is for "instantaneous" tripping on more important and shorter feeders, and those in densely loaded areas.

The interlock system is for longer and less important feeders, or where pilot wires are too expensive but telephone wires are available, and where a time-hesitation is not objectionable.

The ratio-balance system is for longer overhead lines where no pilot wires of any description are available, and where a short time-lag variable with distance, and more complicated connections, may be regarded as a small price to pay for saving the cost of pilot wires.

These three systems cover the whole field of modern requirements, and each has a place in established British practice.

Mr. C. W. Marshall (*communicated*): The paper indicates clearly that a serious effort is now being made to protect overhead lines and cables without the use of pilot wires. In my opinion, only in cases where the importance of lines is extremely great is it possible to justify the installation of the expensive pilots commonly used, for protective purposes alone. Pilot protective schemes have set a high standard of reliability and excel all others, with the possible exception of parallel feeder systems, in sensitiveness and speed of operation; but the cost, and, to some extent, the vulnerability of the pilots makes the general use of such schemes commercially impracticable. It is possible that the sphere of useful application of pilot systems could be extended if the pilots were made to serve for communication purposes as well as for protection. A scheme has already been developed whereby it is proposed to "borrow" communication lines temporarily during fault periods to serve for duty in protective work, but, in my opinion, it would be better to have pilots in constant use for protection and at the same time to use them for communication. Communication-line pilots also appear to be somewhat vulnerable in themselves. Co-operation between protective gear and communication engineers might result in useful developments in this direction. Regarding the pilotless protective schemes developed by the authors, these are representative of the class in which time-lags are obtained by the joint action of springs and permanent magnets. Their weakness, to my mind, lies in their dependence upon accuracy of relay calibration (particularly in the matter of time-delays) for exact discriminative action. It appears to me to be better to incorporate a clockwork time-lag device, which is inherently accurate, rather than to use eddy-current effects produced by the action of permanent magnets, for this purpose. A further possible weakness is that the permanent magnets in the various relays on a system may change in relative strength due to ageing or to the effects of short-circuits. As the authors have long and intimate experience of the behaviour of permanent magnets in energy meters, they could probably give some exact information on the point and this would be appreciated.

Mr. A. T. Scott (*communicated*): The authors have left for discussion the question of earthing the neutral while, at the same time, they suggest that for voltages above 20 000 solid earthing of the neutral is preferable. The relays on any system, however high the voltage, cannot limit the fault-current value; but, provided that they can be relied upon to cut off a faulty line quickly, they can preserve the continuity of supply to a place fed by a duplicate line which forms part of a system having inherent stability. Relays contribute to the maintenance of system stability in proportion to their speed of operation, but the stability during the fault period must be maintained by other means and it is being found, even in America, that neutral impedances are becoming more and more necessary for this purpose. The objection to the earthing impedance is stated to be the excess pressure-rise that can occur on the unearthed phases during the fault condition, but if this excess pressure is less than, or not greater than, the pressure produced during switching operations or by external causes, it is not detrimental; and if, for other reasons, the insulation has been made sufficient to withstand the stress produced during the fault period by an earthing impedance, then the objection ceases to exist. The voltage-rise may not be an objection, as it can be controlled in amount by the value of the impedance. Since the desirable properties of the device are generally admitted, I would suggest that the best ohmic value and type of impedance should be the question for discussion, rather than the desirability or otherwise of a solid earth-connection. It has been shown by analysis that the maximum voltage during the arcing period on an insulated neutral system (i.e. a neutral impedance of infinite resistance) is about 5 times the normal phase-to-neutral voltage, while for a solidly-earthed neutral system the rise is approximately zero. Thus any degree of fault-current limitation can be arranged for between these limits of voltage-rise. On any reasonably well-designed system a voltage-rise up to twice the normal line-to-earth voltage would be permissible for a period of, say, 1 or 2 secs. If on such a system the fault were cleared (as it undoubtedly could be with relays as described by the authors) within ½ sec., a voltage-rise up to 2½ times the normal voltage could be allowed with safety. The actual ohmic value of the limiting impedance to give this result will depend upon the fault capacity-current, the length and voltage of the line, the impedance of the generating and transforming plant and that of the transmission line up to the fault. By the combination of an instantaneous earth-leakage tripping device and a limited earth-fault current system, stability during the fault condition can be very greatly improved; the power in any arc to earth is reduced so that the arc's tendency to spread and cause a short-circuit between lines is lessened, and the damage to insulators during flash-over is very much reduced. Also, the difficulty of running safely along routes parallel with Post Office lines is largely overcome and, as a consequence, the choice of routes for overhead lines is greater and wayleave difficulties are less. It is possible, particularly on short lines, that the fault current may safely be reduced to such a low value that it becomes a limiting feature with regard to relay operation. The improvements described by the authors, however, indicate that this limit is being considerably extended, so that instantaneous tripping of earth faults can now be achieved with small earth currents. The normal value of the harmonics of the third order must, nevertheless, be kept well below the relay settings.

[The authors' reply to this discussion will be found on page 849.]

SOUTH MIDLAND CENTRE, AT BIRMINGHAM, 20TH JANUARY, 1930.

Dr. C. C. Garrard: The subject embraces such a wide range of knowledge that the paper can only be expected to deal with the methods adopted by a single firm; a comprehensive treatment would require several volumes. There are many alternative methods for solving each of the problems which the authors have considered, so that it is impossible for the purchaser to decide between the conflicting claims of manufacturers by relying solely upon the evidence of the paper, valuable though it may be, Attention is drawn in it to the difference between the English and the Continental protective problems arising from the fact that in the first case the neutral point is earthed, while in the second that point is insulated. In spite of the statement quoted from the paper of Messrs. Wright and Marshall in support of the earthed neutral as a safeguard against interference with telephone circuits, I believe that the insulated neutral was insisted upon by the German Post Office because of its alleged superior merits in this connection. A device like the Petersen earth coil will not be readily accepted by British engineers, because it introduces undesirable complications and is of doubtful utility. Some years ago a device for suppressing arc-overs on overhead-line insulators which made use of a temporary earthing of the affected phase was developed in America, but it does not seem to have met with any success. I am in favour of solidly earthing the neutral point on all voltages above 33 kV and of earthing through a liquid resistance on lower voltages: such a resistance eliminates the danger of fire which occurs in connection with those of other types. Protective gear should be rapid in action and of high sensitivity; low fault-settings are a necessity if the latter feature is to be obtained. For example, consider the case of a 5 000-kW oil-filled transformer protected by the circulating-current system with a setting of 60 per cent of full load. A fault current of 3 000 kW, due to a defective terminal-bush for example, might flow for an indefinite period and the heat evolved would probably set fire to the transformer. Viewed in this light the sensitivity of 30 per cent or more which has been claimed for the Translay system is far from ideal. The figure of 5 per cent will have to be approached before a reasonable guarantee of safety can be given. Moreover, such a sensitivity can be attained combined with absolute stability on through faults. The key to the problem of low fault-setting is the bias system which was first applied in practice by Mr. McColl. The Translay system is only one of many of the same type which have since been evolved. On page 815 the authors indicate that the bias was adopted as an afterthought, although it seems to me to be the most essential feature. The use of a time-element characteristic is, I think, a disadvantage. The authors correctly point out the disabilities of the original simple opposed-voltage balanced system of feeder protection, and although such equipment has given good service in the past the biased systems now available are much to be preferred. These completely eliminate the necessity of sheathed pilot-wires. Referring to the systems of earth-fault protection (Figs. 6 and 7), are these only applicable to single dead-ended feeders? If they are unsuitable for protecting two feeders supplying a substation in parallel, the proposed systems would appear to have no advantage over ordinary leakage protection. The device shown in Fig. 13 for correcting for arc resistance is of interest. The figure of 3 per cent of the normal voltage, which is described on page 812 as the maximum voltage across the arc, surely does not apply to insulated systems in which an earth-fault current can be less than the load current. In such cases it is necessary to use a reactance-measuring element rather than one of the impedance type. The resistance of the arc has no effect upon the reactance in circuit and therefore does not alter the time of operation of the device. The calibration curve of Fig. 12(*b*) is almost ideal. The distance relay finds its most important applications on long overhead lines; in cable systems it is less suitable and the demand for it is not so keen because pilot wires are more easily applicable. The time element involved in the distance relay is a grave disadvantage which serves to provide the d.c. pilot-wire methods (page 819) with a claim to importance. They allow of the use of a single-core pilot and, although this has little, if any, advantage over a 3-core cable from the point of view of cost or protection with regard to underground cables, it does command a definite monetary advantage on the overhead system. The d.c. single-core pilot can be incorporated in the overhead earth-wire without much increase in cost. thus providing a protective system which combines economy and discrimination with an instantaneous release. The arrangement will probably be widely adopted in the future. As the distance relays shown in Figs. 9 and 11 have an operating torque proportional to the difference between E and T they cannot be true impedance relays. In a relay of the true impedance type the operating torque is proportional to the ratio of these two quantities.

Mr. A. E. Strong: I notice that the authors are in favour of multiple earthing. Apparently, when a switch is opened on a ring having more than one earthed neutral, there is a risk that the out-of-balance currents which are liable to be produced may operate other switches. I should be glad to know whether trouble is not also likely to be experienced as a result of triple-frequency disturbances, not only by the well-known interference with telephones but also by the production of high-frequency surges. When earthing systems on which the pressure exceeds 20 kV the use of resistances appears to be an advantage, at any rate up to 33 kV. Earth faults should be allowed to clear themselves before they develop into short-circuits, provided that the earth-leakage protection is sufficiently sensitive. The arrangement shown in Fig. 3, however, is not very satisfactory for this purpose. The induction-type relay with a definite time-lag is undoubtedly successful in providing discriminative protection, but it is well known that it suffers from the drawback that a greater time-lag is given to the switches nearer to the power station where fault conditions are more severe. Some engineers are on this account reluctant to set up their station switches, and I should be interested to know the authors' opinion as to the time-lag necessary for the feeder switches at the power station in order that discrimination may be obtained outside. What method would the authors adopt for testing directional relays at the end of parallel feeders without interrupting the supply, and, if possible, without disturbing the secondary connections?

Mr. J. Morton: The question of circuit protection, always one of great importance in connection with continuity of supply, has never been more serious than at present when so many large generating stations are being grouped on to a common transmission system, thus increasing the amount of energy which would be liberated in the event of a fault. With regard to that type of apparatus which is designed to provide the necessary protection without the introduction of pilot wires, it seems to me that the authors began by assuming that the older type of apparatus, the overcurrent relay either with or without the time characteristic, had proved reasonably satisfactory and that by the addition of suitable refinements it would be enabled to cope with present-day conditions. Owing, however, to the fragile nature of the numerous moving parts and the difficulty of solving the problems which arise in consequence of the feeble mechanical forces available, that assumption appears to me to be unwarranted. The higher voltages now in general use result in a reduction of the actual load current and necessitate the introduction of a type of protective transformer which is itself less reliable than the line with which it is associated. The acknowledged success of pilot-wire protective gear is, in my opinion, the result of the possibility of using a relay of greater electrical stability and more robust mechanical construction. This system admittedly introduces an additional capital charge, but it can be relied upon to clear the fault in the shortest possible time. The advantages of increased stability in the remainder of the system, reduction of damage and therefore of the period for which the faulty line provides no revenue, easily outweigh the additional cost. Although unaccountable interruptions have occurred on sections protected by pilot wires, the majority of these are the result of regulations which require the earthing of the secondary system of the protective transformer. If, for example, the point where the earth connection is made lies at one end of an 8-mile line, while the breakdown occurs at the other end between the primary and the secondary of the protective system, the voltage-drop between the fault and the earthed point will tend to maintain the dangerous pressure at the insulated end, thus cancelling the original reason for the necessity of earthing. By taking such precautions as will make it impossible for the secondary of the protective transformers to become charged from the primary side, and by using pilot wires efficiently insulated from earth so as to rule out the possibility of the admission of vagabond currents into the protective system, greater stability and rapid clearance will be obtained with settings lower than those which have hitherto been considered safe. The necessity for rapid clearance is great in view of the general tendency toward single transformer units of high capacity. With one of these transformers at each of two large stations operating in parallel a short-circuit power of 1 million kVA can easily be obtained. Consequently within a few seconds a temperature high enough to alter the physical properties and the mechanical strength of the materials in the line, can be produced.

Major A. M. Taylor: There are wide variations in standard practice regarding the correct settings for relays. The authors suggest the figure of 30 per cent, the General Electric Co. recommend 5 per cent, while many relays are set at 100 per cent of full load. Relay manufacturers are probably disinclined to employ fine settings because they have misgivings as to the effect of disturbances other than those produced by breakdowns in the cables of a transmission line; such for example, as the surges set up when a 30 000-kW generator is switched in without a field, or when a complete short-circuit takes place between two phases of the 5 000-volt system near a substation. A disturbance of the latter type which occurred in Birmingham resulted in a violent rupture of the connections between two stations, with temporary discomfiture of the whole system. Although I fully appreciate the argument advanced in London by Mr. Kapp, that a fault on a super-tension cable immediately develops into a short-circuit, it is my opinion that cable engineers really know more than has been suggested about what takes place in a cable when a fault develops. Mr. W. Wilson has shown in a recent paper* that 35 kW-sec. of energy are required for boiling *and* vaporizing a teaspoonful of oil. A fault almost invariably commences either just inside the lead sheath or just outside the copper core and the oil begins to boil locally —to a depth of about 1/10th or 1/100th of the dielectric thickness. This part is virtually short-circuited by ionization while the remaining portion of the cable begins gradually to warm up towards the inside. As the process goes on, an increasing proportion of the whole voltage is applied over the sound insulation. Soon both the voltage and the current in the faulty portion have greatly increased and, further, energy is liberated in the sound portion of the insulation. The voltage increase on that portion follows the curve given in Fig. 44 of Dunsheath's paper (vol. 64, p. 119) provided that the time intervals are measured from right to left; the current through the sound portion shows approximately the same kind of variation. Until the lead has burst and vaporization on a large scale has occurred there cannot be sufficient space to allow of the formation of an arc. I have made a preliminary attempt to calculate the increase of the instantaneous watts in the successive parts of the oil and paper on the basis of the data provided in Mr. Wilson's paper. Taking into consideration the limitation of the current through the faulty portion of the compound which occurs in the early stages, as a result of the residual wall of insulation, I find that an integration carried out over a complete second on a 33-kV cable cannot account for the liberation of more energy than is required merely to boil the oil which surrounds the faulty portion. Thus the energy necessary for complete vaporization cannot be liberated within the space of one second from the start of a serious local breakdown; *the process may require a period of considerably greater length.* The difficulty is that present forms of protection are only intended to act when the fault current has reached something like 100 amperes (50 per cent setting). At this stage the rapid rate of increase of the current makes effective protection impossible. It should, however, not be impossible to develop relays which will be as reliable and as stable in action with a setting of 1 per cent as those at present in use. In my opinion, it is important that a fault in one core of a 33 000-volt cable should not result in so much local heating that the dielectric characteristics of the other two cores are appreciably affected. Overload relays are of no value as a stand-by to protective gear unless their time-limit is such that, under the most severe conditions, such as those produced by a "through surge," their operation is delayed for the maximum time consistent with avoidance of damage to the cables and transformers. The latter could easily be designed to "hang on" without damage for 5–10 seconds, provided that the cables are run underground. The disturbance of the Birmingham system, to which I have referred, could have been avoided by rapid operation of the oil switches on the low-tension end of the circuit, if only the overload relays on the high-voltage cables had kept in.

---

* "Insulation Faults: Their Causes and Behaviour," *World Power*, 1929, vol. 12, p. 432.

Mr. W. Wilson: The authors' opening statements as to the demands, due to modern conditions and requirements, upon protective gear are by no means exaggerated, and an advance in the general standard of this apparatus is much overdue. There is no doubt in my mind that an error of judgment was committed when the opposed-voltage principle was selected some 25 years ago for feeder protection, in place of that based upon circulating current. The latter has always been used for safeguarding other types of electrical equipment, including parallel feeders and machines of all kinds; but the designers seem to have been unduly influenced by the difficulty of modifying the circuit diagram in order to provide for a relay at each end of the feeder, and also by the fear that a balanced-current system would consume more power than is consistent with sensitivity. Thus a wrong choice was made, and a faulty method has been bolstered up with added complications without being able to render it either sensitive or definitely stable. The drawbacks of the split-core current transformer are well shown by the authors and, while admiring the ingenuity of the 8-gap pattern shown in Fig. 16, one can agree with them that it is better to avoid the use of such a device. The sheathed pilot is another complication due to weaknesses of the balanced-voltage scheme, and here again the authors are wise in eliminating it from their own designs. It is a very expensive component which, by giving an exaggerated idea of the cost of pilot-wire protection, has effectively hampered the adoption of pilot-wire schemes generally. Since the opposed-voltage method depends upon the current being nil when the feeder is sound, every small irregularity due to external or internal causes tends to produce instability. An open-circuit in the pilot wire will throw the whole protective system out of action without warning, and thus frequent testing of the pilot itself is essential. This last drawback is obviated by the schemes shown in Figs. 20 and 21, since the capacity current would be interrupted by such a disconnection, although the statement on page 815 that " no current will flow in this circuit under normal operating conditions " hardly seems to bear this out. I am glad to find that a circulating-current system has been worked out in Fig. 23, and I should have preferred the authors to have gone further and adopted the balanced-current principle instead of merely improving the other. It was clearly shown by McColl [*] 10 years ago that the circulating-current method can be effectively applied to feeder protection without involving elaboration, high fault-settings or large current-transformers. Moreover, he showed that a scheme consisting only of an ordinary current transformer, beam relay and resistance unit at each end of the line, without sheathed pilots or special devices of any kind, can provide completely for all the eventualities that may occur in practice. I am in complete agreement with the authors as to the advantages of using a bias, but question the correctness of their use of the term on page 806, in which they state that " The wattmeter element has very little bias or spring control." Bias implies that the restraint is proportional to the load; it is essentially different from control, which is constant under all load conditions and is possessed in some form by every instrument and relay. From their description of the method of biasing the scheme in Fig. 20, I gather that the authors are here using the term in its accepted sense, and the relay characteristic would actually appear to incorporate a fault-setting increasing with the load. It would, however, have been a useful confirmation of their description if a performance curve could have been given showing the actual variation of the setting with the load. Their reduction of the fault setting from something over 100 per cent, for the usual opposed-voltage scheme, to the figure of 30 to 50 per cent mentioned on page 816 is welcome, but their claim that " these settings compare very favourably indeed with the settings obtainable with older types of gear " is hardly accurate. I have for the last 10 years been designing relays for feeder protection with a setting of 5 per cent, and I can assure the authors that there has been no difficulty in securing stability at these settings. The above figure applies to ordinary underground feeders up to about 5 miles in length, but I have never employed a higher setting than 25 per cent even for long or overhead feeders, or those including step-up, step-down and regulating transformers in the protection. The scheme shown in Fig. 20 is a reasonably simple one, but I am sorry to see (on pages 815 and 816) that additions to it are contemplated in order to provide further stability. In particular, I consider tuning methods to be particularly undesirable in situations where reliability and robustness are so necessary as in protective equipment. The scheme of Fig. 23 suffers through possessing a cascade arrangement not only of current transformers but also of relays. Such a multiplication of parts means that the chances of failure are multiplied by the number of components used in cascade, and greatly decreased reliability is the result. When suitably designed, a circulating-current system is rendered immune from instability due both to capacity currents in the pilot wires and to high-frequency transient currents, by the capacity current flowing in the pilots themselves. This is accomplished by arranging that the capacity current restrains the relays, in which case it is found that excess currents due to high-frequency surges are actually by-passed through the capacity of the pilots and rendered incapable of causing improper tripping. The desirability of sensitiveness has been scouted by protective-gear designers in the past, although they were willing to admit its value for protecting machinery. One cannot avoid the suspicion that this opinion was dictated by their inability to secure sensitivity with the usual feeder relay equipment. Actually, all the functions carried out by protective gear are the more perfectly fulfilled the more sensitive the protection, and this opinion has been borne out by all my practical experience.

---

[*] A. E. McColl: "Automatic Protective Devices for Alternating-current Systems," *Journal I.E.E.*, 1920, vol. 58, p. 525.

Mr. R. H. Rawll (*communicated*): The authors are of the opinion that, from the protection engineer's point of view, the earthing of the transformers at several points on the system has much to recommend it. The recent annual report of the Electricity Commissioners in which permission is granted to the Central Electricity Board to use multiple earths only in circuits connected to transformers is of interest in this connection. This permission is only given provided that the Post Office authorities are satisfied that it will not cause interference with their communication circuits. It is stated in the paper that, in order to improve the operation of Continental systems using an insulated neutral, arc-suppression coils have been installed. I suggest that where such devices are installed the neutral is placed in metallic contact with earth, although, on account of the special resonance effect set up by the arc-suppression coil, the result differs from that obtained with a solid earth or with an earthing resistance. In order to compensate for the capacity of any section of the network which may be switched in or out, it is suggested that each section should possess its own arc-suppression coil which could be brought into action simultaneously with the operation of the network section-switch. While this would be quite feasible on a number of feeders all proceeding from a common busbar adjacent to the earthed neutral of the transformer, it would be very difficult to apply the method to sections of the network which are switched at remote points. Either multiple earthing in the form of artificial neutral points, or pilot wires connecting these points to the main earthed neutral point of the system, would be necessary. With regard to the d.c. pilot-wire balance scheme, I notice that it is now proposed to use metal rectifiers of the copper-oxide type in place of batteries. I should like to know the voltage at which these rectifiers would be required to operate, as my own experience of them has proved that, at the usual supply pressure of 200–250 volts, a small transient voltage-excess is sufficient to cause a breakdown. The surge which would undoubtedly be present under fault conditions might have a similar effect.

[The authors' reply to this discussion will be found on page 849.]

North-Eastern Centre, at Newcastle, 10th February, 1930.

Mr. F. C. Winfield: During the past 2 years a very definite change has taken place in our attitude towards protective problems. The bulk of e.h.t. transmission work in this country has in the past been carried out by underground cables. Side by side with cable development came the development of the Merz-Price system of protection, which made possible the extensive interconnected system in this area and the high standard of service upon which this country prides itself. The Merz-Price system of protection, or one of its numerous present-day modifications, offers, as I think the majority of us will agree, the quickest, most efficient and most flexible type of protection available to-day. It has, however, one definite disadvantage—the cost of the pilot cables. So long as distribution was effected by cables this was not a serious matter, as the cost of the pilots was that of the pilot cable only, the excavation charges being borne in any case by the main cables. Even where overhead lines were employed, this factor was still not very serious with relatively low-voltage lines employing wood poles and short spans. In the period referred to, however, a distinct increase in the use of overhead lines has taken place and is fairly certain to continue. Two factors have been responsible for this, the development of schemes for rural and semi-rural electrification, and the operations of the Central Electricity Board. In the first of these, the relatively small revenue to be obtained and the high capital outlay necessary rendered imperative the utmost economy in construction, resulting in the extended use of overhead lines, the abandonment of pilot protection except for the more important feeders and, effectively, the acceptance of a lower standard of service. In the second case, in view of the very long spans employed, it was found to be economically impracticable to support pilot cables on the 132-kV lines of the Central Electricity Board, and accordingly pilot cables, if provided, must bear separate excavation charges or the cost of a separate pole line. When it is remembered that some of the line sections under consideration approached 50 miles in length and that the minimum cost for a separate pilot cable is of the order of £600 per mile (or, say, £30 000 for a 50-mile length), it will be readily understood why the Central Electricity Board was forced to consider other forms of protection for this work. These two factors, however, whilst militating against pilot forms of protection for the classes of work mentioned above, have to some extent served the industry in forcing the development of alternative forms which, whilst falling short of pilot ideals, are still considerably in advance of previous non-pilot systems and, I think, somewhat ahead of similar types used abroad. It is for this reason that the present paper is so timely. Although it naturally does not deal with all the developments which have taken place, but only with those with which the authors have been directly concerned, it nevertheless serves its purpose in indicating the new point of view. Notable amongst these developments are the impedance protection described by the authors and the ratio-balance system developed in this area. With the latter, however, we are not at present concerned. The advocates of pilot-wire systems have not yet given up hope of outclassing their rivals in the two classes of work referred to, and strenuous efforts are being made to reduce the cost of pilots. The chief lines of investigation at present being followed are: (*a*) The reduction in the cost of laying pilots in the ground. This is a point which, I think, ought to be taken up by cable manufacturers. Considerable ingenuity has been shown by cable manufacturers in designing, but very little in laying cables. This art is still literally in the " pick and shovel " stage. (*b*) The use of telephone pairs as pilots (probably for forms of protection other than the Merz-Price type). (*c*) The provision of a cheap pilot circuit by insulating the centre conductor of the earth wire used on overhead lines and employing the surrounding sheath as a return circuit. This proposal is due to Kapp and Carrothers. (*d*) The substitution for physical pilot wires of a carrier-wave circuit superimposed on the main power-circuit. I should be glad to know whether the authors are in any way interested in schemes of this type. The impedance forms of protection so far developed have not yet proved practicable for lengths of less than 10 miles on the 132-kV lines, and for such lengths pilot forms of protection are being used. I am doubtful whether the use of impedance forms of protection, even for lengths as small as 10 miles, does not encroach somewhat on the margin of safety, and I should have preferred the minimum to have been set at 12 miles, pending experience. The most outstanding development referred to in the paper, in British practice at least, is the impedance protection developed by the authors, but at the top of page 811 doubt is expressed as to the advantage of the definite time element. In my view, one of the major disadvantages of impedance forms of protection as compared with protective systems of the Merz-Price type, is the long time of operation. Leaving out of account the practical problems involved, I feel that the contribution which the definite time element offers, as shown on the curve of Fig. 12, is of the greatest importance. One of the most serious troubles which confront us to-day in dealing with major power systems is the disturbance which occurs to synchronous load, particularly plant supplying railways, on the occurrence of close-up faults. It has been often and freely stated that provided a fault is cleared within 2 seconds no disturbance will occur. In actual practice this is quite wrong. Two factors are involved—voltage-drop and time. The first can be controlled only by the extensive use of feeder reactors, which are both expensive and awkward of application. If the time factor alone is to be relied upon, times considerably less than 1 second are imperative. In their remarks on page 811 about the effect of resistance on the arc, the authors appear to neglect two very important sources of variation—change of the impedance of the earth-return path and alteration of the resistance of earth plates. The first of these may give a variation of the order of 8 per cent, I believe, whilst earth-plate resistance may vary from, say, 2 to 20 ohms. The authors also remark that the resistance-drop across an e.h.t. arc is small. I have had very conflicting reports on this point. It certainly seems more reasonable to suppose that the arc resistance should fall with increasing current, but at least two authorities who have made tests allege that extremely high values of resistance are possible. The pure impedance system stands or falls by this decision, and I should be interested to know whether the authors can give any account of tests to substantiate their statement. The compensating arrangement indicated in the paper certainly improves matters, but its effect is hardly so direct or so complete as that of a reactance relay. Doubt is implied whether it is possible to produce a time-reactance relay, although I can assure the authors that I have seen and tested at least one example of this type. A serious difficulty with impedance-type relays is the necessity for a voltage supply. The authors refer to this difficulty in connection with earth-fault relays, but they omit any reference to its effect upon impedance relays. On the 132-kV lines now being erected there is generally a natural reluctance to compromise the reliability of the lines by adding 132-kV potential transformers, and the method adopted is to employ a potential transformer on the lower-voltage side of the connected power transformers, and to compensate this for changes in load-drop or in transformer-tap position. So far as I have seen, this solution is not very satisfactory and the probable error in voltage reproduction would appear to be of the order of 10 per cent. Changes which are being considered may reduce the figure to, say, 7 per cent, but even this is unsatisfactory and other means of obtaining a potential supply are being explored. I should be glad to have the authors' experience on this matter. No reference is made in the paper to the operation of the impedance system when simultaneous faults occur, and I should welcome the authors' comments on this. With regard to pilot-wire protection, a detailed consideration is not required as we are all familiar with such equipment in this area. The Translay scheme is a novel development of the Merz-Price system. In essence it appears to be promising, and it has been successfully applied in a number of cases already. It is our experience on the North-East Coast, however, that it takes some years to prove the worth of a new protective scheme, so that I hesitate to be more definite. The authors suggest that a non-inductive resistance is useful as a high-frequency shunt. Our experience on a large 33-kV system is that it is of little use except where the pilot cables are of the sheathed type, and I should certainly prefer to see some form of tuning adopted in connection with the Translay scheme. Time-delays as a preventive of high-frequency troubles are of little value where recurrent or arcing earths are possible. If there is any feature of Translay pilot protection which I am inclined to query, it is that the effect of pilot capacity-currents is supposedly eliminated by the fact that the relay is of the wattmeter type, so that capacity currents produce no torque in the relay. In practice, the phase angle of the capacity currents differs greatly from 90° and often is as low as 45°. I should be glad of information from the authors on this point. I am interested to hear that practical applications have been made of the self-compensating type of pilot-wire protection. Can the authors give any particulars of these applications and of operation under conditions of heavy through-fault? The authors make a number of references to fault setting, and I should like an expression of their opinion on this point. There is a school of thought which declares that the most sensitive settings possible should be employed. We in the North do not subscribe to this view, but consider sensitive fault-settings to be a snare and a delusion. The suggestion appears to be that super-sensitive protective gear can detect a fault in the development stage and thus reduce system disturbances. For overhead-line work it is extremely unlikely that there could be any appreciable development stage within the current-range of protective gear. For underground cables, it is our experience that up to voltages of 22 kV quick-acting protective gear of the Merz-Price type will generally disconnect an earth fault on a 3-phase cable before it becomes a phase fault, but this does not hold as yet for voltages of 33 kV. We have also encountered a serious practical disadvantage of super-sensitive protection for cables in that it is often difficult and troublesome to trace the cause of the interruption, and thus much time is wasted in re-commissioning. The most serious objection to super-sensitive settings is that they almost invariably result in stability troubles and inadvertent operation. My own view is that for feeder protection more satisfactory operation is obtained if the relay setting approaches the maximum permissible to ensure certain operation on all faults, rather than some hypothetical lower value, and that for generator protection it is not important to pay much attention to the possibility of earth faults low down near an earthed neutral. This is well borne out in North-East Coast practice. In this connection, it is also my view that in almost all forms of protection it is desirable, as a general contribution to the elimination of stability difficulties, to have a time-delay approaching 0·1 second in operation on all tripping relays, as I feel that this would give useful protection against incipient faults and occasional transient disturbances. Beyond this I would not go, for the reasons previously stated. In fact, I think one of the most desirable contributions to the protective problem would be the speeding-up of the tripping time of circuit breakers. The authors' remarks on the desirability or otherwise of earthing are interesting. I think that they omit one important consideration when they state that American practice is to earth the neutral and Continental practice to insulate the neutral. Until a few years ago, American practice was largely divided between earthed and unearthed systems and it is only recently that the earthed system has been generally favoured after considerable experience with the unearthed system. In my opinion, Continental systems which do not earth the neutral are considerably less complex than our own and, despite assertions to the contrary, there must inevitably be a practical difficulty in applying Petersen coils to systems so interconnected and so subject to variant switching conditions as our own. Without Petersen coils, a second fault due to the increased voltage-strain when one line is earthed by a phase fault would be likely to occur very frequently in this climate, if past experience with resistance-earthed neutrals is to be relied upon. On the other hand there is, I believe, a distinct opening in this country for the unearthed neutral in connection with rural supplies. Where the capital expenditure which can be justified is so small, the ideal way to deal with this type of supply would seem to be, as suggested by Mr. Gregory, to run a single-circuit line with unearthed neutral, eliminate as far as possible all expensive protective gear or switchgear and spend some of the money so saved in improving the line insulation. By adding to this a Petersen coil or other arc-suppression device it should be possible to obtain a very reliable supply at low cost. Our experience with earthed systems on the North-East Coast is that a second or third earthing-point often facilitates protection and, by ensuring disconnection of faulty lines, results in a considerable lessening of telephone disturbance. Such disturbance has only proved troublesome in this area during actual fault conditions, or where plant with excessive harmonics is used. The latter should be corrected. It is questionable whether the dispersion of earth current due to multiple earthing would not give more relief to telephone circuits than the concentration of earth-capacity and fault currents on a single earthing point.

Mr. H. W. Clothier: I should like to refer to the history of the subject, and to the pioneer work done under the guidance of Bernard Price about 25 years ago. Reviewing the position at that time, we had some experience of reverse power relays and a great deal of suspicion of them. We were acquainted with time-limit devices, and had a good deal of experience with mal-operation of fuses. Andrews had been working on discriminating protection for duplicate feeders. Price started to work on some definite lines which are exceedingly interesting to-day. He laid down as one of his principles that there must be no potential element; potential transformers in substations were a nuisance. They were liable to failure, and the ideal protection was by current alone. Instantaneous operation was essential and almost anything should be sacrificed to it. The protection had to be universal in application, that is, suitable for ring mains, loops, tees, interconnections, etc., and such that it lent itself to ready extension without interference with existing protective gear. The relay was to be of simple magnet construction, easy to understand and without springs or other delicate apparatus. Suspicion was always to be attached to anything complicated in a relay. Moreover, the protective system was to be free from additional apparatus necessitating extra terminal connections, every one of which meant something more to go wrong and give trouble. In reviewing these features of the ideal system, we find little in the paper which would have attracted us at that time. For example, in Fig. 1 there is no discrimination as required for ring mains or feeders in series. With regard to Fig. 5 we should have said that the time-limits up to 2·2 sec. were quite out of the question, as synchronous plant would be put out of step. The system of Fig. 6 would have been rejected because of the potential transformer. Fig. 21 would have interested us, except that the relay would have appeared complex and we should have asked for further information as to tee-connections. The scheme shown in Fig. 26 would have been discarded as lacking speed and discrimination on ring mains; its use is limited to a string of feeders in series. So also Fig. 28 would have failed to gain approval because of the directional relays requiring potential transformers. We were dealing then with comparatively short lengths of cable and heavy fault-current conditions. There were no arbitrary limits to the demand for sensitivity in fault settings, it being realized that the fault currents were large in relation to the load current, and so the accepted heavy settings of relays were based more upon the amount of the fault current than on the size of the circuit. The first place was given to reliability. The problem of balancing the current transformers was met by raising the straight-line characteristic to the maximum straight-through current to be expected in any feeder. 5 000 amperes was the amount first determined; it was afterwards increased to 10 000 amperes. Other interferences were experienced, such as those due to pilot-wire capacity current and interaction between the fields of adjacent current transformers and their neighbouring conductors. These were dealt with by using coarser settings on the relay, and 900- to 1 000-ampere fault settings were not considered to be impracticable. I have it on record that in 1908 there were 200 miles of cable protected in this district, with an aggregate plant capacity of 50 000 kW behind it. I believe that practically all of that gear is still in service and that 400 miles with protection of a similar kind have since been installed, the only modifications, other than mechanical improvements in constructional details and the sheathed pilot, being the alteration of the single to the multi-air-gap transformer similar to that shown in Fig. 16 of the paper, and even this was in use as long ago as 1914. However illuminating it may be to dwell on the past, I must not omit to refer to the differences shown by the practice of to-day. These differences include much greater lengths of lines, heavier fault conditions (although I do not agree with the authors that this constitutes the chief difference), higher voltages, a demand sometimes, though not always legitimate, for extreme sensitiveness (a more intimate knowledge of and experience with the phenomena which interfere with the perfect balance, allows a more scientific treatment of the design of systems and relays), and last, but by no means least, the economic necessity for the elimination of the pilot wire on long overhead lines. Mr. Winfield said that the paper did not include all the protective systems. I sympathize with the authors in their task of trying to keep the subject within reasonable limits, but in my earlier contributions to the discussion (see pages 824 and 827) I referred to three important omissions.

Mr. B. H. Leeson: Electrical undertakings in this country have a high reputation for continuity of supply, and it may be claimed that this is due in no small measure to the superiority of British protective equipment. The Merz-Price system is an example of the latter and it has been proved satisfactory in service on feeders 25 miles long and at voltages up to 66 kV, and it can be applied to higher voltages and longer feeders when required. Cables forming interconnectors, ring mains, tees, etc., and subject to heavy fault currents have been satisfactorily protected for many years, and in this respect I think that conditions have not changed very much during the last few years. The power transmitted through a feeder has increased, but this has been accompanied usually by a correspondingly higher voltage so that fault currents have not become materially greater; in many instances they are less on modern high-voltage systems than on numerous lower-voltage systems. In my opinion, the factors which have influenced the development of certain modern protective systems are to be found in the use of long overhead transmission lines, such as those forming the 132-kV British grid, and the reason for the development of new systems has been an economic rather than a technical one. Technically, the Merz-Price system is still the desirable protection, but the cost of running a pilot cable in the case of the 132-kV grid lines becomes uneconomic when a certain length is exceeded, because the spacing of the towers does not permit the pilot cable to be slung from them as it can be in the case of lower-voltage lines. Consequently, the pilot has to be either buried or run separately overhead, thus involving extra capital cost and wayleave charges. The advent of the 132-kV grid lines has thus given rise to a need for two types of protective systems—a pilot-wire type for the shorter lines up to, say, 15 miles long, and a non-pilot-wire type, having characteristics approaching as nearly as possible to those of the Merz-Price system, for longer lines. Neglecting the schemes shown in Figs. 26, 28 and 30, as being inapplicable to ring feeders, the authors' proposals for meeting the two needs just outlined are the Translay and self-compensated pilot-wire, or Merz-Price, systems, and the impedance-relay non-pilot-wire system. Dealing with the latter first, I would point out that discriminative operation cannot be obtained correctly with a relay which adjusts its time-delay by measuring the impedance value of an overhead transmission line upon the assumption that such a value is proportional to the geographical distance of a fault from the relay. In practice, the resistance of the earth connections (apart from that of the arc-in-air forming the fault) corresponds to a very considerable length of transmission line, so that the impedance value measured by the relay represents not the real geographical distance of a fault from it, but the increased distance of what may be called an apparent fault situated far beyond the real fault. In consequence, the relay adjusts its time-delay upon a false basis and discriminates wrongly. To eliminate the effect of arc and earth-plate resistance I am of the opinion that distance-type relays should measure reactive voltages as stated on page 811, and such reactive relays are being used in the ratio-balance systems which are being installed on the 132-kV grid lines. Referring to protective systems of the pilot-wire type, the authors have given a very useful record of the characteristics they should possess. The use of distributed-air-gap transformers balanced against a standard, compensation of pilot capacity-currents, the tuning of protective systems to render them immune from oscillatory effects, immunity from the harmful effects of induced voltages, and safety, are all characteristics which have for a number of years been embodied in protective systems associated with this district. On examining the Translay and self-compensated pilot-wire systems I find that neither has all the meritorious characteristics advocated by the authors, but, instead, these characteristics appear to be distributed between the two in the following manner. The good balancing characteristics of the distributed-air-gap type of transformer, as shown in Figs. 17 and 18, are not used in either system; on the other hand, although the Translay system is provided with a bias to compensate for the unbalance which the authors associate with solid-core transformers, the self-compensated system has no such compensation and appears to be prone to the effects of transformer unbalance. The self-compensated system is immune from oscillatory effects by reason of the characteristic of its mechanically-tuned relay, but the Translay system is only partially compensated by the use of shunting resistances and it appears to be liable to be affected by unbalanced oscillatory currents in the feeder. The self-compensated system has the desired characteristic of tripping the circuit breakers at each end of a feeder irrespective of whether the fault is fed one way or both ways, but with a fault fed one way in a feeder protected by the Translay system only the switch through which the fault current is fed will trip. If the feeder protected is an interconnector between two generating stations, one of which is used to earth the neutral of the interconnected network, and if the feeder develops an earth fault the earthed generating station and its section of the network will be isolated from the fault by the switch opening at the near end. The other station and its network, however, will be left as an insulated system with one phase earthed, because the switch at the far end of the interconnector will not have opened. In neither the Translay nor the self-compensated system does the operator appear to be protected from the effects of the induced voltages, mentioned on page 814, should he happen to touch the relay connections. Applying the authors' figures to a 10-mile line with a straight-through current of 5 000 amperes, the operator would appear to be liable to a voltage of 6 500 volts. The self-compensated system is given the characteristic of simplicity and is easier to test on site than the Translay system, because the operation of the relays depends upon a current value only, whereas in the Translay system the operation of the relays depends not only upon the value of the out-of-balance current in the pilot wires but also upon its phase relationship with respect to the voltage vectors. I think that the use of current, voltage and their phase relationship for the purpose of discrimination in the Translay system is tending towards complication rather than simplification and this is an important point to remember because the measurement of the quantities mentioned is more difficult to carry out on site than the measurement of current only. I should like to know whether the Translay and self-compensated pilot-wire systems can be applied to the protection of tee'd feeders. With regard to Fig. 25, I note that with mechanical tuning a 10 per cent drop in system frequency results in the fault setting of the protective system being nearly doubled. I therefore prefer the alternative method of electrical tuning, because with the same drop in frequency the increase in setting does not exceed 5 per cent. I do not agree with the statement on page 814 that safety can be assured by earthing one or both ends of a pilot-wire system through spark-gaps. If the gap is set to break down at a voltage low enough to protect an operator mal-operation of the protective gear will result. In my opinion, it is essential for pilots to float electrostatically in respect to earth; complete safety can then be afforded to the operator by interposing an auxiliary transformer between the pilots and the relay, which can then be earthed on one pole, and this method is incorporated in the split-pilot protective systems which are being installed on the 132-kV grid lines.

Mr. H. Leben: Although I agree with the authors that pilot protection of the Merz-Price type, owing to its simplicity, is superior to non-pilot protection, and that the former can be designed to give satisfactory service on e.h.t. overhead lines of any length, I also think that considerations of cost make it desirable to have some form of pilotless protection available for use on long overhead transmission lines. Of the pilotless types of protection described by the authors the distance relay appears to be the only one suitable for an interconnected network, and I wish to comment on the section dealing with this type of protection. It is stated on page 810 that "it is usually assumed that for phase-to-phase faults the impedance value remains nearly constant for a given length of feeder, but this does not hold good for earth faults, when the impedance of the earth return may vary considerably." This appears to me to be the most important statement about distance relays, because the great majority of faults on e.h.t. overhead lines are earth faults, and the distance-relay type of protection therefore stands or falls by its ability to clear these faults discriminatively. Distance relays cannot, however, give satisfactory discrimination if the variation in the quantity upon which their operation is based (i.e. the impedance, in the authors' system) exceeds certain limits. This consideration has led me to an investigation of whether it would not be desirable to base the discrimination of the distance relay upon one of the components of the impedance, namely, the reactance; that is to say, to make the distance relay of the reactance type rather than of the impedance type. In order to arrive at a definite conclusion, it is necessary to take into account the effect of the variation of the components of the impedance, viz. reactance and resistance, upon relays of the distance type, and the probability that such variations will occur in practice. The position may be summed up as follows:—(1) Since reactance is the preponderant component of the impedance of e.h.t. overhead lines, any variation in its magnitude will produce a practically equal percentage variation in the impedance, and therefore, as regards variation of the reactance component, there is little to be gained by making the distance relay either of the impedance or of the reactance type. (2) A variation in the resistance component does not affect the reactance component, but it does affect the impedance. The reactance relay is therefore to be preferred to the impedance relay if there is any likelihood that the resistance component will vary to an appreciable extent. (3) The reactance of the earth-fault loop of an overhead line provided with a multiple-earthed earth wire is sensibly constant, as can be shown by calculation based upon tests. Physically, this may be explained by the fact that a change in the reactance of the loop formed by the line conductor and the earth does not produce a proportional change in the total reactance of the earth-fault loop because of the presence of the multiple-earthed earth wire, which has a constant reactance. In any case, as has been shown in (1) above, the effect upon distance relays of a change in the reactance of the earth-fault loop is practically the same irrespective of whether these relays are of the impedance or of the reactance type. (4) An increase in the resistance component may easily occur, and may be due to the arc resistance, to the earth-plate resistance, or to other variable factors that cannot be calculated or predicted with any degree of accuracy. This variation, however, as has been shown above, does not affect the distance relay of the reactance type. These considerations have led me to the conclusion that it is preferable to base the discrimination of distance relays in respect of earth faults on overhead transmission lines, on the reactance rather than on the impedance of the line, and this reactance principle has been embodied in the so-called "ratio-balance" feeder protective system. The authors' endeavour, illustrated in Fig. 13, to devise a means for correcting for arc resistance appears to bear out my contention that the operation of distance relays applied to the clearance of earth faults on overhead lines should be based on a quantity other than the impedance of the line. Apart from the fact that the problem is much wider than one of correction for arc resistance only, it seems to me that the authors' correcting device will not fulfil the purpose for which it is provided, but will in some circumstances produce the opposite effect. A definite example will help to make this clear. With a very heavy fault quite close to the busbars of a station in which an impedance relay fitted with the correcting device illustrated in Fig. 13 is in use, the voltage across the potential transformer will collapse practically to zero, but owing to the heavy fault current a large voltage will be injected into the restraining coil of the relay by the voltage-drop in the correcting resistance. This restraining voltage will prevent the relay from operating instantaneously, as it should operate, and thus not only will the object of the correcting device be defeated but a definitely harmful effect will be introduced, which would not be present without the device. On page 812 it is stated that the voltage-drop across the fault arc does not exceed 3 per cent of the normal voltage. To those unfamiliar with distance protection this may appear to be small, but a glance at Fig. 14 will show that it is actually of the same order of magnitude as the voltage available for discrimination under fault conditions. The values given in Fig. 14 (*a*) are (i) line impedance voltage, producing discrimination, 859 volts, and (ii) arc voltage, producing an error in the correct measurement of the line impedance, 570 volts. The results of recently published tests indicate, however, that the arc voltage may be considerably greater than the value which the authors give. It has been reported, for example, that in a 50-kV system with comparatively large generating capacity connected to it the average arc voltage was found to be from 10 to 12 per cent of the normal voltage. In reply to the authors' comments (page 811) about the design of reactance-type relays, I wish to say that this is not, as they state, "difficult, if not practically impossible, to accomplish." On the contrary, such relays have actually been made quite successfully and form the main feature of the ratio-balance feeder protective system.

Mr. D. A. Murphy: I should like to make a few remarks from the operator's point of view. Relays operating on a vertical spindle are much in evidence throughout the paper. This form of relay is usually very sensitive to vibration, and such relays operating on the shaded-pole principle can hardly be classed as instantaneous. This becomes more pronounced when an effort is made to overcome vibration trouble by increasing the amount of travel of the moving parts. Time-limit fuses for shunting trip-coils or relays are strongly denounced for their lack of discrimination on heavy faults. It is quite true that they have this failing, but when carefully selected they are satisfactory in the majority of cases and are used extensively in this area. Their success is probably due in a large measure to the system being fairly well equipped with balanced protection. One feature of the time-limit fuse, however, which is apt to be overlooked, is its ability to prevent damage to the relay coil on a very heavy fault—a trouble which was not uncommon before such fuses were adopted. Low-impedance earth leakage relays are in most cases unnecessary. A 0·8-VA relay of either 20 or 80 ohms impedance gives almost the same fault setting with an ordinary current transformer, the setting being about 5 per cent of full load of the latter. Low-impedance relays are, however, essential if current transformers of very low impedance are employed, and especially where the protection is of the definite time earth-leakage type combined with overload, so as not to increase unduly the overload setting in case of earth faults. I should like to ask whether the relay mentioned on page 806 which will operate with 4 per cent of full load and 1 per cent of normal pressure, would safely withstand short-circuit conditions. So sensitive a relay could not be very robust for general use. With regard to distance relays, this type of gear seems to be promising, but it does not lend itself to adequate protection for a long transmission line from a generating station, as an earth fault or even a short-circuit at the far end would not affect the busbar pressure sufficiently under modern working conditions. With automatic voltage regulators on the generators and lines without continuous earth wires, the satisfactory application of this gear would appear to be very difficult to accomplish. The time-lag with this equipment is inclined to be rather long, and when this exceeds 1 second the copper conductor of an overhead line is invariably burnt through. The severing of a conductor on a modern line with long spans necessitates an awkward and expensive repair. From this point of view, the title of the paper does not coincide very well with recent developments in the construction of transmission lines. With regard to Translay protection, as the pilot only supplies a fraction of the energy necessary to operate the relay, an earth fault fed from one end would not trip the feeder at the far end. This may in some cases leave a faulty feeder, such as a line on the ground, alive from the far end. The same thing could be effected with a simple earth-leakage relay. The Translay system has many possibilities, but it does not appear to be suitable for tee protection, a failing with many other protective devices. Is it suitable for combined feeder and transformer protection where the currents to be balanced are unequal and 30° out of phase? Directional earth-leakage protection is adaptable to many circuits between generating stations; its drawback lies in the provision of a suitable potential. In many cases with ordinary directional overload protection the potential supply is derived from the most convenient source and is not necessarily directly connected with the apparatus to be protected. The arrangement shown in Fig. 6 (*b*) could readily be adopted in most cases. The Longfield system shown in Fig. 26 is good as far as it goes, but as the pilot, which is the chief objection to the Merz-Price system, is already provided a more satisfactory scheme of protection could in such cases be arranged at little extra expense. The direct-current balance system shown in Fig. 28 is rather vague, and I should like the authors to describe it in greater detail. The arrangement shown in Fig. 30 would be inoperative for short-circuits between the two outer phases, as the currents in the corresponding elements of the summation transformer would cancel out, but this could be easily remedied. With regard to balanced protection for parallel feeders, any protective arrangement which requires vigilance on the part of the station operatives, as this does, is most unsatisfactory. Another bad feature is its function in rendering the protection on the sound line inoperative in the event of a fault on the other; this it has to do as the load on the sound feeder is then in a condition of maximum out-of-balance, in which case it must be backed up with overload. Otherwise, on double-circuit lines a fault on one spreading to the other would not be catered for. This protective arrangement also does not discriminate in the event of faults near the far end. Overload at one end and reverse power at the other is a much simpler and more reliable arrangement. The Translay system as applied to this form of protection does not, unfortunately, remove any of the bad features inherent in the principle, as the Translay appears to be applicable only at the far end.

Mr. E. W. M. Scott: A resistance inserted between the neutral point of a supply system and earth serves the dual purpose of permitting sufficient current to flow to earth, in the event of a fault in a remote part of the network, for operating selective protective gear and limiting such current so that it does not cause undue shock to the system. It is my opinion, therefore, that systems operated at voltages between 6·6 kV and 33 kV should be earthed through a resistance capable of passing at least 500 to 1 000 amperes, depending upon the size of the system. Systems below 6·6 kV are preferably earthed solid, as the earth-plate resistance, which on an average may be about 3 to 4 ohms, will limit the earth-fault current as much as is necessary. Usually it is not permissible for systems above 33 kV to be earthed through a resistance, owing to insulation difficulties. I am interested in protective systems of the "locking" class as I am convinced that there is a great future for them, particularly where existing telephone pairs are available. The Longfield system illustrated in Fig. 26 of the paper, however, seems to me to fall short of the ideal in that it is of the non-unit type, that is to say, the stability of the protective gear of one feeder depends upon the operation of the protective gear on feeders and apparatus in series with it. This is likely to lead to complications; for example, in a substation having two incoming feeders, two outgoing feeders and two step-down transformers for supplying a local load, the locking of each incoming feeder must be so arranged that tripping is prevented in the event of a fault on any of the five other circuits in the station, viz. the other incoming feeder, the two outgoing feeders and the two transformers. Such complications do not enhance the reliability of the protective system. I should like to know whether the system illustrated in Figs. 28 and 30 is applicable to ring mains. It seems to me that in the arrangements illustrated tripping would not be accomplished for a fault fed into the line from right to left. Do the authors recommend the use of an earth return? Might not this render the system liable to incorrect operation from vagabond direct currents? The limitations of parallel feeder protection, whereby vigilance on the part of station operators is involved to ensure that the circuit breakers at both ends are opened whenever a feeder is taken out of commission, can be overcome by the use of a device known as a "surge-proof" relay. This cuts out the differential relay when no current is flowing in the circuit breaker concerned, and enables unfettered switching operations to be carried out.

[The authors' reply to this discussion will be found on page 849.]

WESTERN CENTRE, AT CARDIFF, 17TH FEBRUARY, 1930.

Mr. W. F. Cooper: I wish to ask the authors three questions. First, do they consider that the fuses provided in the Merz-Price circulating-current system for the purpose of overload protection are of any value, in view of the fact that, if these fuses were sufficiently small to blow on a reasonable setting, the chances would be that a heavy straight-through fault current caused by trouble external to the protected circuit might easily rupture these fuses and isolate healthy apparatus? Secondly, what do they consider to be the maximum time in seconds at which definite time-delay relays can be set? Finally, what do they consider to be the minimum safe difference in time between two adjacent relays in substations protected on the graded definite-time principle?

Mr. T. H. Haigh: The authors asked for expressions of opinion as to whether a system should be run completely insulated or with an earthed neutral. The South Wales Power Co. in their early days employed an insulated system and found that breakdowns never came singly, but that there were always two or three simultaneous troubles, usually at points many miles apart. To prevent this, the neutral of one of the generators was earthed through a 6-ohm resistance. This answered very well until a single-phase fault occurred which burnt out a portion of the resistance, thus turning the system into an insulated one and resulting in 7 breakdowns in the course of 4 hours, due to surges set up by persistent arcing earths. Since that time the neutral has been solidly earthed, and I am of opinion that this is the best practice. The authors state that the violence of faults may be reduced by installing reactors at suitable points on the system. I should like to hear of a reactor that can be depended on not to break down when a heavy fault occurs close to it, as the South Wales Power Co. has had a rather unhappy experience with reactors. My experience with relays covers the impedance and directional overcurrent types. In 1923 I noticed an advertisement of the Westinghouse impedance relay, and later I obtained literature stating that relays of this type could be placed at substations 1¼ miles apart on a system such as that of the South Wales Power Co., and would successfully select the length of feeder in which the breakdown occurred. Three sets of these relays were obtained by the company and placed on a ring main at three substations separated by 3½ miles and 6½ miles, but although much time and trouble was spent on them, and Mr. Ross (one of the authors of this paper) was called in to give advice, it was found that on heavy through faults all three relays would operate. I understand that impedance relays have been much improved since 1923, and I should like to ask the authors what distance apart these relays must be to ensure proper selectivity. Three years ago, the South Wales Power Co. installed in three substations on one ring main Metropolitan-Vickers directional overcurrent relays such as are described in the paper. These have been quite successful and have cleared 6 feeder faults, in each case opening the faulty section only. The great drawback to these relays is that half a second must be allowed between each setting, with the result that if the maximum time-setting of the feeder switches at the power station is 2 seconds, it is possible to place only three sets of relays on the ring main, and if, as is the case on the South Wales Power Co.'s system, there are some 20 or 30 substations on each ring, the operation of a relay means that 5 or 6 substations are cut off and steps have to be taken to send switchmen out to locate the faulty section. However, if a ring main has only three substations in it, I consider these relays to be ideal for the purpose. I have considered the use of Translay relays on a feeder some 5 miles long, working at 22 000 volts, and consisting partly of overhead line and partly of underground cable, and have been informed that no special pilot cable is necessary and that it would be quite in order to erect open wires on the poles immediately below the power wires. I should like to ask the authors if trouble is to be expected through induced charges from the power lines, and if these can be minimized by transposing the pilot wires at every pole. Also, I should like to know exactly what class of pilot cable is generally used and whether it is lead-sheathed and armoured.

Mr. W. Holley: As a generating station engineer, I am only concerned with the feeder switch at the station end and with the effects of a heavy fault on the generating plant. To such engineers, faults are divided into two categories, those close to the station and those at a distance. The latter do not trouble us as they are equivalent to added load, and we are quite willing for our switch to remain closed while timed relays near the fault clear. But faults near the station are different, and cannot be cleared too quickly for our liking. We have found it best to have two separate relays on the station switchboard: one to operate at 500 amperes with a delay of 2 seconds and to take care of faults at a reasonable distance, say, beyond the first substation; the other relay is set at about 750 amperes, with a very small time-limit (about 0·1 sec.) and this takes care of faults near the power station. We have found that this method works exceedingly well and faults of both kinds have been cleared with almost no disturbance. There is no reason why both relays should not be combined in one instrument. I think that an ideal relay should not require pilot wires or any special kind of cable such as a split conductor, and I hope that the discovery of some new principle will lead to the production of the perfect relay.

Mr. I. Jones: Reliability of power supply is of the greatest importance, and the rapid disconnection of faulty lines or apparatus used in connection with the power supply is an essential idea at which to aim. The difficulty on large interconnected systems lies in the choice of protective gear which will automatically isolate only the faulty lines or apparatus, without disturbance to the remaining healthy lines or equipment, although the latter may have to carry the heavy fault current momentarily. For ring mains and interconnected feeders the balanced-voltage system of protection, combined with a definite minimum time overload relay, has much to commend it. The objection to this system is the use of pilot cables, particularly in the case of overhead lines, as the maintenance of suspended pilot cables is an item to be considered, especially when the overhead-line routes pass through very hilly districts. For such routes I prefer the split-conductor system of fault protection, and on quite a number of lines in use I find that this system of protection is extremely satisfactory. With some of the relays described in the paper protection appears to become more complicated, as there are so many variables affecting the stability of the system. With regard to the question of the insulated versus the earthed neutral, the latter is undoubtedly the more favoured in this country and it also gives a more stable condition for the adoption of leakage or balanced-current or balanced-voltage systems of protection. Earthing of the neutral point through a low resistance, or earthing solidly, is, I think, preferable. In one case, on a 33-kV system with split-conductor protection, it was the practice to earth the neutral point of the 33-kV system through a resistance which limited the fault current to earth to 330 per cent of the leakage current necessary to operate the relays; this represented approximately 60 per cent of the full load of the main transformers. Whilst this arrangement permitted easy disconnection in the event of earth faults, the disadvantage was that during wet weather an earth fault on one phase often resulted in a flash-over on one of the two remaining phases, due to the momentary rise in voltage of these two phases above earth. Another trouble due to voltage-rise which occurred on this system arose where the line was tee'd off to a step-down transformer: the neutral point of the 33-kV windings was left free and the insulators provided on the neutral point were for 11 000 volts working pressure. It was found that this insulator flashed over when an earth fault occurred on one of the lines. It was then decided to cut out the resistance and to earth solidly, since when these troubles have disappeared.

Mr. T. R. Kernick: Impedance relays were tried on the mains of the South Wales Power Co., but due to the distance between substations where the relays were installed (about 4 miles) their operation was unsatisfactory. Where a ring main over a scattered district is to be protected, it is essential that relays should be positive in their action, as indiscriminate tripping means having the system split up into sections. Engineers then have to be sent to various points to find out which switches have tripped; this means more inconvenience to some of the consumers than when main station breakers come out. Incidentally, it was found difficult to estimate the value of the average fault current, but by adjusting some old ammeters with an independent " tell-tale " pointer a value of about 500 amperes (average fault current) was obtained. Moreover, judging by the class of fault on a " mixed " system, the voltage at the point of fault was, in the majority of single-phase faults, nearer to line voltage than zero. Whilst mentioning fault current, there is decidedly a field of usefulness for an ammeter with a good torque which would register fault current by means of a " tell-tale " pointer and give approximate fault-current values in less than half a second. What I have in mind is an instrument with a circular scale, calibrated into four or more sections, say, 230, 500, 750 and 1 000 amperes. The readings need not be critically accurate, for as long as the pointer registers correctly in each section the operating engineer knows between what values his fault current lies. Time-limit relays have been tried with success and have proved reliable in service, but they should be tested on site for overall timing, the minimum overall timing being about $\frac{1}{2}$ sec., half of which time is taken by the mechanical mechanism of the switch. In connection with this subject, a plea must be made for the old plain protection breaker of the overload-fuse type. On a ring main fitted with time-limit relays it was found necessary to link up in various ways for voltage regulation, which interfered with the time-limit relays by splitting the fault current. On fitting certain circuit breakers with current transformers of suitable size these breakers came out under fault conditions in less time than the lowest relay setting ($\frac{1}{2}$ sec.), thus clearing the relay ring for discriminative operation.

Mr. H. J. Norton: The subject of the paper is of very great importance, especially at the present time when super-tension lines are being erected all over the country, and also in view of the necessity for adequate leakage protection of a discriminating nature against faults in order to maintain continuity of supply. The authors appear to favour protection by systems involving in all cases the use of pilot wires connected with relays of types suited to the particular conditions involved, whether those of a network or of ring mains. The use of pilot wires when lines are of moderate length does not represent an important addition in the way of price, but as the lines are extended over a considerable area the cost of pilot wires becomes prohibitive. Moreover, there is always the question of maintenance, and there are many lines protected by means of pilot wires and installed 15 years or less ago, for which the pilot cables have had to be completely renewed owing to deterioration of the lead sheath or other protective covering of the insulation. The result of this deterioration had been that faults in the insulation of the pilot wires had developed, making the protection unreliable. Since those days vast developments have taken place in protective systems, innumerable systems have been put on the market and installed, and a number have been found wanting, or lacking in discrimination. Undoubtedly the simplest method of leakage protection for straight line feeders is that of the Merz-Hunter, more commonly called the " split-conductor " or " split-phase " system. This system of protection for straight lines possesses inherent characteristics which have the advantage of obviating the use of complicated current transformers and relays, as in its simplest form it depends on current balance alone in the split phases, provides complete stability on through surges and can be designed to give satisfaction down to a very small leakage current. But when the system develops and tee-off lines become necessary owing to demands for power, and when ultimately the system becomes an extensive network of lines and cables coupled up in various ways to meet the prevailing demands, the split-conductor system is found to lack the necessary fine discrimination. Further protective systems have been developed with a combination of split pilot-wires, in order to minimize the effect of circulating and other currents, and it has been developed still further until ultimately a system has been evolved which completely obviates the use of pilot wires in any form. This is known as the " ratio-balance " system of protection, and the apparatus may be divided into two classes: (1) Initiating apparatus comprising the starting elements and phase selectors, which serve the purpose of connecting time discriminating elements to the circuit on the occurrence of a fault, and (2) discriminating apparatus consisting of time discriminating elements and a definite timing device, which together form the main discriminative feature of the relay and trip the circuit breaker when required. The main advantage of the system is that it uses a null method of reactance measurement which gives accuracy and consistency of performance. It provides practically instantaneous tripping on the occurrence of faults on the greater portion of the protected feeder. Improved discrimination is obtained by a greater rate of increase of time-delay with increasing distance outside the " instantaneous zone." Stability is maintained on straight-through currents by the introduction of a definite and accurately measured time-delay, the time discriminating elements (which may be called the reactance elements) operating independently of voltage-drops. The operation of the system on the occurrence of earth faults is entirely unaffected by a drop in voltage. The correct discrimination of earth faults is not impaired by the simultaneous occurrence of a phase fault. The time/ratio characteristics of relays are easily adjusted to suit any special conditions of service. Busbar protection is also included, and a feature which will appeal to users is that the equipment is of standard component parts which are exactly alike for any part of the protected network. It is obvious that such a system, eliminating as it does the use of pilot wires with their prohibitive cost over long distances, will be preferable to a supply authority on account of the substantial saving entailed, not only in first cost but in subsequent maintenance.

THE AUTHORS' REPLY TO THE DISCUSSIONS.

Messrs. T. W. Ross and **H. G. Bell** (*in reply*): The discussion can in general be divided under five separate headings and we propose to reply to the remarks of the various speakers as they arise under these headings. This we consider to be preferable to replying to each speaker individually, particularly as their remarks in many cases cover the same ground.

Pilot-Wire Protection.

Mr. Beard has given a very interesting résumé of the early history of pilot-wire schemes and we should like to associate ourselves with him in paying tribute to Mr. Price and Mr. Wedmore, because there can be no doubt that they were the pioneers in the development of what may be termed the " British " method of feeder protection. With balanced protective systems stability must of course be the first consideration of the designer, and whilst the Merz-Beard system is in successful use to-day there are also cases in our knowledge where conditions render this system unstable. It is for this reason that the systems described in the paper and also other systems such as that mentioned by Mr. Clothier have been developed.

Mr. Clothier and Mr. Leeson both refer to the " split pilot wire " system as a Merz-Price system, but like all other recent developments the split-pilot system is very different from the simple system developed by Mr. Price. The greater complexity has been brought about by changed conditions, and to compare the relative characteristics from the point of view of simplicity is misleading. The fears they express of difficulties in commissioning and testing " Translay " gear *in situ* are quite unfounded, as the relays cannot by any stretch of the imagination be termed wattmeter relays but are in principle and construction little different from the well-known induction overcurrent relay. The Translay system is essentially a current-balance system and as such it offers no greater difficulties in testing than any other pilot-wire system. We would also point out that in all systems of balanced protection the secondary current at which the relays operate is not necessarily a measure of the fault current which must flow to obtain operation. With regard to the compensation of the Translay relays against unbalanced oscillatory currents, we find in practice that the non-inductive shunt is satisfactory on cable systems up to 15 miles at 33 kV, but for cables longer than this a small shunting condenser is used which renders the relay inoperative at frequencies above 80 cycles per second. The resonant characteristics of the relay used in the " self-compensating " system have proved entirely satisfactory in practice, which is, of course, the " acid test " of any protective scheme. There seems to be some misapprehension as to the possibilities of the two d.c. pilot-wire schemes described in the paper, and in order to clear up any misunderstanding it should be explained that Figs. 26, 28 and 30 are intended for explanatory purposes only, and slight modifications in the arrangement make the scheme suitable for any condition. It would be as well to point out that the essential difference between the scheme shown in Fig. 26 and that shown in Figs. 28 to 30, is that in the former one pair of telephone wires can be used to protect any number of parallel feeders between two stations, whereas the latter necessitates a pilot circuit for each feeder. It should also be pointed out that in both schemes telephone communication is possible over the same wires. These systems are simple interlocking systems using telephone wires, and although it is also possible to use telephone wires for the Translay system we have had no experience with this arrangement. However, apart from the regulations of the Post Office, we see no difficulty in this direction. The Translay gear has been successfully applied to the protection of feeders with " T " connections.

Mr. Lane and Dr. Garrard have raised the question of the " bias " device for balanced relays and it will be noted in the paper that we make no claim to be the originators of this suggestion, which has been adopted by many designers in the past. We have, however, devised a novel method of obtaining this bias and, moreover, a method which has many advantages over previous attempts to adopt this principle. We quite agree that there are methods by which the bias may be eliminated, but these methods must be confined chiefly to those requiring special current transformers, whereas with the Translay system standard current transformers are successfully employed. We do not agree with Dr. Garrard that the slight time-delay which can be introduced into the Translay gear is any practical disadvantage, as at the most it is only about 25 per cent of the time taken by the oil circuit-breakers to open, and it has so many practical advantages that we are satisfied that it is desirable, this conclusion having been confirmed by results.

The multi-air-gap balanced voltage transformers described in the paper are the result of a demand for more accurate transformers for Merz-Price protection than were procurable in the past, and in reply to Mr. Clothier it would be too much to hope for a balance between this type and the less accurate 4-gap type mentioned by him. Mr. Baird and Mr. Murphy ask whether the Translay gear can be applied to the protection of combined transformers and feeders, and in reply to this important point we can state that Translay gear is in successful use for this purpose.

Distance Relay Protection.

The application of this type of protection is of course new to this country, although relays of British design and manufacture have been in use in other countries for some years. As the discussion has indicated, there are two schools of thought as to the principle upon which distance relays should operate, since the distance can be determined by measurement of either the impedance or reactance of the feeder from the point where the relay is connected to the position of the fault. Those engineers who favour the reactance method do so on the assumption that by measuring the reactance a more accurate indication is obtained of the distance of the fault, because any variation in the impedance due to the resistance of the " fault " arc will not be included in the measurement. Tests which have been carried out, have, however, shown that for currents above 200 amperes the arc resistance is comparatively small and can in practice be neglected. It is also significant that 75 per cent of the firms manufacturing distance relays have designed them on the impedance principle, and that a conservative estimate is that more than 90 per cent of the distance relays in successful operation are of this type. There can be very little doubt that a relay, or more correctly a combination of relays, which will pick out the reactance component of the voltage will, as Col. Edgcumbe points out, be a much more complicated design than the simple impedance relays in use to-day. We must therefore carefully balance the doubtful theoretical advantages against the known practical disadvantages of delicate and complicated apparatus, the maintenance of which may be a difficult matter. It is chiefly for this reason that we advocate the type of relay described on page 809 and illustrated in Fig. 11. We do not agree with Mr. Leeson that the basis of the impedance relay is fallacious. There has never been any doubt that the impedance relay is the better solution of the distance relay problem, unless its operation is adversely affected by high arc-resistance at the fault. Even if high values of resistance did exist in the fault arc, failure to discriminate could not result from this cause, the worst result being a slight lengthening of the tripping time under the most adverse conditions. Actually the fault arc on high-voltage systems has been found to have a very low value, particularly where heavy currents are involved (see Appendix), so that in our opinion it is almost impossible to justify the additional complexity and cost of reactance relays. Mr. Kapp suggests that the curves in Fig. 12 (*a*) are too flat and presumably Mr. Clothier also holds this view, but we submit that in this matter it is only possible to make a compromise between longer back-up clearance times and the possible lack of discrimination due to sluggishness in circuit-breaker operation. The relays can, of course, be adjusted to give any desired " slope " in the curves. We agree with Mr. Kapp that the characteristics illustrated in Fig. 12 (*b*) are superior to those shown in Fig. 12 (*a*) in view of the quicker clearance time obtained in the former case for faults over the first 60 per cent of the feeder length. Against this, however, must be set the disadvantage of greater complication; in many cases we believe that this will outweigh the advantage of reduced clearance time. Mr. Marshall appears to favour a clockwork relay rather than the induction type described in the paper, and without in any way doubting the possibility of using clockwork devices for protective purposes we feel strongly that the induction movement provides not only an accurate relay but also a very simple solution to what in the past has been a difficult problem, i.e. not the exact measurement of small differences of time but accurate discrimination by means of small differences between intervals of time. There is practically no possibility of the permanent magnets changing in strength sufficiently to endanger this discrimination. The permanent magnet used on this type of relay is mainly intended as a means of quickly bringing the movement to rest when the overcurrent subsides, and the braking during the operation period is largely provided by the a.c. flux. As an illustration of this the change in relay time with a 25 per cent change in the magnet strength is only 10 per cent, and experience with watt-hour meters has shown that permanent magnets do not vary to anything approaching this extent. The relay described is thus not dependent upon its calibration but upon design constants. The possibility of inaccurate calibration does not arise and it is remarkable how close the characteristics of the different relays are to each other before calibration.

Sensitiveness.

The term " sensitiveness," when applied to protective gear, is usually intended to mean the minimum fault current at which the gear will operate. Certain speakers during the discussion gave the impression that they considered it of extreme importance that the fault settings should be of the order of 5 per cent of the normal current of the feeder, but this is certainly not supported by experience in practice, and very few operating engineers would agree to have their gear set so low as this. Major Taylor has suggested that the limitation to sensitiveness is the relay, but of course the real limitation is stability in the case of balanced systems, and discrimination in the case of other systems of protection. Taking the stability question first, this can in no way be attributed to the relay, because, as we have pointed out in the paper, lack of stability results from effects produced in the lines or cables, pilot wires or current transformers. It has, however, been shown that relays are available which assist in overcoming such difficulties, but nevertheless we are of the opinion that it is extemely inadvisable to jeopardize the continuity of supply by setting the gear to operate at a fault current lower than necessary. The chief factor in determining the maximum setting allowable is the impedance of generators, transformers and lines, and the important point is to be sure that the minimum possible fault current is sufficient to operate all protective gear on the system. There can be no doubt that fault currents will always reach the estimated value in a very small fraction of a second, and so far it seems to be practically impossible to design a perfectly stable form of discriminating protection which will operate to break the circuit before the fault current has reached this value.

There is also the fact that many engineers consider very sensitive protection undesirable because of the difficulty it creates in locating the fault position in a cable before repairs can be effected. This important point was mentioned by Mr. Winfield and there is no doubt that the introduction of a slight time delay in the relays is an advantage from this point of view. In the case of impedance or distance protection the fault current at which the relay will trip must exceed a certain value, otherwise the voltage-drop between successive switching points will not be sufficient to allow of discriminative action of the relays and circuit breakers. Taking everything into consideration, therefore, it is difficult to see any convincing argument in favour of a lower setting than that necessary to ensure satisfactory operation of the relays at the calculated minimum fault current.

Earthing of System Neutral.

It is apparent from the discussion that most of the speakers favour the earthed system as opposed to the unearthed system. There is still, however, some difference of opinion as to whether the neutral point should be connected directly to the earth plate or through a resistance. That brings up the question of the definition of the term " earthed system," and in this connection it may be of interest to quote the following extract from the " American I.E.E. Standards ": "A circuit shall be considered directly grounded when transformer connections and characteristics are such that not less than twice the combined rated line currents from the bank or banks of transformers supplying the circuit will flow to ground when a line is grounded at a terminal of any of the transformers supplying the circuit." This establishes the difference between " earthed " and " unearthed " circuits and removes any ambiguity which may arise when reference is being made to them. Mr. Rawll suggests that it is incorrect to use the term " insulated neutral " for systems on which arc-suppression coils are installed, but if the above ruling is adopted the term is used correctly. It is of interest to read the divergent views on the subject of earthing resistance expressed during the discussion by engineers responsible for the operation of large supply systems. For instance, Mr. A. T. Scott is of the opinion that it is desirable to limit the earth current to the smallest possible value and suggests that this value should bear some relation to the electrostatic capacity to earth of the lines. It is not at all clear, however, what gain is expected from the use of this method in estimating the value of the earthing impedance, unless it be to limit any possible excess voltage of a transient nature. It is difficult to reconcile this point of view with the remarks of other speakers, particularly Messrs. Winfield, Haigh, I. Jones and E. W. M. Scott and Dr. Garrard, who all favour either solid earthing or earthing through a comparatively low resistance. We agree with Mr. Winfield that the Continental systems which are operating with insulated neutrals with or without arc-suppression coils, are usually much less complicated than the majority of networks in this country, and this difference may also explain the divergent views on the question of earthing resistances.

Mr. Gregory's suggestion for rural supply as outlined by Mr. Winfield has much to recommend it and we believe that on such installations arc-suppression coils may prove very useful, because of the importance of capital cost and the consequent necessity of economy in switching equipments.

Miscellaneous Points.

We agree with Col. Edgcumbe that the definite time-delay relay will give results equal to those obtained with the inverse definite minimum time-delay relay on simple feeder systems, but its application becomes very difficult, if not impossible, on more complex networks. This is because, with the former, discrimination depends entirely upon the grading of time settings, and no advantage is taken of the current distribution in the various feeders. Due to the distribution of fault currents in the network, some feeders will be carrying much less current than the faulty section, and if inverse and definite minimum time relays are used, advantage can be taken of this to obtain discrimination between a greater number of circuit breakers without increasing the maximum time delay. We also believe that the induction type of inverse-definite minimum time relay is less complicated than the definite time-delay relay, which is usually of the clockwork type requiring winding up periodically by an attendant.

In reply to Dr. Garrard, Figs. 6 and 7 show arrangements of directional earth-fault relays which are obviously applicable to parallel or ring feeders. We feel assured that a little further consideration will convince him that the relays described in Figs. 9 and 11 are true impedance relays. In reply to Mr. Strong, we think that multiple earthing assists in obtaining discrimination by non-pilot-wire protective systems on ring mains, owing to the concentration of neutral currents at the stations nearest to the fault. We agree with Mr. Morton that certain designs of over-current relays have many fragile parts; these are not inherent, however, in the overcurrent relay and there are designs on the market which are robust and simple.

Mr. Winfield raises the question of carrier-current protective schemes. These are very attractive, but practical difficulties arise in their application, and so far we have no knowledge of the successful use of such schemes except in the case of a simple feeder arrangement to which other types of protection could have been applied. He raises also a very important practical difficulty in the application of reactance and impedance relays to high-voltage lines, namely, that of obtaining the relay voltage from the lower-voltage side of power transformers, and compensating for the voltage-drop due to the transformer reactance. Whilst this is not an ideal arrangement, we consider that by suitable compensating means it is possible to obtain sufficient accuracy for the correct operation of impedance relays, but this sometimes entails complications which could be avoided if voltage transformers were used. There is no difficulty in obtaining correct operation of impedance relays, even when two faults occur simultaneously on a system. As regards the pilot capacity currents in the Translay system, the relay is, as stated in the paper, so designed that the leading component of the current in the pilot wires will produce a backward torque. The self-compensated system has been in successful use for some time on several large supply systems in this country.

We can assure Mr. Murphy that the relay described in Fig. 4 will withstand short-circuit conditions and is of extremely robust design. Mr. E. W. M. Scott fears difficulty with the application of the locking system in a specific instance, but gear of this type is actually in successful operation in stations similar to that which he describes.

In reply to Mr. Kapp, we have carried out some experiments with current-type phase filters applied to relay schemes, but we have had no experience with phase filters for the supply of potential to directional relays. We are of the opinion that sensitive wattmeter elements are preferable to the more complicated phase filter, and it has been our experience that if such elements are designed to operate down to 2 per cent of normal voltage, correct operation is assured.

The later communication by Messrs. Clothier and Leeson does not call for any further reply as the systems described therein appear to be merely variants of systems already fully dealt with in the paper and discussion.

DISCUSSION ON

"LOW-TEMPERATURE CARBONIZATION OF FUEL (ENGLISH PRACTICE)."*

North-Western Centre, at Manchester, 4th March, 1930.

Mr. J. Frith: I am sorry that the paper stops where it does, for although a description of a plant of this kind is interesting we knew beforehand that coal could be gasified, could be turned into coke, that the coke and the gas could be burnt under a boiler and that motor fuel, oils and creosotes could be obtained by distillation. Many of those present have no doubt been wondering whether the process is really going to pay, for no figures as to finance are given in the paper and only a few have been submitted by the authors since it was printed. These were not, however, sufficient to enable one to form an opinion as to whether this great expenditure of money, space, labour and brains will prove to be a practical proposition. I also am interested in smoke prevention, but how many power-station engineers would face this mass of complicated machinery in order to bring it about? The running of a distillation plant, a chemical factory and all the equipment shown in the diagrams, as adjuncts to the generation of electricity, is no light task. I am afraid that people will not enter upon it until figures showing how it will work out financially are available. It is gratifying to think that 15 shillings' worth of by-products can be produced from a ton of coal and that this still leaves 75 per cent of the original heat value in it. If plants dealing with 5 000 tons per week were installed, however, what would happen to the markets for the by-products? Is there an unlimited market for creosotes and fuel oils? They will be difficult commodities to dispose of. If the process were taken up in our large power stations, would there be any guarantee that the market would remain open for the by-products or that the selling price would not drop to a very low figure? The paper describes an interesting experiment, but the first thing to be done now is to produce a balance sheet.

Mr. R. M. L. Evans: At the joint meeting with the Institute of Fuel the descriptions of American and Continental practice, by Mr. McEwen and Prof. Rosin respectively, laid great stress on the vital importance to the economic stability of low-temperature carbonization of fuel of the preparation of a gas suitable for town supply. While this seems a poor policy, as the fundamental aim of the more economical combustion of fuel in the generation of electricity is to cheapen the latter and hence by competition to destroy the market for its own by-product gas, it is significant that the authors of the present paper lay no such stress on this point; in fact they consume the gas produced by the Dunston plant, after stripping it of its volatiles, in the carbonizing plant and beneath the boilers. How do they explain this apparent discrepancy, and are we to assume that they regard the stripped tar oils as of greater economic value than a town-supply gas of suitable calorific value and density? With regard to the much-discussed nuisance of the sulphur content of flue gases, this appears to be actually increased by the process described. In order, therefore, that this nuisance may not become aggravated, and also to remove a possible deterrent to the installation of low-temperature carbonizing plant, may it not become necessary to attack the problem at this point and to remove the ammonium sulphate, even though this plan may be uneconomical? In connection with the quenching of the coke after it leaves the retort, a great deal of heat seems always to be lost here in every method of carbonization of coal, but this is notoriously so in the ordinary coking process. In their chain-grate stoker type of retort the authors seem to have eliminated this loss, yet they interpose quenching apparatus, although they state that the quenching is only partial. Could not this quenching be omitted altogether, and the coke be supplied direct to the stoker at the temperature at which it leaves the retort?

Mr. J. D. Paton: Incipient combustion by the return of supposed inert gases is in all probability the cause of the sulphur increment in the coke above normal bulk ratio, on the conversion basis only. Quenching steam and flue gases carry in sulphur fumes that increase the sulphur content. I wish to point out the authors' appreciation of the words "distillation" and "phase of action" when they work on the basis of getting the maximum of contents value by the introduction of distilling gas at a temperature of 600° C. I was originally a low-temperature carbonization enthusiast, but I now regard carbonization by itself as a failure as far as maximum extraction of value is concerned, and I believe in it only where coke and gas production is necessary. The maximum values in coal exist in three constituents, namely the petrol, cresol and benzol sections. I should like to project on the screen a coloured section of a piece of coal which gives 20 per cent of volatile matter by standard carbonization procedure, and if it is examined with a view to extraction as distinct from carbonization the percentage of oil-yielding constituents is much higher. [The speaker here exhibited on the screen a lantern slide of a piece of Durham coal the constituents of which he defined, estimated and explained.] My basis for the estimation of the liquid return from any coal is the amount of transparency and the extent and nature of the colour halations of the three shades, white to yellow, yellow to brown and brown to red. These indicate the petrol, cresol and benzol fractional components, respectively. The opaque zones are either fixed carbon or inert ash infusions, and whilst I admit the necessity for carbonization where coke is desired or fixed gas is needed I do not accept the modern belief that the proposed high-pressure, high-temperature hydrogenation procedure is the best means for maximum recovery of the constituents of coal which it is possible to liquefy. Why produce fixed carbon by carbonization if oil can be recovered by contact distillation and transference or eventually by direct extraction, under normal industrial pressures and temperatures? Coal is an organic substance and its phases and stages of growth or oxidation (i.e. carbonization) are defined by the transparency or colour-index or on any other basis which one may care to adopt for the halations described above. Bergius is attempting to obtain total liquid recovery at enormous pressures and high temperatures, and I forecast a probable liquor recovery of 50 to 60 per cent from the sample shown, without the use of high pressures, high temperatures, or catalysts in the near future. This is the reason for my interest in attempts at distillation, or, more correctly, at extraction. Mention is made of pioneers, and in this connection I remember forecasting some of these results as far back as 1912, when the process advocated by the authors was partly suggested in a paper read before the Institute of Mining Engineers. My conception of future progress and my present personal procedure are along the lines of the extraction of maximum liquid values of the oil constituents in the coal. It would be an advantage if the gas undertakings would develop along the lines followed by the authors, for in conjunction with electric power production we might then have gas at a reasonable price. In a city like Manchester, which is dependent upon its industrial activities, why should we pay 3s. 4d. per 1 000 cub. ft. for industrial gas? In my business I have to use gas for production purposes, at a cost of between 3s. and 4s. per 1 000 cub. ft., and although the calorific value is given as 500 or 600 B.Th.U. I am doubtful whether it exceeds 450 B.Th.U. per cub. ft. I congratulate the authors on being located in an area where statesmanship has visualized the possibility of coal, steam, gas and electrical power being the foundations of industrial prosperity. I only wish that this city had sufficient vision to recognize the possibilities of its own canal area for this purpose. My last lantern slide gives the details of an industrial grouping which included all the features described by the authors, as far back as 1917–18, when M. Frith and I submitted a paper on fuel economics to this Institution.

---

* Paper by Messrs. E. H. Smythe and E. G. Weeks (see page 219).

Mr. A. L. Lunn: I noted with disappointment the sulphur content of the coke (page 220), because I was hoping that the problems associated with this undesirable constituent had been successfully solved. The analysis of the moisture-free coke obtained by treatment of this coal gives the total sulphur content as 1·61 per cent, whereas in the analysis of the Northumberland coal which is being treated at this coal distillation plant the figure is given as 1·26 per cent. Consumers of fuel in Northumberland are fortunate in having at hand coal with a lower sulphur content than is the case in Lancashire and Yorkshire, and more particularly in the former county. I should like to have some information with regard to the plant installed for firing this semi-coke, and particularly as to the type of boiler—its arch and the size of its combustion chamber and the class of stoker employed. What thickness of fire can be used, is any difficulty experienced in maintaining combustion, and can the maximum evaporation be obtained from the boiler? In other words, is it necessary to incur expenditure on additional boiler plant in order to compensate for the effect of distilling the coal? The work described by the authors is very valuable, and it would be interesting to know whether it is proposed to extend the system to other power stations consuming thousands of tons of coal per week, where the experiment could be carried out on a large scale. At a recent smoke abatement exhibition I was interested in a certain type of fuel shown which was claimed to be smokeless, as well as clean to handle and use. I decided to try this fuel at home in an ordinary kitchen grate, but it compared very unfavourably with coal. In the first place, it was expensive. Secondly, it was very dirty, and contained an abnormal percentage of ash. It was decided to give the fuel a further test, this time in the dining-room. It was found necessary to switch on the radiators in this room to keep it comfortably warm. Approximately every hour the fire had to be attended to, as it was found to take about 40 minutes to reach the maximum heat value and then it gradually died down. In addition to these disadvantages, a large quantity of dust was deposited all over the room. It was observed that on each occasion when fresh fuel was added to the fire a quantity of light-coloured smoke ascended the chimney; this was not so black and dense as that obtained when using raw coal—thus the outside atmosphere was kept much cleaner—but much more work was involved in keeping the house clean. I am particularly interested in the use of semi-coke at the power station, and although the authors referred to the burning of this fuel in pulverized form they did not make it quite clear whether they have actually accomplished this or whether it is only contemplated. If they are already doing this, I should like to know whether they have had any trouble with the pulverizing plant. It has been stated that screw conveyors are used. There is, perhaps, a difference between the hardness of semi-coke and that of coke breeze, but in my experience the abrasion caused by the latter has resulted in this type of conveyor having a very limited life. The development of a process such as that described by the authors, of installing low-temperature coal-distillation plant at a power station, savours of the introduction of a gasworks into the electricity supply industry. Would not the ideal be to establish gasworks and power stations together, for their mutual advantage, the two being worked as a combined unit?

Messrs. E. H. Smythe and **E. G. Weeks** (*in reply*): The questions raised by Mr. Frith are of such a general nature that it would be somewhat difficult to answer them in detail within the limits of space available for this discussion. We should like to point out again that the scope of the paper is purposely confined to a description of the process and the results obtained from this process as worked at Dunston. We have shown that raw coal can be treated to produce certain solid and liquid by-products, but we have purposely kept the paper free from considerations of a commercial nature, complete with balance sheets, etc. There is, however, no difficulty in preparing a proposition of this kind, provided suitable data are submitted concerning the class of coal to be treated and the type and market prices of the by-products it is desired to produce. If Mr. Frith is interested, we suggest that he should submit an inquiry to the manufacturers of the plant who, we are sure, will be only too pleased to go into this aspect of the proposition and give him all the information he requires. As regards the other points mentioned, we do not agree that it was known that satisfactory means were available for converting large quantities of coal into semi-coke, or that coke can be burned under a boiler with satisfactory results. It would, in any case, necessitate considerable alterations to existing draught arrangements and furnace design. Semi-coke, as produced by the process described, is, on the other hand, an entirely suitable fuel for this purpose, and this was not known to be the case until we had proved it by practical working at Dunston. As regards co-operation at the power station, it is quite possible to operate low-temperature plant independently, so that the power station merely takes fuel from the plant while the liquid by-products are dealt with by a separate organization, thus relieving the power station of any responsibility in this respect. We agree that if the installation of low-temperature plant became general the supply of certain liquid by-products might be greater than the demand, but this possibility is very far distant, and long before it is reached the liquid by-products would most probably be dealt with in other ways, e.g. by "cracking" for the production of motor spirit.

In reply to Mr. Evans, the process described produces only low-grade gas having a calorific value of about 100 B.Th.U., and this gas is of no use to the gas companies except as a diluting medium. We certainly do not regard this stripped gas as being of greater economic value than town gas, and, in fact, if burned under the boilers it is only credited to the plant at the same price per therm as that paid for the coal. We do not claim to reduce the sulphur contents in the flue gases, though they are actually reduced when certain coals are treated. In any case, we do not think that the removal of the ammonium sulphate is worth while. As regards the quenching of the coke, Mr. Evans does not seem to have appreciated the fact that the object in quenching the coke as it leaves the retort is to recover some 60 per cent of the low-pressure steam required in the operation of the process, so that actually no heat is lost by quenching. We do not think it advisable to omit this quenching as, if hot coke is supplied direct to the stoker, difficulties will arise in storing the coke in the event of the boiler being out of action, and it is, on the whole, preferable to supply quenched coke to the bunkers rather than direct to the stoker.

With regard to Mr. Paton's opinion that in all probability the cause of the increment of sulphur in the coke is the sulphur derived from the distilling gases, we would say that in the event of the whole of the sulphur present in the distilling gases being transferred to the coke the increase in the sulphur content of the coke would only be of the order of 0·06 per cent. What actually happens is that the bulk of the sulphur in the raw coal appears in the coke, and as the weight of coke is less than that of the coal it follows that the percentage of sulphur in the coke is higher than in the original coal. With certain coals the percentage of sulphur in the coke is less than in the coal, but this does not apply to the coals normally used at Dunston. We were much interested in Mr. Paton's lantern slides and we are thoroughly in agreement with his view that it would be an advantage if gas undertakings were to take an interest in low-temperature carbonization with a view to the production of suitable smokeless fuel for household purposes, and also with a view to still further cheapening the cost of gas by diluting town gas and supplying gas of lower calorific value than is at present the case. The use of gas from the Babcock process as a diluent for town gas is advantageous as it can be supplied at a cheap rate, but in addition, owing to the low content of carbon monoxide in the gas, its admixture with town gas does not increase the percentage of carbon monoxide in the gas to be distributed to the consumers, as is the case when town gas is diluted with water gas.

In reply to Mr. Lunn, the design of furnace used for burning semi-coke differs in only minor respects from that used for burning coal; in fact a shorter arch may, with advantage, be used, thus reducing the cost of construction. Otherwise, the type of stoker and size of combustion chamber are the same as those normally employed. The thickness of the fuel bed on a chain-grate stoker using semi-coke is approximately twice that normally used with coal. No difficulty whatever is experienced in maintaining combustion, as the coke is very free-burning and maximum evaporation is obtained. We are sorry to hear that Mr. Lunn has had such an unsatisfactory experience with smokeless fuel and we can only conclude that it was not a very good example of its kind and was made from inferior coal. Our own experiences with Dunston semi-coke have not shown any disadvantages in connection with dust or ash, though it is certainly the case that the fire has to be attended to more often than when coal is used. On the other hand, an intense fire is reached very rapidly, which is an advantage, and the fuel is light and clean to handle and certainly very economical, taking into account the quantity received, ton for ton, as compared with coal. We have so far not experienced any difficulty with pulverizing semi-coke. As the semi-coke is comparatively soft it is easy to pulverize and does not possess the same abrasive qualities as high-temperature coke.

SOME DEVELOPMENTS OF THE PIEZO-ELECTRIC CRYSTAL AS A FREQUENCY STANDARD.

By H. J. LUCAS, Associate Member.

(*Paper first received* 16*th December*, 1929, *and in final form* 31*st January*, 1930; *read before the* WIRELESS SECTION 5*th March*, 1930.)

SUMMARY.

Part (1) deals with some observed errors in quartz piezo-electric resonators employed as frequency standards. It is shown that these are due to (*a*) frictional loading, and (*b*) losses arising from atmospheric humidity. The methods adopted to eliminate these are discussed, and the development of calibration apparatus employing the resonators as reference standards is dealt with.

Part (2) is in the main concerned with the use of the improved quartz crystal as a control element in a valve-maintained source of oscillations. The frequency-stability characteristic of such a system is investigated, the errors are found to be largely due to the valve system, and methods designed to eliminate these are discussed.

Finally a complete calibration equipment consisting of a multivibrator system with a range of 1–6 000 kilocycles per sec. in steps of 1 kilocycle per sec., centrally controlled by a quartz crystal, is shown.

INTRODUCTION.

Up to and including the War period the author was interested in the maintenance of a sub-standard wavemeter for the calibration of wavemeters in bulk. An accuracy of 1 per cent was found sufficient for all needs at that time. In the years immediately following the War accuracies up to 1 part in 1 000 were called for, while at present the sub-standard has to be correct to within 1 part in 10 000.

The first phase calls for no comment. The requirements of the second were met by the use of a wavemeter employing an oscillating triode. The accuracy of this was maintained by reference to a calibrated low-decrement closed oscillatory circuit. The latter has since become known as an " absorption wavemeter " and the reference was carried out by means of the phenomenon known as the " Ziehen " effect.

The third phase is met by similar methods, but the reference standards are in this case quartz resonators. The first part of the paper deals with the development and applications of these reference standards.

PART (1).

SUMMARY OF THE RELEVANT POINTS IN THE MODERN THEORY OF COUPLED CIRCUITS.

In practice it is found that the application of the " Ziehen " effect in the second phase and the various applications of quartz oscillators and resonators in the third phase are governed by the same fundamental principles. Nearly the whole of the practical applications of quartz crystals conform to the laws of coupled circuits. With suitable adjustment of the circuit these, in common with magneto-striction devices and valve-maintained tuning forks, exhibit the characteristic frequency-discontinuities of a system consisting of a low-decrement circuit tightly coupled to a source of free oscillations.

In certain instances the control member is used to obtain retroaction over a narrow frequency band and simultaneously to stabilize the resulting oscillations, but in no sense does it act as a generator.

The equivalent coupled-circuit conditions for the quartz crystal have been deduced by D. W. Dye[*] and other writers. The following relevant points in the theory of coupled circuits have been taken from papers by J. S. Townsend[†] and H. G. Möller.[‡] A coupled circuit with a fixed primary impedance and a secondary capable of being tuned to resonance with the frequency of the applied e.m.f. is fed by a valve or other source of free oscillations. Provided that the coupling is greater than the value defined by Möller as the " critical " value, continuous variation of frequency with secondary tuning cannot be obtained. Abrupt frequency discontinuities appear on either side of the resonant points —Möller's " Ziehen " effect. Fig. 1 illustrates this point.

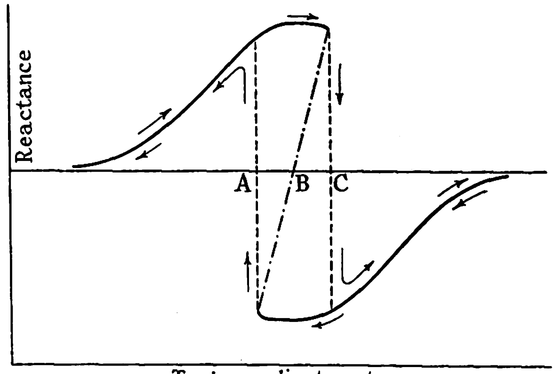

FIG. 1.

It will be noted that the portions of the operating curves bounding the hysteresis area show a very marked frequency stability, a comparatively large change of tuning producing but a small frequency change. A mathematical analysis of the simple coupled-circuit as described shows that there are three possible modes of oscillation, f_1, f_0, f_2, where f_0 is the frequency of the applied e.m.f. with the secondary removed. An examination of Fig. 1 shows that in the vicinity of resonance (B) the mathematically possible oscillation, f_0, cannot in practice be obtained, whereas f_1 and f_2 can be obtained at will. Möller gives a reasoned case as to why these conditions obtain.

---

[*] " The Piezo-Electric Quartz Resonator and its Equivalent Electrical Circuit," *Proceedings of the Physical Society of London*, 1926, vol. 38, p. 399.

[†] " Oscillations obtained by Coupling a Secondary Circuit with a Continuous Wave Valve Oscillator," *Radio Review*, 1920, vol. 1, p. 369.

[‡] " Zur Theorie des Ziehens," *Jahrbuch der Drahtlosen Telegraphie*, 1920, vol. 16, p. 402.

The deductions from these observations are as follows:—

(1) All mechanical vibrator-valve combinations which obey the laws of coupled circuits produce frequency-stabilized oscillations.

(2) Such combinations have two possible modes of oscillation. In the case of quartz either may be obtained by connecting the crystal to (*a*) grid-filament, or (*b*) grid-anode.

(3) The combination cannot oscillate at the natural free period of the mechanical vibrator.

The complete argument may not be strictly true in all cases of quartz-valve combination, as the frequency break, while invariably present, is displaced, and f_1 and f_2 are higher in frequency than f_0. A very close approximation to f_0 may be obtained by the Cady crevasse method, but in this case the crystal is not used as a "control" member.

A further point may be made at this juncture. The cases referred to above are in general for free oscillations, but the outputs from such combinations behave as forced oscillations, and they may be used to control other free oscillations of approximately the same periodicity and certain far-removed periodicities, as will be discussed later.

FIRST APPLICATION OF THE QUARTZ RESONATOR.

In view of the lack of uniformity in the nomenclature used in the literature on the subject of quartz crystals, in accordance with Dye's practice the following conventions have been adopted:—

(1) Longitudinal vibrations—the mode of oscillation employing the longest dimension of the crystal. The cut for this may vary, but for the purposes of definition a cut normal to any two parallel faces of the natural crystal may be accepted.

(2) Transverse vibrations. This mode of oscillation employs the thickness of the crystal, i.e. it is at right angles to the longitudinal mode.

(3) Resonator—a crystal used non-retroactively. In general the longitudinal mode is employed.

(4) Oscillator—a crystal used retroactively or to control a retroactive circuit. The transverse mode is usually the more effective in this connection.

Practically the whole of the investigation which follows is concerned with the longitudinal mode of vibration. Considered purely from the precision standpoint, the longitudinal mode presents great advantages over the transverse. As an instance, the temperature coefficient of the former is only about one-twentieth of that of the latter. This important fact was first pointed out by Dye.

The introduction of the quartz resonator by W. G. Cady * was welcomed by the author with considerable relief. It was appreciated that the closed-circuit reference standards then in use were not to be relied upon for the accuracies demanded, and quartz appeared to offer a completely reliable alternative. Its inherent nature suggested absolute permanence and stability, its natural period could be determined with a high degree of accuracy and its reactions on the oscillating circuit were sharp and positive. An ideal solution appeared to have been arrived at, and for a time it was accepted without question. However, certain variations, apparently of the sub-standard wavemeter, were observed and these (of the order of 1 part in 3 000) could not be definitely traced to the wavemeter. It was decided, therefore, that an investigation into the behaviour of the quartz resonator was necessary.

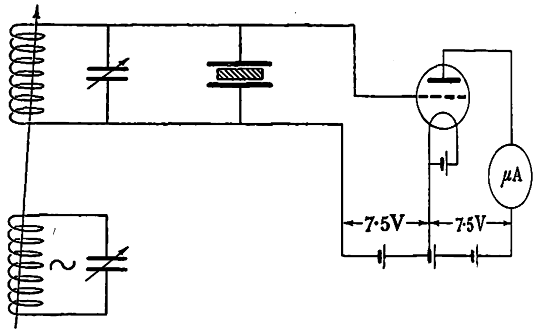

FIG. 2.

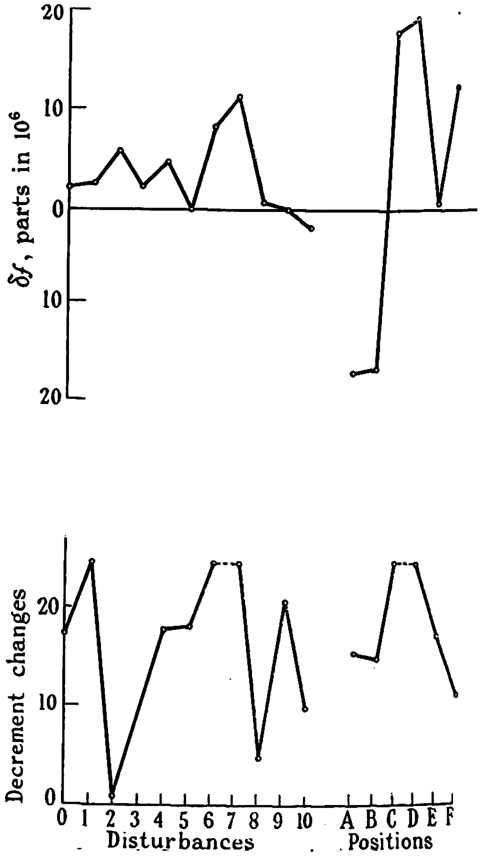

FIG. 3.

Reference to a multivibrator confirmed the opinion that the resonator or its mount was responsible for the variations. Suspicion naturally fell on the mount and a full investigation was undertaken to determine the cause of the variations.

---

* "The Piezo-Electric Resonator," *Proceedings of the Institute of Radio Engineers*, 1922, vol. 10, p. 83.

The method of observation was that of the Cady crevasse, the only difference from the then standard practice being the use of a heavily biased valve voltmeter instead of the more usual thermo-junction and galvanometer. The circuit is shown in Fig. 2. This enabled less power to be used in the oscillator and gave a more sensitive record of the minute variations of potential in the operating region at the bottom of the crevasse. Fig. 3 shows a typical series of observations. The logarithmic-decrement variations shown are only relative, as they were disclosed partly by changes in the depth of the crevasse and partly by the sharpness of what is, in effect, the crest of the resonance curve of the resonator. It was evident that within the limits of 1 part in 3 000 the crystal was very unstable. In fact the slightest disturbance in the laboratory, such as closing a door, altered the readings. It was known that the frequency variations could, in part, be accounted for by changes in the small air-gap, but this would not account for the decrement changes.

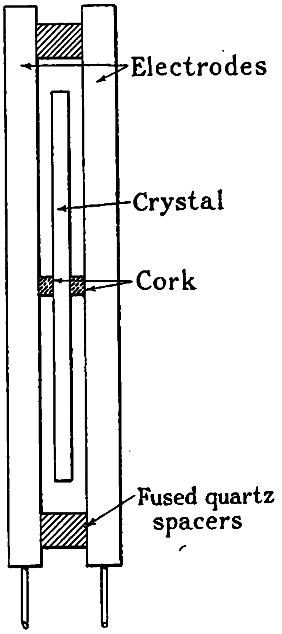

FIG. 4.

To investigate this point the resonator was supported centrally in a large air-gap (1 mm each side). The variations were found to be worse, and the decrement was also increased. This gave the clue to the trouble, as the supports for centring the crystal were obviously adding to the existing sources of error. These were finally traced to the effect of frictional loading between the crystal and its supports, which was altering both the period and the damping factor of the resonator.

The solution was simple. The resonator was firmly gripped at a nodal point of mechanical displacement for the fundamental longitudinal mode (in the centre of its length), so as to leave it free to vibrate without friction. Fig. 4 is a plan view of a resonator mounted in accordance with this method. The whole of the short-period variations shown in Fig. 3 had now vanished and the resonator could be placed in any position or could be jarred without alteration of frequency or decrement, and readings could be reproduced with a high degree of accuracy. For the first time a really consistent plot of the Cady crevasse could be obtained, enabling the numerical value of the logarithmic decrement to be computed.

This specially-mounted resonator was kept under observation for some time and long-period variations of frequency, of the order of 1 part in 10 000, as well as decrement changes were noted. These were eventually associated with changes in atmospheric humidity and the relation between the cause and its effect was soon confirmed by tests in:—

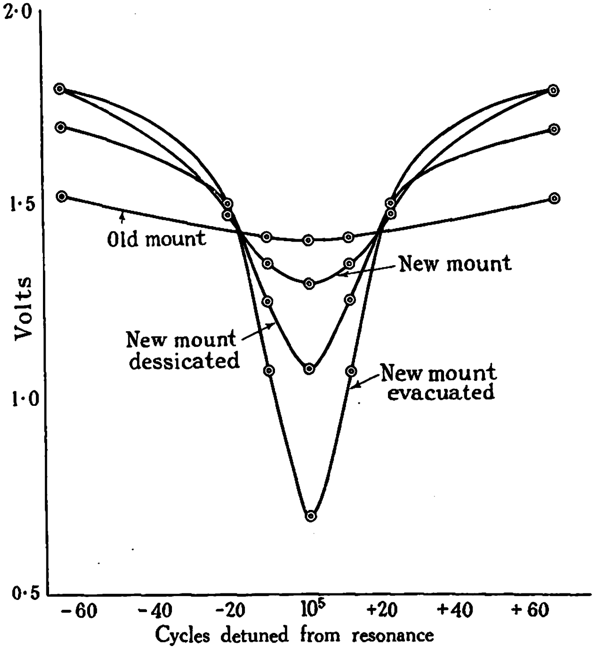

FIG. 5.

(1) a saturated atmosphere (when the piezo-electric effect disappeared), and
(2) a sealed test-tube, with a desiccating agent.

In the latter case definite stability was obtained, after a period of slow drift during which the moisture was absorbed, together with an improvement in the decrement. An increase in the frequency of approximately 1 part in 10 000 was also noted; this point will be further discussed in Part (2). The frequency change may be partly due to the removal of the loading effect of the film of moisture on the surface of the crystal, while the improvement in decrement may result from the elimination of the hysteresis loss in this film. Dye has shown that the equivalent capacity of a similar resonator is of the order of $0 \cdot 08\,\mu\mu F$. As the logarithmic decrement is a function of the capacity as well as of the resistance, it will be realized that a small loss in such a minute capacity will have a marked effect upon the decrement. Dye comments upon the probable effect of humidity on frequency and has also adopted a form of nodal-support mounting.*

The obvious step of evacuating the enclosure which contained the resonator was now taken, and the anticipated further improvement in the decrement due to the removal of the air-loading was obtained. It is doubtful whether evacuation or even desiccation without the mounting precautions would be of much value. The frequency variations and decrement depreciation due to frictional loading would to a large extent mask the improvement due to the removal of air loading. Fig. 9 shows the improvements in decrement as indicated by the depth and sharpness of the crevasse, produced as a result of the successive stages of development. The frequencies have been reduced to a common value for convenience—in practice these differ to the extent of 1 part in 5 000 for the extreme cases.

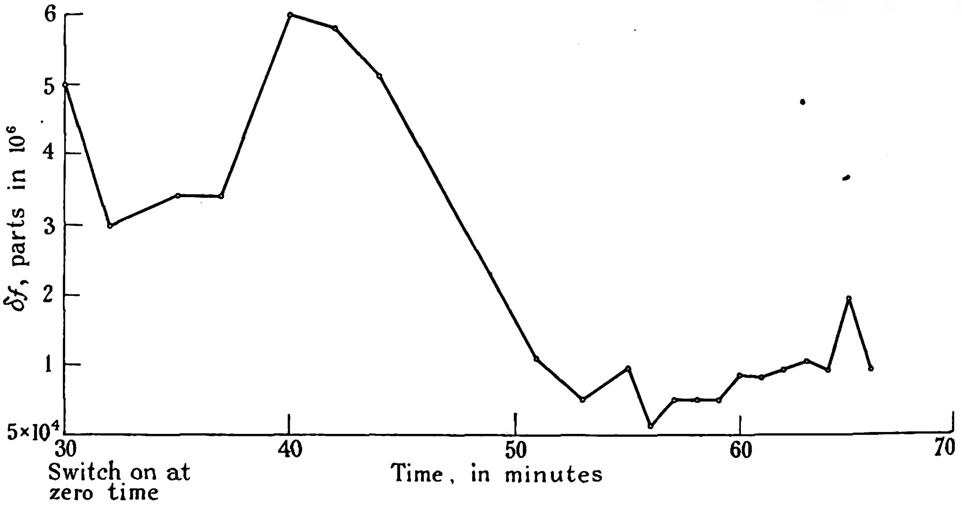

Fig. 6.

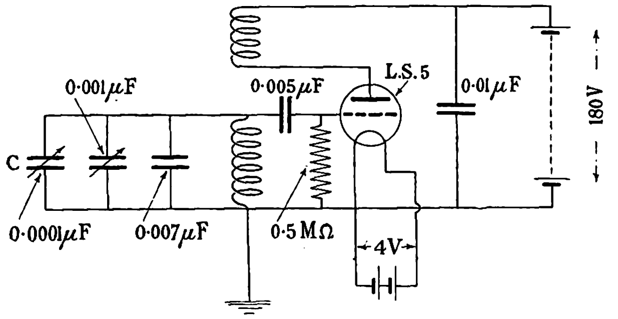

Fig. 7.

The "figure of merit" of a resonator or similar system is the degree of accuracy to which the true resonant frequency can be determined. This in turn is related to the logarithmic decrement. In the case of the mounted and evacuated crystal, Fig. 10, an open-scale plot of the bottom of the crevasse, shows that this determination can be made to an accuracy of 1 part in 200 000, whilst the normally-mounted crystal gives a value of the order of 1 part in 5 000 which is not at all constant. During the investigations described in the foregoing it was found possible to design and build valve-maintained oscillators which would remain constant in frequency for reasonable periods to within 1 part in 100 000. A typical time/frequency curve for such an oscillator is shown in Fig. 6.

It was found that the principal causes of the variations which are usually attributed to this system were changes in the capacity of the variable condenser for any given setting, together with alterations in the valve characteristic. The inconsistencies of the variable condenser could be reduced by careful design of that component, and the residual effect could be diminished to negligible proportions by the use of a fixed shunting-capacity, which should be as large as is consistent with the provision of the necessary tuning-range. Variations of valve characteristic and of anode and filament-supply potentials were all shown as changes in the equivalent capacity of the valve. As this capacity was in parallel with the tuned circuit its effect was reduced by the provision of a shunt capacity in the latter. The circuit and values used are shown in Fig. 7. This circuit could be checked back to the quartz resonator when necessary by using it as the variable source in the Cady crevasse method, and it was found desirable to distort its output to produce the requisite number of harmonics for use in calibrating other oscillators. Further development of this method produced the equipment of which the circuit is shown in Fig. 8.

The 10-kilocycle oscillator was built on the principles set out above, while the power amplifier followed normal practice. The 10th harmonic of the distorting circuit was selected by a tuned circuit and referred to the 100-kilocycle quartz resonator by the Cady crevasse method. The adjustment was carried out by means of the fine tuning condenser C (Fig. 7), while the output from the coupling coil L gave a full range of harmonics from 10 to 2 000 kilocycles per sec. in steps of 10 kilocycles. As the adjustment of the oscillator frequency was carried out by referring the distorted output to the resonator, any errors due to coupling were allowed for. The rectifying valve was found to be the most convenient method of producing the requisite number of harmonics.

---

* Pp. 417 and 447, *ibid.*

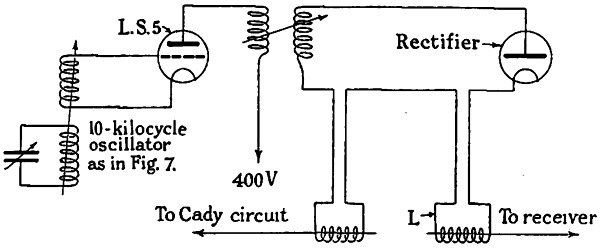

FIG. 8.

The fine-tuning condenser was calibrated in terms of the number of cycles per second by which it departed from the resonator frequency.

At the time when this equipment was developed, the B.B.C. stations were all, with the exception of 5 XX, working on a frequency which was a multiple of 10 kilocycles. Hence each station was nominally on a harmonic of the 10-kilocycle oscillator and any departure could be noted by the difference between the 10-kilocycle adjustment of the fine-tuning condenser and that obtained by referring the appropriate harmonic to the frequency of the station's carrier wave by the double-beat method; this difference was multiplied by the harmonic order of the station relative to the oscillator. Some interesting observations were made on the accuracies and stability of these stations and it was particularly noticed that 5 GB, whilst seriously departing from its nominal frequency, showed remarkable constancy. This was subsequently confirmed by Captain Eckersley's paper.* The result of a series of observations on 2 LO is shown in Fig. 9, in which the curve commences at the instant at which the station begins to radiate.

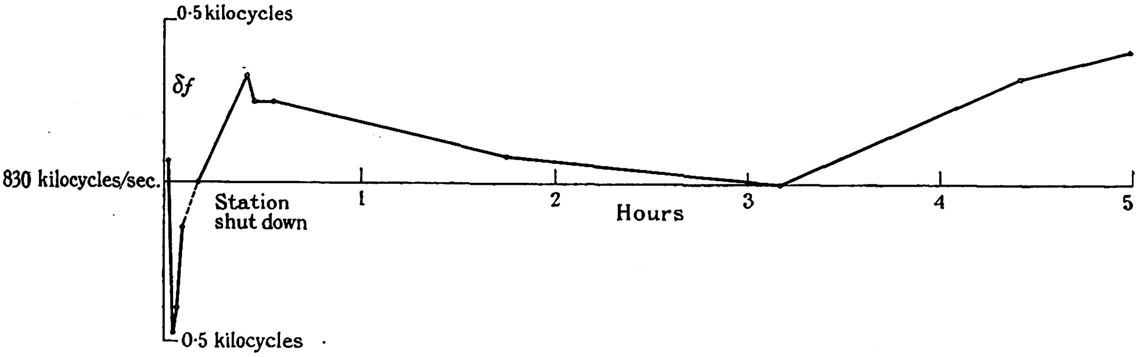

FIG. 9.

This equipment was found of very great use in the calibration of sub-standard wavemeters to the required degree of accuracy. It was also used for the measurement of inductance and capacity at various high frequencies. Further, it was and still is considered that the ideal use of a frequency standard is as a means of adjusting the frequency of a separate oscillating system and not as a " drive " or " control." The analogy to the pendulum is the employment of a free undriven pendulum as a check on a driven system, by some means which does not cause the free pendulum to deviate from its true period. It is believed that modern methods of high-precision horological determination have developed in this direction.

Briefly, the advantages of a system employing a resonator as a reference standard are:—

(1) The resonator is not doing any work—it is fed with just sufficient energy to enable the determination to be made, and the load applied by the indicating device (valve voltmeter) is practically one of potential.

(2) Provided that the " Cady crevasse " closed circuit is accurately tuned, the true period of the crystal-mount assemblage is obtained.

(3) Any variation in the electrical circuit is immediately made manifest and is under complete control.

The principal disadvantage of the system is a slight uncertainty in the value of the true resonant-period due to the approximately straight line which exists at the bottom of the crevasse and which at present limits the accuracy of adjustment to about 1 part in 200 000 (Fig. 10). It is considered, however, that this could be

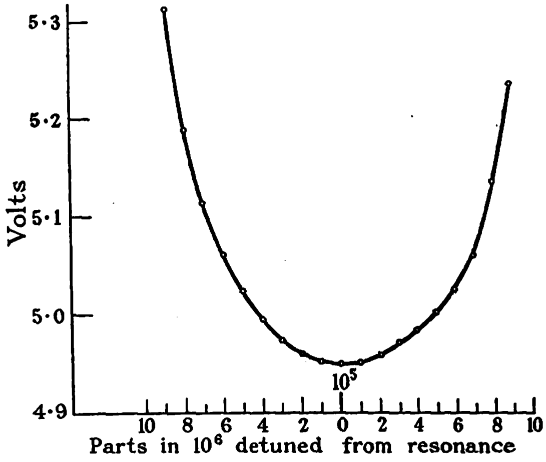

FIG. 10.

greatly improved by further research, one suggestion being the employment of a high-frequency amplifier between the resonator circuit and the valve voltmeters. It has been found necessary to postpone these experiments owing to the need for the developments discussed in Part (2).

The fork-driven multivibrator had proved to be such a useful piece of apparatus that the possibility of applying the quartz standard to a similar scheme presented an irresistible attraction. Also a source of precise forced oscillations was required for general investigational work. It appeared that a great deal of research work would be needed to enable the resonator system to be used with the accuracy which, it was felt, would be called for in the near future. A wide-range low-frequency oscillator was also necessary for interpolation between the 10-kilocycle harmonics.

Further consideration of the resonator was therefore postponed and the work which is discussed below was undertaken, with the intention of returning to the reference standard in the near future.

PART (2).

DESIDERATA OF THE DRIVE CIRCUIT.

(1) Experience has shown that any attempt to introduce retroaction produces a tendency to frequency instability, therefore the circuit should be capable of oscillating with no retroaction with the exception of that inherent in it.

(2) The controlling member should have a low temperature-coefficient.

(3) The coefficient of coupling between the mechanical component and the valve system should be of as low a value as possible.

In applying these principles, (1) is met by a tuned anode circuit with the crystal connected between the grid and the filament. Oscillations are more readily produced by the grid-anode connection but they are feebler and less stable than those produced by the alternative connection. (2) is ensured by the use of bars employing the longitudinal mode of vibration. This gives a temperature coefficient of the order of 2 or 3 parts in 10^6 per degree C. The transverse modes give values of the order of 40 to 70 parts in 10^6. The reason why these latter modes are frequently used is that serviceable oscillators are more easily produced from them than from the longitudinal mode. (3) is met by the use of air-gaps of the order of 1 mm between the crystal and its electrodes. In any case the electrostatic coupling of the crystal is much less than that of magneto-striction, fork, and other such electromagnetically-driven devices.

DEVELOPMENT OF THE DRIVE CIRCUIT.

Preliminary work showed that very good samples of this type of crystal would produce oscillations under the stipulated conditions provided that no air-gap was used, but that they failed to function when nodally mounted with an air-gap. Utilizing the experience gained on the resonators, some of these crystals were mounted in a desiccating chamber and the best of them were found to oscillate. One of these was used in a sealed tube for the preliminary development work, and the only drawbacks noted in its behaviour were a failure to oscillate below 10° C. and the fact that it would not operate with a grid-leak and had perforce to be used under free grid conditions. At a later stage the evacuated type was employed and these limitations disappeared. To eliminate the possibility of frequency variation due to grid contact-potential, bombarded, non-"gettered" valves of the L.S.5 class have been used in all the later stages of the work. The drive circuit is given in Fig. 11 and presents no novel features.

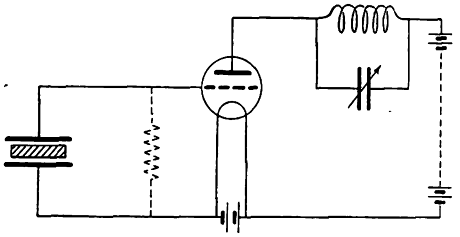

FIG. 11.

FREQUENCY STABILITY OF THE DRIVE SYSTEM.

The reference standard used for the majority of the work is a valve-maintained tuning fork. An N.P.L. Certificate gives its period, 1 kilocycle per sec., to the seventh figure, the last being "dropped," and a zero temperature-coefficient over the working range of temperature. It is considered that the former can be relied upon to 3 parts in 10^6, and such accuracy met the needs of the preliminary investigations. The method adopted for referring the drive output to the reference standard was as follows:—

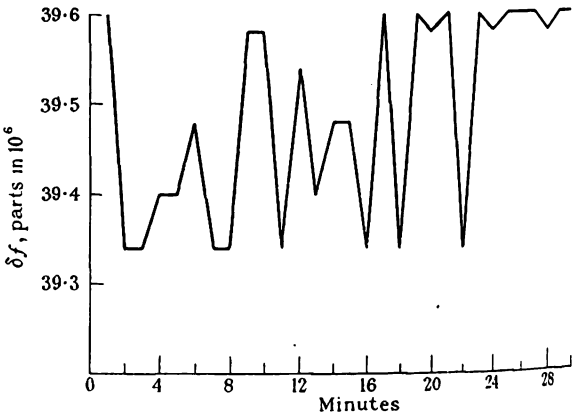

FIG. 12.

The fork was used to drive a 1-kilocycle multivibrator circuit through a biased coupling-valve. The 50th harmonic of this was beat against the drive circuit and the resultant beats were counted over a definite period of time.

Determinations of the period of such systems as these are usually effected by reference to a time standard by means of some form of synchronous motor. The method has the advantage that the comparison may be made with a fundamental time standard, but it suffers from two disabilities:—(*a*) the intervention of the synchronous motor has the effect of masking any short-period variations which may be present, and (*b*) a run covering a number of hours, and in some cases several days, is necessary to obtain a determination to within 1 part in 10^6. The method outlined above enables a determination to 1 part in 10^6 to be obtained in time periods of the order of 1 minute, for in this time (3×10^6) cycles are completed and any difference between the crystal circuit and the 50th harmonic of the fork appears as beats. Extended experience has shown that observations to 1 in (3×10^6) of beats of the order 3 per second are easily possible by taking counts over periods of 1 minute. To produce an error of this order requires an uncertainty in the chronometer reading of 0·4 sec. in 1 minute. In general, 200 beats are timed.

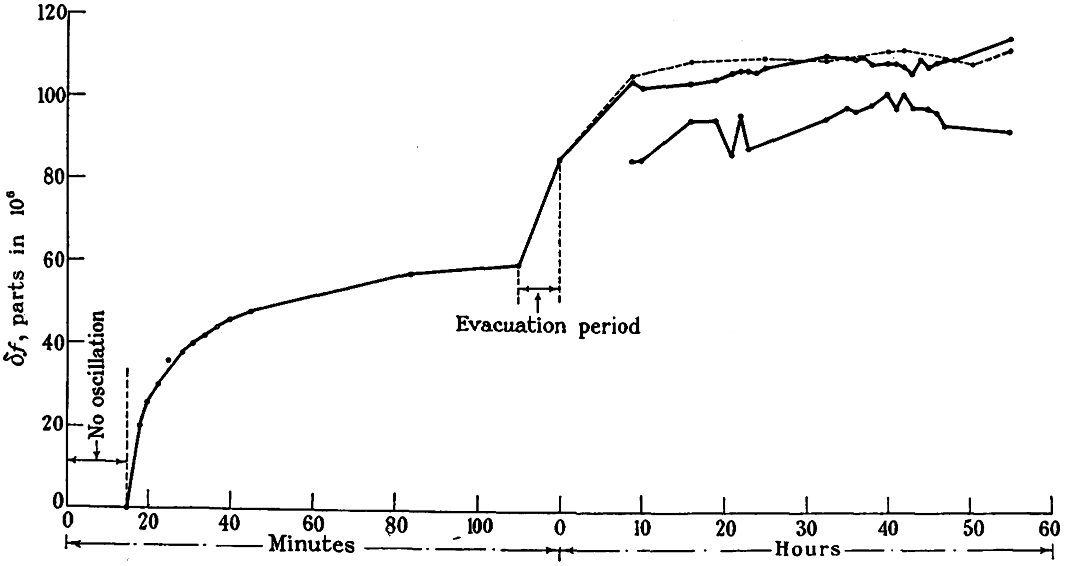

FIG. 13.

This method also permits observation of short-period variation, and the author believes that these are the first records of this nature. The crystal oscillator is adjusted by means of the anode condenser and other controllable variables so as to obtain a round number of beats in 1 minute, say 100. The count is carried on continuously and it is only necessary to note and record the variation of the chronometer seconds-hand from the 60-second mark on the completion of each hundred beats. Here again, possible errors introduced by slight inaccuracies of the chronometer reading are much less than the uncertainties due to the reference standard. An instance of an observation of this character is given in Fig. 12.

The method suffers from two defects:—(*a*) the reference is not direct to a fundamental time-standard, and (*b*) it is only applicable where the system under observation is sufficiently close to the standard to produce beats of the order 4 per second, or less. This latter condition has in all cases been easily met in these investigations.

The first observations were carried out on the non-evacuated crystal, using a free grid circuit. It was promptly found that the frequency was varying in an erratic manner and no consistent readings could be obtained. This condition was explained by reference to some work * carried out by the author's colleagues on the operation of valves under free grid conditions. The remedy consisted in bonding and earthing all free metal parts in the vicinity of the grid circuit. A permanent frequency-change of about 25 parts in 10^6 was noted and the system was quite stable.

This system was in use for some weeks and no frequency change greater than 5 parts in 10^6 was noted. Indeed, when a biased-grid system was adopted later it was found to be a most difficult matter to obtain an accuracy of this order. The reason is not far to seek. The free-grid system operates in such a manner that no grid current is flowing and there is a very close relation between grid current and frequency change. It is

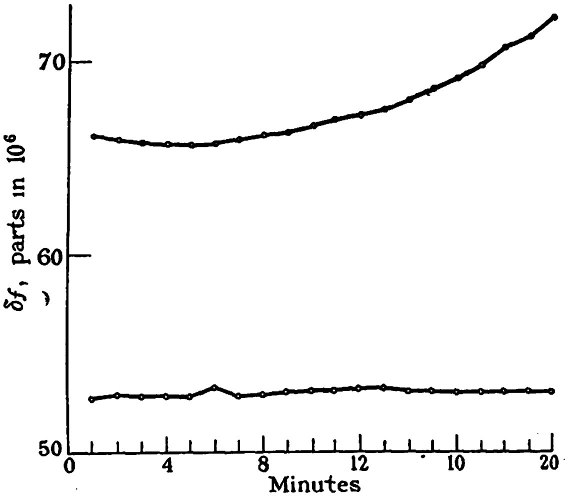

FIG. 14.

* P. L. WOSTEAR and R. H. BILLINGSLEY: "Improvements Relating to Thermionic Valve Circuits," British Patent No. 12880—1926.

considered that such a system, properly screened, would be suitable for further investigation. It was felt, however, that the conventional biased-grid would prove more generally acceptable. In the meantime the system had been sufficiently improved to operate with grid bias.

The lower curve of Fig. 13 and the upper curve of Fig. 14 show some observations on this biased system. Fig. 13 shows a number of intermittent readings taken over 50 hours. The general upward drift is largely accounted for by temperature. Rapid fluctuations, however, are present. Fig. 14, upper curve, shows the results of a 20-minute run under continuous observation, and one of the larger excursions from the mean value shown in Fig. 13 is evidently taking place. The magnitude of these changes caused surprise and the system seemed definitely inferior to the free-grid system in previous use. As at the time no plausible reason could be offered for these fluctuations, an investigation of all the variables under control was undertaken.

FREQUENCY-CHANGES DUE TO THE CONTROLLABLE VARIABLES.

(*a*) *Anode Variable-Condenser.*—Fig. 15, top curve, gives a typical example; the other two curves show grid and anode currents. This demonstrates that while the frequency is by no means independent of the condenser setting, it is practically independent of any small fortuitous capacity-variation for a given setting. An appreciable range of capacity gives $df/dC = 0$, but unfortunately this coincides with minimum output conditions. Maximum output occurs, just before oscillations cease, at 400 $\mu\mu$F. The form of the curve obtained agrees very well with that which might be deduced from the theory outlined in Part (1), this curve being a part of one of the boundary curves in the region of instability in Fig. 1. In this instance, if a similar crystal were also connected to the grid and anode, on the extinction of the oscillation f_1 at the point of maximum capacity a new frequency f_2 would develop. These points, however, have no bearing on the question of frequency stability.

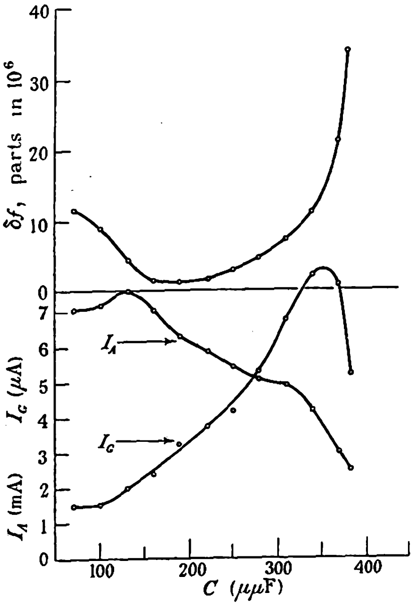

FIG. 15.

(*b*) *Anode-Inductance Variation.*—Table 1 shows that the system is independent of any possible normal variation of this nominally fixed component.

TABLE 1.

Inductance	Time for 100 beats	Variation of frequency from 5×10^4 cycles per sec.
μH	secs.	parts in 10^6
27 000	33·4	59·9
12 400	30·0	66·6
35 000	33·8	59·2

(*c*) *Anode-Potential Variation.*—In Fig. 16 a working range of 2·1 to 1·8 volts per cell has been assumed as the possible maximum voltage-variation. This gives a variation of 105 to 90 volts for a nominal 100-volt accumulator battery, and the frequency variation for this is 7 parts in 10^7. Fig. 17 is a similar curve for the standard fork which shows a frequency variation of 1 in 10^5, a ratio of 1: 14 in favour of the crystal.

(*d*) *Filament-Potential Variation.*—Figs. 18 and 19 show the variation of frequency with E_f for the crystal and fork respectively. In this case the comparison is even more in favour of the crystal, the ratio being 1: 70. Over the working range of voltage the frequency change for the quartz is 1 part in 10^7, and for all practical purposes this is negligible.

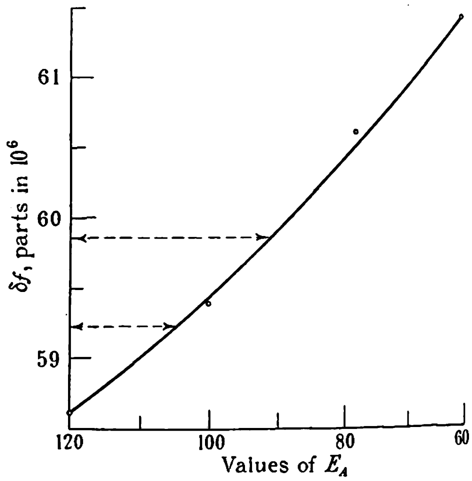

FIG. 16.

(*e*) *Grid-Potential Variation.*—This was effected by changing the value of the grid-leak, or by connecting a cell in series with it. Table 2 gives the frequency values obtained. In practice, such changes in the grid conditions are unlikely to develop.

An analysis of these results, while illuminating in themselves, gave no clear guidance as to the cause of the variation shown in the lower curve of Fig. 13.

General observation, however, gave rise to the following considerations:—

Whilst no definite proof was forthcoming that the changes were not due to the crystal or its mount, it was felt, particularly as the resonators which had been under observation for nearly three years showed no sign of this condition, that the valve circuit was more likely to be the seat of the trouble. This conclusion may appear somewhat weak when it has been shown that the fork, which is presumably free from these variations, is much more susceptible to circuital variations. The inference is that the transfer of the frequency of operation from 1 to 50 kilocycles per sec. is responsible for the greater frequency instability. Also, occasional variations of greater magnitude than those shown had been noted. These were accompanied by an increase of the anode current and were associated with extreme values of atmospheric humidity. The deduction made from this was that the stray capacity-resistances such as the valve holder and cap, the two-pin connector of the crystal mount, and the grid-leak mount were varying with atmospheric conditions. These were in shunt with, and affected, the valve input-impedance and, in turn, the resultant frequency.

TABLE 2.

Conditions	Time for 100 beats	Variation of frequency from 5×10^4 cycles per sec.
	secs.	parts in 10^6
Grid-leak A = 3MΩ; no bias ..	33·4	59·9
Grid-leak A = 3MΩ; − 1·5 V bias	32·5	61·6
Grid-leak A = 3MΩ; + 1·5 V bias	32·2	62·1
Grid-leak B = 2MΩ; + 1·5 V bias	31·0	64·5
Grid-leak B = 2MΩ; − 1·5 V bias	32·4	61·8
Free grid	34·0	58·9
Grid-leak C = 1MΩ; no bias ..	34·5	58·0

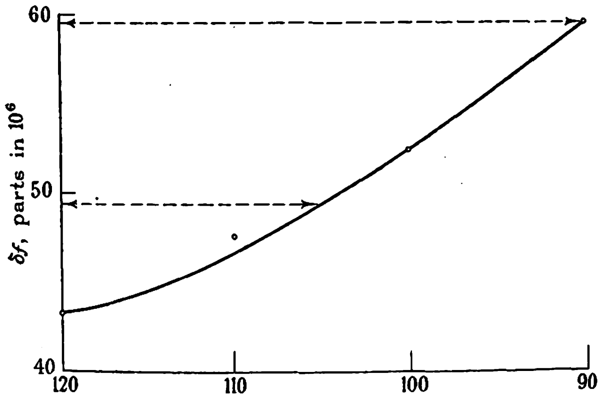

FIG. 17.

This deduction was confirmed during the development of the laboratory standard to be described later. In this instance the circuit was as described. A second circuit had the crystal and grid-leak in a desiccating chamber at normal air-pressure. Steps had been taken to reduce to a minimum the amount of dielectric in the remainder of the grid circuit. The circuits in other respects were identical and were exposed to normal atmospheric conditions. The evacuated crystal was, however, much the better oscillator. On one occasion during a spell of extreme humidity the evacuated crystal refused to oscillate, while the inferior one in the desiccator oscillated normally. After drying the mount of the evacuated crystal oscillations were obtained with a very high value of anode current and a large frequency change. As conditions improved, the input current and the frequency gradually returned to normal. The other circuit remained constant throughout. This experience was checked by reproducing the conditions artificially. The grid-leak and valve holder, etc., were breathed upon so as to produce a film of moisture and the resultant changes in frequency and anode current were noted. Two tests are recorded in Table 3. The frequency-changes of 30 and 36 parts in 10^6, due to this

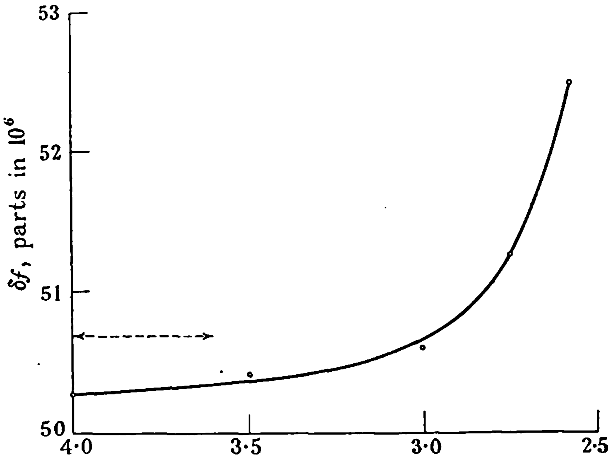

FIG. 18.

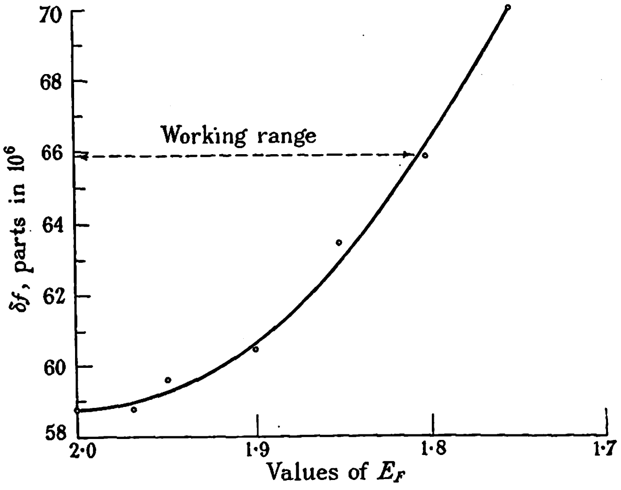

FIG. 19.

cause, are more than sufficient to account for those previously noted. As the deposited moisture was insufficient to stop oscillations and, indeed, to cause the anode current to reach values which had been observed, it can be stated that this treatment is not drastic and does not exceed the conditions produced by normal atmospheric variations. It must also be pointed out that this phenomenon is quite distinct from that produced by humidity on the crystal itself. It is purely a circuital reaction. It is proposed to investigate the matter quantitatively under controlled humidity conditions, paying particular attention to the grid-current variations. Meanwhile, it was clear that definite precautions would have to be taken in the design, lay-out and mounting of the grid circuit of the valve. Alternatively it would be essential to control the degree of humidity of the whole circuit.

The first condition was partly met by the employment of a new design of L.S.5-type valve, the L.S.5.D. This has the grid connection made to a terminal on the glass envelope, thus eliminating the valve holder and cap from the grid circuit. Also, advantage was taken of some features in the design of the laboratory standard which will now be described.

TABLE 3.

Conditions	Capacity	I_g	I_a	Time for 200 beats	Variation of frequency from 5×10^4 cycles per sec.	Difference
	μμF	mA	mA	secs.	parts in 10^6	parts in 10^6

After breathing on grid circuit	145	3·25	8·5	45	88·8	+30·2
10 minutes later	145	2·5	7·0	66	60·4	+ 1·8
Normal values for damp weather	200	3·5	6·0	65	61·6	0
After breathing on grid circuit	200	2·5	8·2	41	97·6	+36·0
After fanning grid circuit for 2 minutes ..	200	3·5	6·0	64	62·4	+ 0·8

THE LABORATORY STANDARD.

The limit of accuracy to which a crystal, mounted as described, can be adjusted has been found in practice to be of the order of 1 part in 10^4. Also, when once the envelope has been evacuated no further adjustment is possible. The small adjustment of frequency available in the controllable variables is of the order of 1 part in 10^5 and power considerations limit the full use of this. This is satisfactory enough for the purpose for which the instrument was designed—that of a portable standard. It is, however, desirable to eliminate the correction factor for departure from its nominal value when the standard is capable of being adjusted to an accuracy better than 1 in 10^6. To meet this condition, the following controls are available for final adjustment of the frequency:—(*a*) air pressure, (*b*) electrode air-gap, (*c*) anode condenser, (*d*) temperature, (*e*) anode and filament potentials, (*f*) humidity. It was decided to provide for the use of all these.

The design includes a bell jar and desiccator with Fleuss pump, vacuum gauges and an ether-type thermostat. The crystal is mounted directly on the fused-quartz insulating washer of the bell jar with the grid-leak connected to the same terminal inside. The lead from this terminal goes direct to the grid connection on the glass envelope of the L.S.5.D valve. The only dielectric materials in the grid circuit are the valve envelope, the fused-quartz insulating washer, the glass mounting of the grid-leak and the fused-quartz distance pieces of the crystal mount. Of these, the outside of the insulating quartz washer and the valve envelope are the only dielectrics which are subject to normal atmospheric conditions.

The first run on this equipment is shown in Fig. 13 (upper curve). The curve clearly illustrates the effect of humidity upon the frequency of the crystal itself. No oscillations were obtained until 15 minutes after closing the bell jar, and this was not evacuated until the frequency was approaching a steady value. The observed change due to the action of the desiccator is 60 parts in 10^6; to this must be added the change which took place during the period when there were no oscillations. From previous experience on resonators it can be stated that the total change is usually greater than 100 parts in 10^6. It is desired to emphasize this point as the changes due to this variable are, apart from the effects of frictional resistance, greater than those from any other single source. Most current literature makes no reference to this, and it is not understood how the accuracies quoted have been obtained. The change due to the reduction of air pressure to 0·25 in. of mercury is 10 parts in 10^6.

The continuation of this curve gives the readings for the subsequent 60 hours. The large drift of the first 10 hours is due to the further absorption of residual water-vapour by the desiccator. The early runs were taken primarily to investigate the short-period variables, and the thermostatic control was not employed. The remainder of the readings have therefore to be corrected for temperature. The dotted curve shows the corrected readings, and it will be seen that the departure from the mean value is of the order of 2 parts in 10^6. With thermostatic control this figure would be improved, as the room temperatures were used for correction and the crystal lags considerably on these.

The lower curve gives similar readings for the portable-type standard. Also, Fig. 14 gives a continuous-count 20-minute run in the two cases, with observations at intervals of 1 minute. The upper curve is interesting as it is apparent that it coincides with a point of maximum departure from the mean, the early portion of the curve just indicating the change from a fall to a rise. The lower curve shows the laboratory standard run and Fig. 12 shows a further run of the same type plotted to a very open scale to permit an appreciation of the observational errors. The data are supplied in Table 4, where, under col. 2, the readings of the chronometer seconds-hand for 120 beats are found, each series being taken consecutively. Col. 3 gives the time in seconds for each of these, col. 4 gives the difference in frequency from 5×10^4 cycles per second, and col. 5 shows the same difference expressed as the number of parts in 10^6.

It is estimated that the maximum probable error in reading the chronometer is 0·4 sec. From the table it is seen that this will introduce an error of 0·2 in 10^6. Fig. 12 shows that the maximum departure from the mean value is 0·13 in 10^6. These deviations are, therefore, probably chiefly observational errors. Over the 30 minutes shown, and dismissing the improbable contingency that they are varying at the same rate and in the same direction, the fork and crystal are constant to a value of the order of 1 part in 10^7.

TABLE 4.

Time 1	Reading of chronometer for 120 beats 2	Time for 120 beats 3	Variation of frequency from 5×10^4 cycles per sec. 4	Variation of frequency from 5×10^4 cycles per sec. 5
minutes	secs.	secs.	cycles per sec.	parts in 10^6

16	73·8	61·0	1·967	39·34
17	74·4	60·6	1·98	39·6
18	75·4	61·0	1·967	39·34
19	76·0	60·6	1·98	39·6
20	76·8	60·8	1·974	39·48
21	77·4	60·6	1·98	39·6
22	78·4	61·0	1·967	39·34
23	79·0	60·6	1·98	39·6
24	79·8	60·8	1·974	39·48
25	80·4	60·6	1·98	39·6
26	81·0	60·6	1·98	39·6
27	81·6	60·6	1·98	39·6
28	82·4	60·8	1·974	39·48
29	83·0	60·6	1·98	39·6
30	83·6	60·6	1·98	39·6

From these curves it may safely be assumed that the frequency instability characteristic of the portable type is absent in the laboratory type. A number of observations on the latter, covering some 6 weeks, gave variations of the order of 3 parts in 10^6. This is the degree of uncertainty of the reference standard; thus it appeared that the accuracy aimed at (of the order of 1 in 10^6) was probably attained. Also the data were available for the precautions to be taken to obtain a stability of the same order for the portable type. The work of developing the subsidiary apparatus was therefore undertaken.

THE CRYSTAL-CONTROLLED HIGH-FREQUENCY MULTIVIBRATOR.

The features of the well-tried Dye fork-driven multivibrator * indicated the general lines of development. In the first place, the transfer of the operating frequency from 1 to 50 kilocycles per sec. permits the production of the higher frequencies in one step. A multivibrator for 50 kilocycles per sec. was designed and built, the only differences from the Dye type being the different value of anode impedances necessary to give 50 kilocycles per sec. and the use of a commercial-type filament rheostat. This is possible because there is ample power in the drive to exercise a wide range of control. There is no need to tune this circuit by an accurate adjustment of the filament potential. The circuit used is as in Fig. 20. For accuracies of 1 in 10 000 the coupling valve may be omitted, but for higher accuracy it should be included. The range of this circuit has not been fully explored at the high-frequency end, but no difficulty has been experienced in working down to the 120th harmonic, i.e. 6 000 kilocycles per sec. A well-constructed open-scale calibrated oscillator is used for harmonic identification. This controlled high-frequency multivibrator was put into service and it proved to be quite satisfactory, but the need for a low-frequency controlled source for interpolation and other purposes was felt.

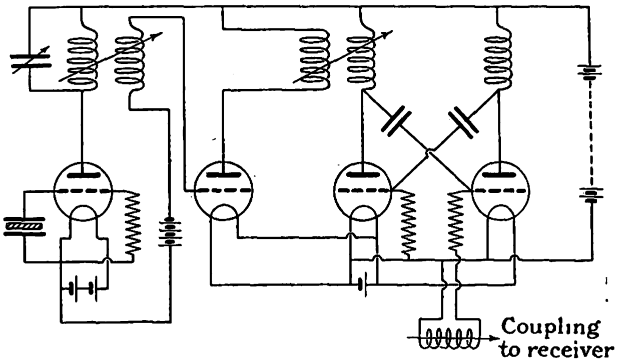

FIG. 20.

A further development of this high-frequency multivibrator, however, is needed. Transmission engineers are faced with the fact that current practice of control

---

* "A Self-contained Standard Harmonic Wave-meter," *Philosophical Transactions of the Royal Society*, 1924, vol. 224, p. 259.

by transverse oscillators and stable master-drive circuits is not meeting the present needs in the matter of precision and frequency stability. Under ideal circumstances it is possible to produce short-wave transverse oscillators of a frequency within 1 part in 10 000 of the nominal value, provided that temperature, circuital conditions and the crystal mount are all strictly specified. To reproduce the frequency within these limits in a power circuit has proved to be an exceedingly difficult matter. It appears that it will be necessary to employ something in the nature of a standard for the frequency control. This has actually been put into practice at the long-wave G.P.O. station at Rugby. It is becoming an urgent necessity to develop the drive of the multivibrator so that it can be utilized in the higher-frequency bands, of the order of 3×10^5, with its present accuracy when used at 5×10^4 cycles per sec. This will permit the harmonics at extremely high frequencies to be used as " drives " of high precision and stability.

THE QUARTZ-CONTROLLED LOW-FREQUENCY MULTIVIBRATOR.

The idea was conceived of controlling a source of relaxation oscillations of the type produced by the Abraham-Bloch multivibrator circuit by impulsing a harmonic with a forced oscillation. This was tried by injecting an e.m.f. from the crystal-controlled circuit (frequency 50 kilocycles per sec.) into a multivibrator of frequency 1 kilocycle per sec., i.e. impulsing the 50th harmonic. This experiment was undertaken somewhat casually and, to the author's surprise, evidence of perfect control was obvious from the first. No difficulty was experienced in combining this with the high-frequency multivibrator with the drive exercising simultaneous controls. The circuit for this is given in Fig. 21.

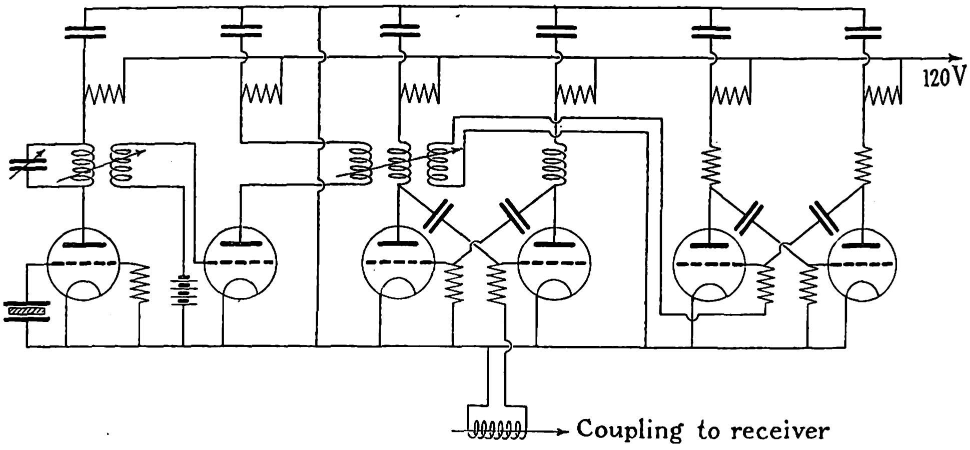

FIG. 21.

This circuit has all the essential features of the standard multivibrator, i.e. a range of 1 to 6 000 kilocycles per second in steps of 1 kilocycle per second, with the addition of the characteristic partial harmonic effects. A minor property is, however, not present. The power to use the 19th, 20th and 21st harmonics of the low-frequency side to control the high frequencies is not available. This property, however, reappears in a more useful form in the centre-drive development. Apart from the 1 kilocycle per sec. of the fundamental of the low-frequency side a number of others on either side of this value are obtainable by adjustment of the coupling, or of the variable condenser. These are the fundamentals obtained by impulsing successive harmonics. Thirteen of these are available in steps as shown in Table 5. These are

$$\frac{f}{n-6}\cdots\frac{f}{n-1}\cdots\frac{f}{n},\ \frac{f}{n+1}\cdots\frac{f}{n+6}$$

where f is the control frequency and n the normal impulsed harmonic frequency, in this case 5×10^4 and 50 cycles per sec. respectively.

TABLE 5.

Harmonic order	Output frequency
	kilocycles per sec.
44	1·135
45	1·111
46	1·086

52	0·962
53	0·943
54	0·926
55	0·909
56	0·983

An interesting proposal to take advantage of this property has been made by Mr. Williams of the Air Ministry Research Establishment at South Farnborough. He suggests the use of a quartz drive at 50 000 cycles per sec. controlling two multivibrators at frequencies of f/n and $f/(n \pm 1)$, where $n = 100$. The outputs of these multivibrators will appear as 500 and 495 or 505 cycles per sec., respectively. These are combined and the resultant beats of the order of 5 per sec. are counted electrically over a period of time by taking photographic records at definite time-intervals. A simple and direct reference to the time standard is thus effected without the intervention of the usual phonic motor or similar device.

This application of the principle of frequency division was made independently and had been in use some weeks when a paper describing a similar application arrived in this country.* This paper describes the control of a multivibrator of frequency 1 kilocycle per sec. by a crystal drive (frequency 50 kilocycles per sec.). The authors state that, although it is possible to exercise control in one step, they actually use two stages. In the present case this has not been found necessary. Four complete sets are in operation, one of which has been in continuous service for over a year, and in all cases complete control has been obtained. The abovementioned paper gives full evidence of the accuracy of control provided.

The development of this system of controlled precision low-frequency oscillations offers considerable possibilities. No reason is seen why oscillations of a frequency approaching 1 cycle per sec. may not be produced. A direct reference to the ultimate time standard would thus be possible. Indeed, venturing into the debatable realm of prophecy, this may be the germ of the time standard of the future.

Another variant of this method of control is under investigation. It has been found possible to exercise effective control by injecting into a multivibrator forced oscillations having a frequency of $1/n$ times the approximate period of the multivibrator. Thus a 1 kilocycle-per-sec. fork was used to control a 10 kilocycle-per-sec. multivibrator. It is hoped to utilize this principle to refer back to the time standard by impulsing a neon-tube circuit of, say, 10 cycles per sec. from a standard clock and using this in turn to control a 1 kilocycle-per-sec. multivibrator.

It is possible that in the case quoted above the 10th harmonic of the fork is the controlling factor.

TREND OF FUTURE DEVELOPMENTS.

While the equipment thus described more than meets the requirements originally laid down, i.e. the calibration and maintenance of a sub-standard wavemeter to 1 part in 10^4, it is fully realized that this is not the time to call a halt. The question of the behaviour of the quartz standard over relatively long periods of time and, in particular, the question of ageing will require years of observation with equipment of the highest precision. This will necessitate the development of improved methods of reference to the time standards. Also the question of the adequacy of the time standard as the final arbiter of frequency may at any time be questioned.

The experience gained as to the behaviour of the valve and its tendency to develop frequency instability at medium frequencies calls for further investigation, and this is actively proceeding. In this direction it is proposed to lower the frequency to 25 kilocycles per sec.; this represents the limit to which the natural quartz crystal can be obtained and worked. It is to be hoped that the production of large synthetic quartz crystals will not prove such a difficult proposition as the somewhat similar case of the artificial diamond. It is, however, felt that the true solution and urgent need is the development of the resonator reference-standard and its associated equipment to accuracies of the order 1 in 10^6 or, if possible, 1 in 10^7.

The author's thanks are due to the Air Ministry for permission to publish this paper. He also desires to express indebtedness to the inspiration of Dr. Dye's classic work already referred to. Part (1) of the paper is obviously a direct practical development of this work. Acknowledgments are due to Messrs. H. W. Sullivan for the loan of the standard valve-maintained fork. Valuable advice has been received from the author's colleagues; in particular from Mr. B. Williams, B.Sc., of the Air Ministry research staff at South Farnborough, and from Mr. R. H. Billingsley, without whose help in checking the experimental work and in the preparation of the paper and drawings a private research of this nature could not have been undertaken in the limited time available.

* L. M. HULL and J. K. CLAPP: "A Convenient Method for Referring Secondary Frequency Standards to a Standard Time Interval," *Proceedings of the Institute of Radio Engineers*, 1929, vol. 17, p. 252.

DISCUSSION BEFORE THE WIRELESS SECTION ON THE PAPERS BY MR. LUCAS (SEE PAGE 855) AND MR. J. E. P. VIGOUREUX (SEE PAGE 265), 5TH MARCH, 1930.

Air Commodore A. D. Warrington-Morris: With regard to the paper by Mr. Lucas, there is no doubt that, with the great increase in wireless communication and the consequent necessity for as many wave channels as possible, the two most important problems which concern wireless engineers at the present time are those of the maintenance of a constant frequency and the improvement of frequency standards. The author has been responsible for inspecting wavemeters for the Royal Air Force, and as a result of those duties he has realized the desirability of a high standard of accuracy. The work described in the paper has been done without the use of laboratory facilities. Table 3, for instance, shows that humidity was varied by the simple expedient of breathing on the grid circuit. Some quantitative measurements of humidity would probably be useful in a paper of this sort. So far as aircraft signalling is concerned, the degree of accuracy referred to by the author is not yet so essential as to warrant the provision in an aeroplane of the additional weight, space and complicated apparatus which it necessitates. For point-to-point services, however, especially on the wave-bands settled for fixed stations by the Washington Convention, the greatest possible accuracy is required. The author appears to view with disfavour the use of a quartz control employing a transverse mode, on account of the high temperature-coefficient. I should like to know whether he has any further objections, and whether he can give some information as to the direct use of the longitudinal mode on short waves without frequency multiplication.

Dr. D. W. Dye: Mr. Lucas has produced a frequency standard of a type superior to any other so far designed in this country for frequencies of the order concerned. The problem of transferring them to lower frequencies has been successfully solved in the system devised by Mr. Williams, whereby two neighbouring harmonics are selected and controlled by a multivibrator. That is, in my opinion, a very ingenious arrangement; it is the first of its kind, so far as I know, to be employed in stepping down. It would be somewhat difficult, I think, to keep these systems in step with the crystal over the long periods of time which would be essential in checking absolute frequency measurements against some other time standard, but the system is evidently worthy of further investigation and development. With regard to the mounting of the crystal, in my own work on the subject I soon found that humidity had a considerable effect upon the oscillations, particularly in making the damping large when there was much moisture in the atmosphere. I did not find it difficult to get satisfactory behaviour, without using special precautions. It was found that a bell-jar and desiccating agent in the enclosure was sufficient to keep the specimens in a dry condition while being investigated, and to ensure that the results could be reproduced from time to time. With regard to mounting, I also have supported the crystal at a nodal point of the longitudinal mode of vibration, but not in quite the same way as that adopted by Mr. Lucas; mine was balanced as on a knife-edge on the narrow edge of the crystal. Fig. 5 led me to think that there was something unusual in the values given, but the author's explanation of the errors in scaling explains the apparently remarkable results. Concerning the use of crevasses, this method is most valuable for determining the damping and elucidating the equivalent networks for oscillators or resonators, but it is not the most suitable for determining or setting a source to the precise frequency of resonance. If the resonator is connected to a small condenser (of, say, 300 $\mu\mu$F) and a practically constant e.m.f. is applied to the combination by the use of a coil of small inductance connected to the condenser, the current in the inductance as a function of frequency is as shown in Fig. A. As the frequency is increased, the current rises to a maximum, turns sharply and steeply downwards to a minimum and then slowly approaches its original value. The frequency of resonance lies on the steeply falling, nearly straight portion, but is not at the point of intersection of this curve with the datum current for frequencies near, but outside, the region of resonance. The graphical construction corre-

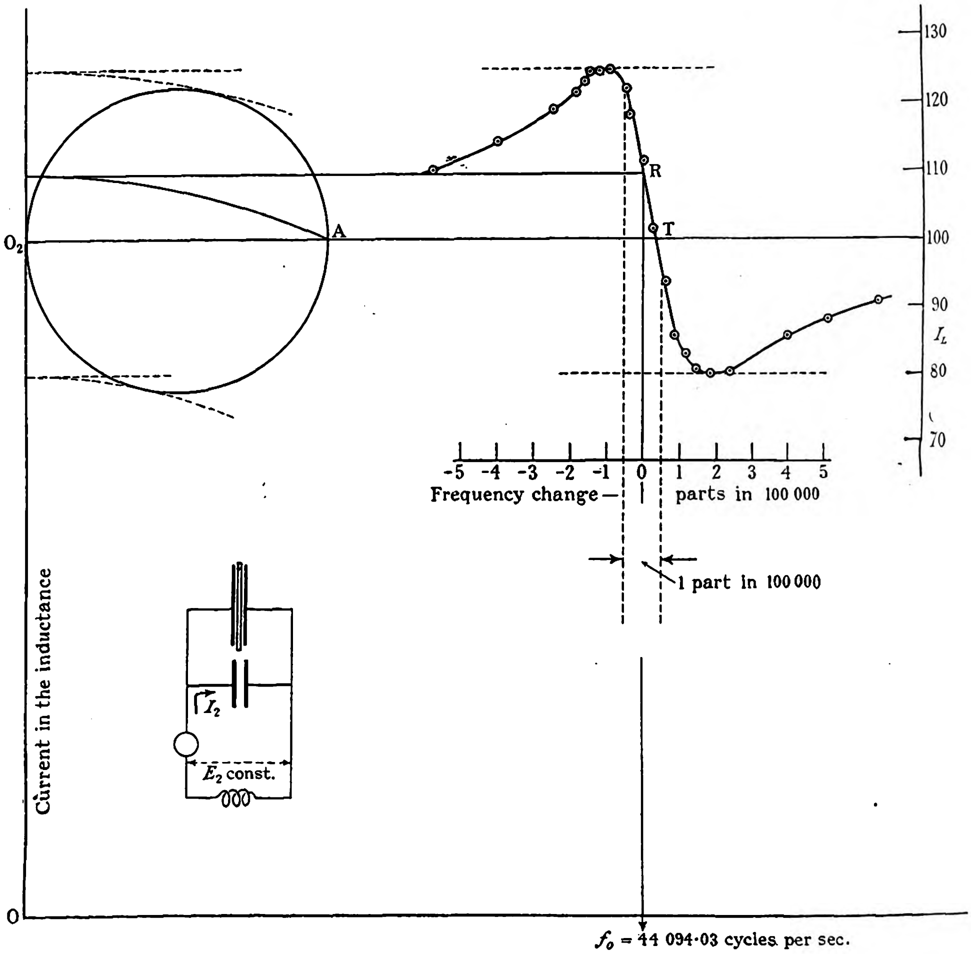

Fig. A.

sponding to this case is very simple and is shown on the left of the curve. A circle is drawn of diameter equal to $(\theta_1 - \theta_2)$, where θ_1 and θ_2 are the maximum and minimum currents respectively. This circle has its centre at the height of the current value just outside resonance. The vertical tangent OO_2 is drawn intersecting the abscissa scale at 0. Any point on the curve of current is transferred to the circle by drawing an arc, of radius equal to the current at the point in question, from the centre O. The intersection of this arc on the circle gives the corresponding point on it. The resonance point on the circle is at A and the converse process of transferring this to the current curve is obvious as shown, giving the point R on the curve. The above construction assumes that the air condenser used has no losses. For the mere purpose of setting a frequency, it is not necessary to carry out the graphical construction. If θ_1 and θ_2 are the maximum and minimum currents, the current at which resonance occurs is given by $\theta_r^2 = \theta_1^2 + \theta_2^2 - \theta_1\theta_2$. The resonant frequency may then be found directly by adjusting it until this current is obtained. It is convenient to have a square-law scale on the galvanometer for the purpose. The two vertical dotted lines show a belt of frequency of width equal to 10 parts in a million. A change of deflection of about 30 cm on a galvanometer scale is given for this change. A setting to about 1 part in 10 million can be made if such extreme accuracy is desired. With regard to the frequency changes given in Mr. Lucas's paper, it would be desirable to indicate on the curves the direction in which the change in frequency occurred; this can only be inferred from the text. I think that in Fig. 9 there must be an error either in the scale of frequency changes observed on the broadcast station 2LO, or in the frequency assigned to the base line. The latter is marked as 10 kilocycles per sec., but the range of frequency is from $+ 0{\cdot}5$ to $- 0{\cdot}5$ kilocycle per sec. This means that the variations were of the order of 2 or 3 per cent, which is very unlikely. I wish now to refer to the frequency-changes dealt with in Part (2) of the paper. Mr. Lucas states, when giving the desiderata of the drive circuit, that experience has shown that any attempt to introduce retroaction produces a tendency to frequency instability; and that the circuit should therefore be capable of oscillating without any retroaction apart from that inherent in it. This seems to me to make a distinction without a difference and, although the meaning is clear, I am not certain that the right conclusion has been drawn. It might be advantageous to make use of the good-quality screen-grid valves now available, and then to introduce the retroaction independently, but that is a matter of opinion. I agree with the other two desiderata given, although the statement that the electrostatic coupling of the crystal is much less than that of magneto-striction, fork, and other such electromagnetically driven devices, may require modification. As a general statement it is probably true, but it must not be supposed that finality has been reached in regard to other forms of oscillator and that these could not be designed to have a coupling as small as, or smaller than, that of the quartz oscillator. The question of the small magnitudes of the damping and of the necessary coupling determines the variability of the whole system with regard to the external conditions applied. In Fig. 3 it would be interesting if another curve, starting at the instant of switching on, could be given. My experience with the transverse form of oscillator shows that the energy absorbed in the oscillator itself, although very small, does raise the temperature by 2 degrees or more above that of the electrodes, in the course of half an hour. This causes a drift in frequency which cannot be overcome by any temperature control, because it occurs inside the oscillator itself. As a result of the use of the thin longitudinal bars, the effect might be worse, but the temperature coefficient would be smaller. Thus, if an anode battery or other external factor varies, besides the possibility of a small instantaneous change, there will inevitably be a drift due to the change in the energy in the oscillations of the crystal. It would be interesting to have some figures on this point. Measurements of the variation of frequency due to a small condenser placed across either the grid-anode or grid-filament of the valve would also be welcome. Considerable variations do occur from these causes and, as Mr. Vigoureux's paper shows, frequency variations of 25 to 30 parts in a million are produced by changes in capacity of a few micro-microfarads. These figures apply to higher frequencies, and I assume that the variations would be smaller for a low-frequency oscillator. Mr. Lucas criticizes somewhat adversely the tuning fork which he employed, in which large frequency variations occurred with changes in the circuit conditions, notably in the filament voltage. These variations are much larger than those of the forks which I have used. I have not investigated the forks manufactured by Messrs. H. W. Sullivan, although they were manufactured more or less to one of my own designs. By means of a new magnetic system on the forks I have been able to reduce all these errors to such a small magnitude that a variation of 30 per cent in the anode voltage produces a frequency change of less than 1 part in a million. A change of 10 per cent in filament voltage also produces a frequency change of less than 1 part in a million.

Mr. C. O. Browne: I notice that Mr. Lucas mounts his quartz resonator by means of two pieces of cork situated at the centre of the crystal, presumably at the ends of the electric axis. Can he give any information as to the effect of mounting the crystal in the same way but with the cork at the sides of the crystal? As described in his paper, the resonator is certainly held at a nodal point of mechanical displacement for the fundamental longitudinal mode, but it is also supported at an antinode for vibrations due to the inverse piezo-electric effect. With reference to the curves in Fig. 15, I notice that changes in the anode-condenser setting have been plotted against the resultant changes in frequency. I would suggest that such errors might perhaps be eliminated by substituting a pure resistance for the inductance-capacity circuit connected to the anode of the valve. It is well known that a crystal can be made to oscillate with a resistance only in the anode circuit. If Mr. Lucas has already tried this arrangement, will he state whether the errors due to the resistance are greater than those due to the inductance and condenser combined?

Mr. B. Williams: The need for deriving the fundamental frequency of the crystal from two successive harmonics arose from a necessity for checking certain claims in connection with this apparatus. As there was no equipment of the required accuracy available, this method suggested itself to me as a means of measuring the absolute frequency. As Dr. Dye has pointed out, although this is theoretically a simple process it presents difficulties in practice. The problem of the control of low-frequency multivibrators from high-frequency crystals involves a considerable number of variables, some of which have already been tracked down. It necessitates the maintenance of a constant output from the drive, and of steady anode and filament values in the multivibrators. I am chiefly concerned with the practical side of Mr. Vigoureux's paper and regard it as most useful from the point of view of the production of sub-standard quartz oscillators, to accuracies of the order of 1 in 10 000. From this standpoint, the variables associated with the quartz and the valve which can be utilized for the production of minute changes of frequency without going to the ultimate limit of grinding, are of importance. They are especially so in connection with the design of quartz oscillators *in vacuo* from the corresponding quartz resonators. In connection with the difference between the range of capacities for the two methods of using the crystal (i.e. the plate-grid and grid-filament modes), Mr. Vigoureux gives, in equation (73), an expression for this range in terms of the anode-grid capacity, and states that for the other mode of vibration the two ranges of capacity are in direct proportion to the inter-electrode capacities. By noting the values of these changes of capacity, therefore, it should be possible to measure the grid-anode capacity of a screen-grid valve. For instance, if Mr. Vigoureux's constants for the quartz and the valve are used in equation (73), but instead of $2 \cdot 4\ \mu\mu$F a value of $0 \cdot 005\ \mu\mu$F is substituted for the grid-anode capacity, the actual change of capacity is found to be $2\ \mu\mu$F. Such a quantity is difficult to measure, but it can be measured. On testing this in practice with a screen-grid valve I obtained values at 50 000 cycles per sec. which were considerably larger than this. I should like to ask Mr. Vigoureux whether the equations would hold for very small values of the inter-electrode capacities. Would the method which I have outlined be suitable for checking the capacities of the screen-grid valve?

Mr. J. E. P. Vigoureux: In Mr. Lucas's paper there is a remark about the accuracy to which the response frequency of a quartz resonator can be determined from the crevasse curve. It may be worth mentioning that there is a certain ratio of minimum to maximum ordinate of the curves for which the accuracy of the frequency determination is greatest. The curves are obtained by measuring either the voltage across the tuning circuit or the current in the inductance of the latter, and if the deflection of the recording instrument is plotted against the frequency a curve similar to that shown in Fig. 10 of the paper results. Dr. Dye has pointed out that if the curvature at its lowest point were a maximum, the location of the response frequency would be as accurate as possible. The minimum can always be altered by changing the ratio of capacity to inductance, or by adding to or reducing the resistance of the tuned circuit. If the deflection of the recording instrument be proportional to the square of the current or voltage measured, best conditions for frequency measurement are obtained when the minimum ordinate is half the maximum ordinate.

Mr. H. J. Lucas: I have been unable to do more than concentrate on those portions of Mr. Vigoureux's paper immediately bearing upon the frequency instabilities which I have been investigating. The conclusion at which I arrived—that these were caused by variations of the valve-input impedance with atmospheric humidity—receives certain confirmation. The frequency changes produced by variations in grid conductance and grid-filament capacity, as shown by Mr. Vigoureux, are in the same sense as those produced by humidity variations. The magnitude of the g_2 variations is, however, too small to account for the observed departures and the C_2 variations only partially account for them. I do not find Mr. Vigoureux's argument in favour of the grid-anode connection very convincing. I submit that the question of frequency stability is of more importance than any consideration of power output. The majority of the curves for this connection show that any given change of circuit constants produces a larger frequency change than in the grid-filament connection. It is of interest to note that the crystal used for this investigation has two well-defined response frequencies and is capable of generating these frequencies simultaneously. This is a common phenomenon of transverse oscillators and is a serious handicap to the production of good crystals for control purposes. A very able paper by F. R. Lack* discusses the point and arrives at the conclusion that it is a characteristic of the "parallel" cut crystal. From the values given by Mr. Vigoureux I deduce that his crystal is a "perpendicular" cut. My own experience also confirms the fact that the latter cut suffers from this disability. Mr. Vigoureux's paper is already proving very useful in solving current problems, and I have no doubt that it will prove invaluable as a standard work of reference for a considerable period to workers in this field.

Mr. W. H. F. Griffiths (*communicated*): I wish to congratulate Mr. Lucas on a paper that conveys no real idea of the vast amount of work which he must have carried out. Only those directly interested in the standardization of electrical quantities can have any idea of the difficulties which are encountered in such work and which can only be overcome by much patience and resource. For this reason one must be careful not to speak lightly of accuracies higher than, say, 1 part in 10 000. As an admirer of Dr. Dye's past work on the development of a valve-maintained tuning fork as a frequency standard, I am naturally at present in favour of the fork-controlled multivibrator system as a standard of radio frequencies, more especially in view of the present improvements which he is effecting both in the fork itself and in the associated equipment for checking and watching the variation of its frequency. The portable crystal standard described in the paper, however, undoubtedly fills effectively the gap immediately below this standard. When viewed as a very precise sub-standard, second only to the fork, its temperature coefficient is entirely negligible while the fault inherent in the portable standard—the inability to adjust the frequency more closely to its nominal value than 1 part in 10 000—is rendered less important, as corrections for accuracies higher than this will only be needed occasionally. The stability appears to be excellent for such a purpose. Very precise sub-standards are absolutely necessary if full use is to be made of standards having accuracies of a few parts in 10^6. Realizing this, I have been working upon the problem in a different way by endeavouring to rely upon the calibration permanence of inductance and capacity in a simple resonant circuit, and the value of sub-standards of this kind would be increased if an occasional check of capacity "drift" were made with the portable crystal reference standard described by the author. By designing special fixed inductances and variable condensers I have found it possible to produce a wide-range wavemeter (it is a comparatively simple matter to obtain accuracy in sub-standard wavemeters of limited range) with a temperature coefficient of the order 1 part in 10^5 per degree C. and with a degree of calibration permanence of the order 1 part in 10^4 over considerable periods of time. The comparatively negligible temperature-coefficient is due to a thermal compensation principle employed in the construction of the inductances, and the high degree of calibration permanence is due to a dimensional compensation principle employed in the construction of the variable condenser which renders it as permanent as a fixed air condenser of first quality. Because of its simplicity and rapidity of operation I feel that this type of continuously variable sub-standard will have a useful field of application, especially if an accurate quartz resonator is used at periods of a few months to give an indication of the ageing of the variable condenser at its maximum capacity setting. At this setting the variable condenser approximates to a fixed air condenser of minimum dielectric gap and maximum plate area, and the greatest percentage capacity change is therefore expected in this position. I should be glad to have the author's views and suggestions upon this application of the reference standard. I should perhaps add that for frequencies lower than 3 000 kilocycles per sec. I have found it possible to increase the utility of this sub-standard by converting it into a generator. This is done by associating its simple resonant circuit with a negative resistance device (i.e. without reaction, in the manner suggested by Dr. N. W. McLachlan) in the shape of a 4-electrode valve in which the inter-electrode capacity is reduced to a value such that a slight relative displacement of the electrodes will not affect the accuracy of the wavemeter. To suit the purpose, a valve has been produced by collaboration between Dr. McLachlan and the General Electric Co., Hammersmith. Used in this manner the wavemeter is practically independent of quite large changes in the potentials of the electrodes of its valve and of the filament current of the latter. Its stability over short periods is such that the frequency has remained constant to 2 or 3 parts in 10^6 for 12 hours in a room of varying temperature, the check being made by short-period comparisons against the 220-kilocycle harmonic of a multivibrator controlled by the fork standard used by Mr. Lucas and in a manner similar to that described on page 861.

---

* "Observations on Modes of Vibration of Quartz Crystal Plates," *Proceedings of the Institute of Radio Engineers*, 1929, vol. 17, p. 1123.

Mr. H. J. Lucas (*in reply*): I wish to thank Dr. Dye for his suggestion of a method of adjusting the frequency of an oscillator to that of a resonator. I consider it doubtful whether any normal oscillating circuit will be sufficiently stable to enable full advantage to be taken of the accuracy of adjustment which the method allows, but I hope to use a quartz-controlled oscillator checked at intervals by comparison with a resonator, using the controllable variables for adjustment. I agree that it would have been better to have indicated the direction of the various changes in frequency, but this can be deduced from the text and the fact that both crystals were approximately 2 cycles per sec. below their nominal frequency. The scale errors in Figs. 5 and 9 have been corrected for the *Journal.* It is interesting to note that desideratum (3) is receiving confirmation in recent improvements in the valve-maintained fork. In view of the improvements indicated by Dr. Dye the advent of the new standard tuning fork will be received with great interest.

With regard to the question of the employment of retroaction, it was considered that the feed-back by the valve inter-electrode capacity, besides being sufficient for all normal purposes, should be a stable quantity inasmuch as it could only vary by movement of the valve electrodes, which would naturally be guarded against. A screen-grid valve was not employed, no bombarded valve of this type then being available, and it was anticipated that variations in grid contact potential would be troublesome in a "gettered" valve.

I regret that time does not permit of experiments being conducted on the rise of temperature of a crystal under oscillatory conditions.

I made no criticisms of the tuning fork during my work and I accepted it as my frequency standard without question. No evidence appeared to suggest that the fork had any inaccuracy greater than that anticipated, that is, 2 or 3 parts in a million under operating conditions when the supply voltages were maintained at their correct values.

I fully concur that quantitative measurements of humidity would have proved valuable, but the conditions under which the work was carried out precluded this. The point raised by Air Commodore Warrington-Morris regarding the use of the transverse mode of vibration for control purposes is interesting, but the objections are (1) the indicated reason-high temperature coefficient, (2) the production of spurious frequencies in the neighbourhood of the fundamental due to the coupling of this and other modes of vibration, and (3), as Dr. Dye has shown, the impossibility of obtaining nodal support for a transverse oscillator. It has not been found possible to make satisfactory longitudinal crystals having a frequency above 300 kilocycles per sec.

An instance of the use of a resistive load referred to by Mr. Browne has been given by Hull and Clapp.* I considered that either method of supporting the crystal, i.e. at the ends of or at right angles to the electric axis, introduces a definite amount of damping by operating on the reciprocal vibration, and this would probably account for the decrement of my best evacuated crystal being no better than that of Dr. Dye's crystal in air.

---

* See reference on page 867.

It is hoped to employ the information provided by Mr. Vigoureux in future work on resonators.

Mr. J. E. P. Vigoureux (*in reply*): Replying to Mr. Williams's inquiry as to the validity of formulæ (42) and (73) for very small values of the inter-electrode capacities, these formulæ are obtained, as pointed out on page 270, on the assumption that the range of capacity in the plate circuit, over which oscillations can be maintained, namely $C \sim C_0$, is fairly large. If the plate-grid capacity is very small, this range will also be small, and formula (73) is not applicable. It is then no longer true to say that " the total range of capacity C over which oscillations are possible with the filament-to-grid connection is to the corresponding range in the plate-to-grid connection as C_3 is to C_2." But an idea of the range can be obtained from formula (71) by assuming usual values for the various constants of the valve. I find that with $C_3 = 8$ $\mu\mu$F, $m = 100$, $g_0 = 10^{-5}$ mho, and the other variables approximately the same as those given in Table 1 of the paper, the range for the plate-grid connection is just over 4 000 $\mu\mu$F. With the filament-grid connection and values of 0·1, 0·08 and 0·07 $\mu\mu$F respectively for the plate-grid capacity, the ranges would be 41, 24 and 12 $\mu\mu$F. When the plate-grid capacity is 0·06 $\mu\mu$F or less, oscillations cannot be maintained. If those figures represent anything like the actual state of things, it would seem that the oscillations observed by Mr. Williams were due to imperfect elimination of capacity between the plate and the grid leads, outside the valve.

A few experiments were carried out to check the theoretical results obtained above. The quartz disc the constants of which are given in the paper was used again, with an air-gap of 0·012 cm. The amplification factor of the valve was 180, its plate resistance was 240 000 ohms, and the plate and screen-grid voltages were 115 and 84 respectively. A 1·2-megohm grid leak was used. At first the oscillatory circuit was made up of a shielded variable air condenser, a 1-ohm vacuo-junction and an ordinary cylindrical 160-μH coil. When no particular precautions were taken to eliminate capacity between the plate circuit and that electrode of the resonator connected to the grid, oscillations took place fairly strongly. By merely screening the lead connecting the plate to the insulated terminal of the condenser, the amplitude of the oscillations and the range of capacity over which they could be maintained were considerably decreased.

A toroidal coil of inductance 100 μH was next wound and enclosed in a copper box; the leads connecting it to the vacuo-junction and to the insulated terminal of the condenser were also screened, and all the screens were maintained at filament potential, either by direct connection or by large condensers. With this arrangement it was impossible to obtain any oscillations. One end of a screened lead was then connected to the plate terminal. To the other end was soldered a thin brass plate 3 × 7 cm, the distance of which from the resonator electrode joined to the grid could be adjusted at will. It was thus possible to add a small capacity between the plate and the grid, although the actual value added could not be estimated in these preliminary experiments. It was then possible to obtain oscillations, provided the added capacity exceeded a certain value. For the limiting value, and for two larger values of this capacity, the ranges were 20, 30 and 47 $\mu\mu$F, and the amplitude of the maximum difference of potential across the toroidal coil was less than 3 volts in the first case; it was 7 in the second and 17 in the third. A 5-$\mu\mu$F shielded condenser between the grid and the plate increased the range to 430 $\mu\mu$F and the amplitude to 35 volts.

These results show that the plate-grid capacity is too small to maintain oscillations, and it seems that the method cannot be employed, without modifications, to measure the plate-grid capacities of screen-grid valves.

On page 270 of the paper, second line above equation (42), F should be replaced by E, and the ordinates of Fig. 6 should be multiplied by 10 000.

A NEW NULL METHOD OF TESTING INSTRUMENT TRANSFORMERS, AND ITS APPLICATION.

By G. F. SHOTTER, Associate Member.

(*Paper first received* 18*th November*, 1929, *and in final form* 13*th January*, 1930; *read before the* METER AND INSTRUMENT SECTION 7*th February*, 1930.)

SUMMARY.

The paper describes some of the common methods and the author's new null method of testing instrument transformers.

The technical points of the method are discussed and examples are given illustrating the simple derivation of ratio and phase-angle error of current and potential transformers.

The accuracy of the method is dealt with, tests on a hole-type current transformer are described, and the number of standard transformers required is discussed.

In conclusion the author sums up the advantages of the method and describes some interesting applications of it in connection with the testing of power transformers, etc.

In the Appendix is given the proof of the method.

INTRODUCTION.

Since the importance of a high degree of accuracy in metering is now recognized, it is becoming more and more essential to obtain a quick and accurate method of determining the characteristics of instrument transformers.

Although it may be claimed that a knowledge of such characteristics is unnecessary when meters are tested with their instrument transformers, it should be realized that no secondary tests can be accurately carried out either *in situ* or in the laboratory when the characteristics are unknown.

Before describing the method which is the subject of the paper, it might be of interest briefly to outline a few of the methods which are available for routine testing and which should be treated separately from the precision methods used by the standardizing institutions.

Perhaps the most obvious method of testing the ratio of instrument transformers is to connect ammeters or voltmeters (as the case may be) in the primary and secondary circuits. An extension of this method is the addition of standard current transformers or potential transformers in the primary circuits.

The disadvantages of this method are: (1) the inherent errors of the instruments themselves, and (2) the difficulty of obtaining accurate simultaneous readings. Both these errors are especially pronounced, particularly when testing current transformers, since in a.c. ammeters the scale closes up rapidly below two-thirds of full-scale deflection. For any reasonable degree of accuracy to be obtained, several sizes of ammeters or multi-range instruments would be required.

Either of these alternatives is objectionable because, since a 1-ampere instrument would be required to obtain accurate readings at the lower range, its burden would cause an additional error which, in some cases, would be as much as 2 per cent, depending upon the type of transformer tested.

Another method involves the use of two wattmeters, the potential circuits of which are connected to a common source of e.m.f. in phase with the current in the primary circuit of the current transformers (in the case of current-transformer testing). Here, also, the use of a multi-range group of instruments is desirable.

The small error introduced by the angle of the transformer when being tested at unity power factor is negligible, and, consequently, the above two methods have so far been used for the testing of ratio only, although it is possible to measure the phase angle if the wattmeters have negligible reactances in their pressure circuits or have identical time-constants.

The scaling difficulties of the wattmeter method are not nearly so prominent as in the ammeter method; the scale is more open and the volt-ampere burden imposed by the wattmeters is less. From a practical point of view the use of two instruments, which have to be read simultaneously by two persons, is unsatisfactory, especially when a variation occurs in the load.

A third method, proposed by Dr. P. G. Agnew of the American Bureau of Standards, consists in the use of two watt-hour meters the discs of which are marked into 100 equal divisions and which are adjusted to run at nearly the same rate. The method of testing is to compare the speeds of the two instruments when connected to the secondaries of a standard and an unknown transformer respectively.

The meters are interchanged with respect to the transformers in order to eliminate the errors of the instruments. This method, with care, gives good results, but one objection is the time taken in carrying out the tests and in working out the calculations. Another objection is the lack of sensitivity at low loads.

A fourth method, developed by S. Silsbee of the American Bureau of Standards, consists in comparing a known standard transformer against the unknown transformer by means of a compensating circuit which balances out the vector difference between the two transformers.

In a modification of this method, also devised by Silsbee, a dynamometer wattmeter is substituted for the detector and compensating circuit. This modification greatly reduces the cost of the apparatus as compared with the null method. Using a suitable wattmeter, such as that described by R. S. J. Spilsbury of the National Physical Laboratory, in the *Journal of Scientific Instruments* for June 1924, an accuracy of about 0·1 per cent in ratio and 5 minutes in phase angle is obtainable at low loads.

With regard to the two-wattmeter method of testing, some of the difficulties of simultaneous readings can obviously be overcome by the use of a double-element wattmeter, and by connecting the known and unknown transformers to it in such a manner as to cause opposition of the two elements, thus enabling the difference between the two secondary currents to be measured.

Although this method may be satisfactory at high loads, it is far from satisfactory at lower loads, even if a specially sensitive wattmeter (whose burden would, incidentally, be prohibitive) were used.

FIG. 1.

The author's method, which is the subject of this paper, is based on the double-wattmeter method just described, but with important modifications which eliminate all the disadvantages cited above. Instead of reading the difference directly from the instrument, the potential circuit of one of the elements is so arranged that resistance can be added to or subtracted from this circuit until balance (shown by null deflection of the pointer) is obtained on the instrument. When the final point of balance is obtained, this fact is apprehended by means of a tapping key inserted to make or break the common potential circuit to the instrument (see Figs. 1 and 2).

FIG. 2.

It was found, when using an ordinary standard wattmeter (2½ A, 100 V) with this modification, that the sensitivity was increased 10 times; with a specially constructed wattmeter such as that described by Mr. Spilsbury and mentioned above, the sensitivity can be increased 50 times, i.e. a sensitivity of 1 part in 25 000 can be obtained at full load, giving a sensitivity of 1 part in 1 250 at 1/20th full load and unity power factor, against 1 part in 250 when using a standard wattmeter.

If the common potential circuit to the wattmeter is excited from a source of e.m.f. which is in phase with the current in the common primary circuit of the current transformers, it can be proved that the resistance added to or subtracted from the potential circuit is a measure of the difference of ratio between the known and unknown transformers (see Appendix).

There still remains the difficulty of obtaining the angle error of a transformer; this, however, can be obtained if a second test is carried out with the source of e.m.f. to the common circuit of the wattmeter displaced 60° from the current in the common primary circuit and values of r_3 are obtained under these conditions.

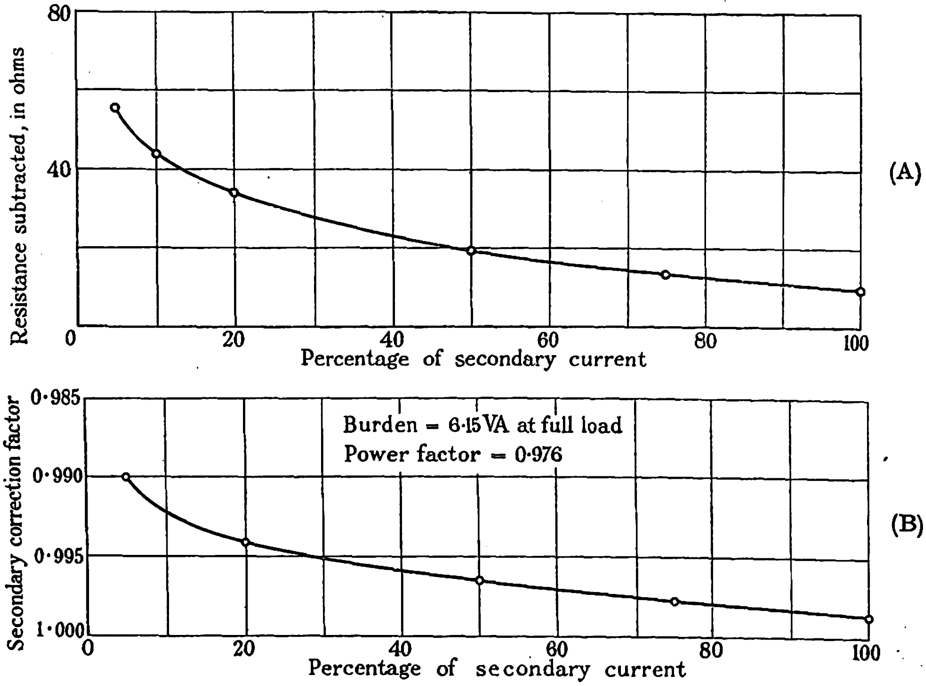


FIGS. 4A and 4B.

Two values of resistance will now have been obtained, one at 0° and the other at 60° phase difference, and assuming that the test is being carried out on a current transformer and that the 60° phase-difference test is carried out with the source of e.m.f. in the common potential circuit leading the current in the primary windings of the current transformers, then a little consideration will show that whereas the resistance added or subtracted in the 0° test is a measure of the difference in ratio between the two current transformers, in the 60° test it is a measure of the difference between the combined ratio and phase-angle errors of the two current transformers.

Assuming, for a moment, that the standard current transformer has no phase angle or ratio error, then the above values expressed as a percentage are proportional to the ratio error and to the combined ratio and phase-angle error respectively of the unknown transformer, and it can be proved that the algebraic difference between the combined ratio error and phase-angle value at 60°

test and the ratio error value at 0° test, is proportional to the angle error of the unknown transformer (see Appendix).

As an example, supposing that the secondary current of the unknown transformer is 1·0 per cent low at the load under consideration (i.e. = 4·95 amps.) and that it has a leading phase angle of 40 minutes, then the value of r_3 obtained in the test at 0° would be equivalent to 1·0 per cent subtracted from the resistance of the right-hand potential element, and the value at the 60° test would be equivalent to 1·0 per cent subtracted and 2·0 per cent added (since a phase angle of 40 minutes means an error of 2·0 per cent at 60° phase difference).

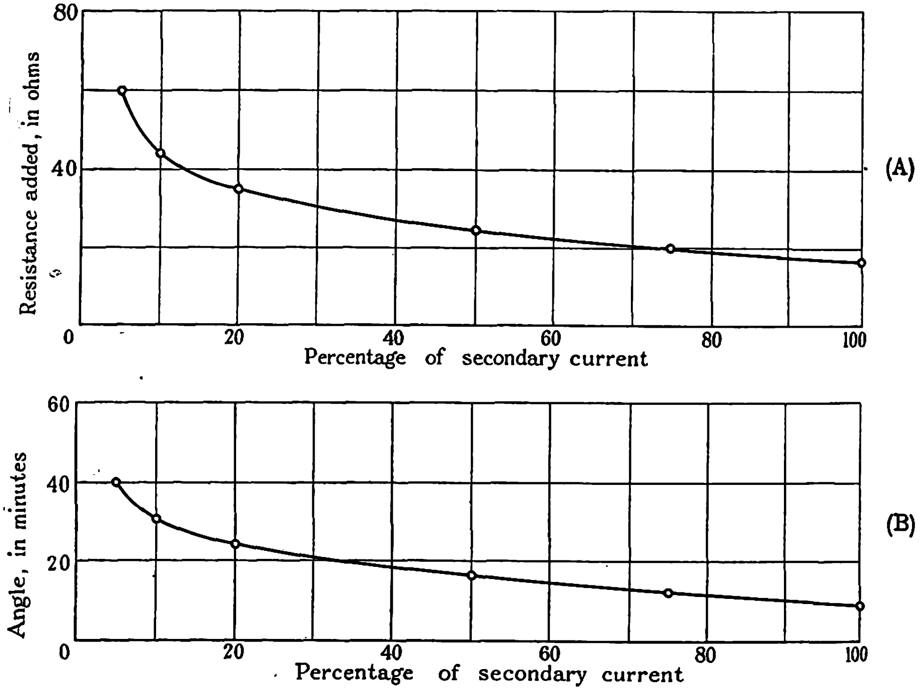
The method can be well illustrated by describing a test carried out on a "hole" type transformer wound to a ratio of 1: 1. It is seen from Fig. 3 that the primary winding of the transformer is connected in series with the left-hand current coil (1) of the detector, and its secondary is connected to the right-hand current coil (2), the two potential circuits of the detector being connected to the supply from the phase-shifter and a tapping key being interposed in this circuit. Another key is interposed in the right-hand element potential circuit to enable the quadrature point (indicated by zero deflection on the detector) to be set on the phase-shifter. r_3 represents the adjustable resistance box, which is suitably marked.

Fig. 4A shows the curve of values of r_3 in the 0° test for various values of secondary current plotted against secondary current, while Fig. 5A shows the curve of values of r_3 obtained in the 60° test for various values of secondary current plotted against secondary current.

Fig. 4B shows the values of secondary current correction factor, deduced from Fig. 4A, plotted against secondary current, while Fig. 5B shows the values of the phase-angle error of the transformer deduced from the algebraic difference of the values obtained in Figs. 4A and 5A, plotted against secondary current.

It will be observed that a test of this character is extremely simple, and it is obviously only one step forward to make the resistance box in such a manner as to give, for any given wattmeter, direct indication of the percentage error. A case of this kind, i.e. a test on a transformer wound for a 1 : 1 ratio, is obviously an ideal one, as no calculation has to be made in allowing for the standard-transformer errors. In any comparison method this is, in the author's opinion, an objectionable feature, since mistakes can easily creep in, especially in regard to signs when calculating; and to obviate this difficulty the following further extension was made to the idea. Another similar resistance box, with suitable dials, is incorporated in series with r_3. If now, for every load, a set of values in terms of percentage ratio error and combined ratio and phase-angle error of the standard transformer (which are tabulated in a suitable form) are dialled on the second resistance box correctly as regards sign, then the same relative conditions can be obtained as in the ideal 1 : 1 ratio case previously cited, i.e. the torque in the left-hand element can be made to correspond, for every load and power factor tested, to the primary current of the standard transformer. It will now be seen that the method reduces itself to one of extreme simplicity and minimizes any possibility of errors.

So far, the illustrations of tests and the above deductions have been applied to current transformers, but the same scheme and modifications can be applied, with the same facilities, to potential transformers. Figs. 6 and 7 illustrate the completed method as applied to the



FIGS. 5A and 5B.

routine testing of current and potential transformers respectively. It will be seen from Figs. 6 and 7 that the adjustable resistances are incorporated in the potential circuit of the right-hand element in one unit consisting of six variable resistances, three for the standard corrections and three for the errors of the unknown transformer.

FIG. 6.

These dials are arranged to give steps of 0·01 per cent from 0·0 to 11·1 per cent, which should more than cover the worst error met with in practice.

Fig. 6 requires no further explanation, since this has been given previously when dealing with current-transformer testing; but with reference to Fig. 7, which illustrates the apparatus applied to the testing of potential transformers, further exposition is required. It will be observed that on the right-hand side of Fig. 7 a small step-down transformer is shown connected to the supply from the phase-shifter. This is required to supply the requisite current (about 5 amperes) to the two fixed coils of the detector connected in series. Apart from the connections and the fact that the potential coils are excited from the standard and unknown transformer secondaries, the arrangement is identical with that of Fig. 6.

Fig. 8 gives an illustration of a plan of the testing box and illustrates the inclusion of charts giving typical standard-transformer corrections.

TECHNICAL POINTS RELATING TO THE METHOD.

(1) *Detector.*—The detector as at present constructed is a double-element instrument of similar construction and sensitivity to that described by R. S. J. Spilsbury and previously mentioned in the Introduction, with the exception that it has a central zero. In addition, the moving-coil systems are arranged to be at right angles to the fixed-coil systems so that the mutual inductance between the fixed and moving coils is zero at the balance point, and so that no error can occur due to an e.m.f. induced from one circuit to another.

FIG. 7.

(2) *Balance of Elements of the Detector.*—The verification of the balance of the elements of the detector can be readily made by setting all the dials of the testing box to zero and connecting the fixed coils of the detector in opposition and the potential coils in parallel to sources of current and e.m.f. respectively. Any difference which may exist can be compensated for by adjusting suitably the dials of the testing box, preferably on the standard correction dials; or, if necessary, a small variable resistance can be incorporated for balance purposes if preferred.

(3) *Effect of Reactance in the Potential Circuits of the Detector.*—With regard to this error, since both elements of the detector are identical in construction it can be proved that so long as the angle error of the two elements is identical no error can occur, due to this cause, in the final result; consequently, this allows for some latitude in the design of the detector.

(4) *Burden of the Detector.*—With regard to the burden of each of the fixed coils of the detector, this is at

the present time a comparatively low figure, of the order of 4 VA, and, since it is seldom that a metering equipment imposes less burden than this in practice, it is not an objectionable feature. If, however, it is necessary at any time to obtain the characteristics of a current transformer at zero burden, this can easily be obtained by testing at different burdens and afterwards extrapolating the curves for zero burden figures.

The burden imposed by the potential coils of the detector is of the order of 10 VA, which is, of course, comparatively small, considering that the volt-ampere rating of the smallest potential transformer is about 50 VA; but where necessary, if the zero burden is required, extrapolation can be resorted to, as above.

(5) *Sensitivity of the Detector.*—At full load and unity power factor this is approximately 1 part in 25 000 when using the tapping key for the final adjustment, which is equivalent to 1 part in 600 at the lowest testing point, viz. 1/20th full load and 0·5 power factor. It will consequently be seen that the method leaves little to be desired with regard to sensitivity for routine testing.

In the case of current-transformer testing, where high sensitivity is really required at low loads, an increase in sensitivity can be obtained by increasing the pressure applied to the potential elements. This is due to the fact that the pressure is only applied to the potential coils when detecting the movement of the pointer of the detector by the tapping key; care, however, has obviously to be exercised in this direction.

FIG. 8.—Plan of testing box.

(6) Error introduced by setting the phase-shifter for quadrature with reference to the secondary instead of to the primary of the standard transformer is generally negligible, and can be eliminated by allowance on the phase-shifter setting (see Appendix, section 4).

SIGNIFICANCE OF SIGNS ON THE TESTING-BOX DIALS.

(a) *Ratio Testing.*

It will be noted from Fig. 6 that the measuring resistances on the testing box are inserted in the right-hand potential element of the detector, and this right-hand element is always shown connected to the transformer under test. Although this is arbitrary, it involves simplified connections.

It will be realized that, assuming for simplicity that the standard transformer secondary current is 1·0 per cent low at the load under consideration and that a correction is to be made for this error, then, in order to make the equivalent torque on the left-hand element proportional to that of the primary current, it would be necessary to subtract 1·0 per cent resistance from the potential circuit of this element. But it will be seen that this can be obtained by adding resistance to the right-hand element, and, consequently, although the corrections for the standard transformer are made by adding or subtracting resistance on the right-hand element, the signs on the dials are made to correspond to correct notation.

The author has found that the best way of expressing the ratio error of an instrument transformer is as a secondary correction factor, i.e. the value by which the nominal secondary current has to be multiplied to give the actual secondary current, or, if preferred, as a percentage increase or decrease in the secondary current. For example, a current transformer the nominal ratio of which is 100/5 A and which has a true ratio of 100/4·95 A would have a secondary correction factor of 0·99, or an error of secondary current of 1·0 per cent low.

In Figs. 6 and 7 the positive sign denotes that the secondary current is high, and a negative sign that it is low.

The same remarks apply to the error of the unknown transformer.

(b) Phase-Angle Testing.

A little explanation is required to show the sequence of stages compensating for the phase-angle error of the standard transformer and obtaining the angle error of the unknown transformer.

Case (1).—*Current-Transformer Testing.*—The effect of a leading angle (i.e. where the reversed secondary vector leads the primary vector), which is the normal characteristic of a current transformer, upon the detector at lagging power factor (i.e. when the current supply to the primaries of the transformers lags behind the potential-coil supply) is to increase the torque of the element to which it is connected, and, consequently, assuming that a correction has to be made for a leading phase-angle error of the standard current transformer, resistance would, in effect, have to be added to the left-hand element of the potential circuit of the detector in order to make it appear that the standard transformer had no phase-angle error. This, however, is effected by subtracting resistance from the right-hand element. For a lagging angle the reverse procedure is, of course, adopted.

It will, of course, be realized that in the 60° test both ratio and phase-angle errors have to be compensated for on the standard transformer, therefore the setting on the dials of the testing box would have to be set for the algebraic sum of the percentage error of the standard current transformer and the percentage error due to its angle error at 60°.

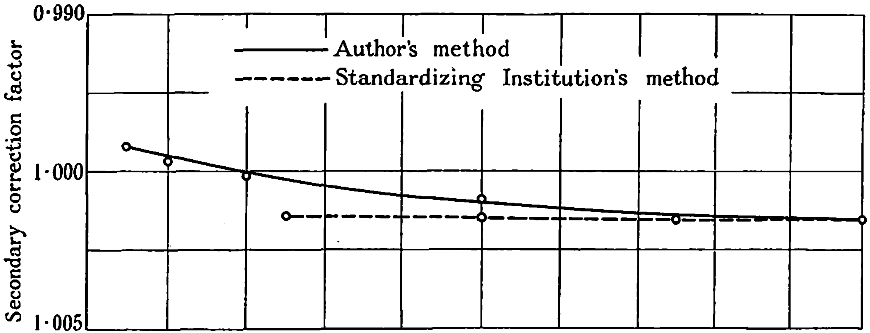

FIG. 9.

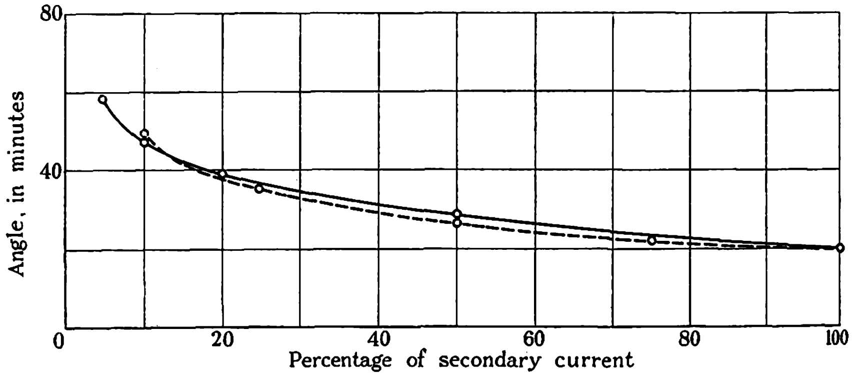

FIG. 10.

As an example, take the case of a standard transformer the secondary current of which is 1·0 per cent low at the load under consideration, with a phase-angle error of 40 minutes leading.

In the 0° test, the standard correction-dials will be set at — 1·0 per cent, which is equivalent to subtracting resistance of this amount from the left-hand element, thereby making the torque of this element equivalent to the primary current.

At the 60° test the dialling, as stated before, will have to be arranged to give a torque on the left-hand element which is equivalent to the primary current and the phase difference between the primary current and the potential-coil supply, i.e. 60°. To procure this result, from the error assumed (40 minutes), resistance would have to be added to the left-hand element of an amount equal to 2·0 per cent (since 40 minutes phase-angle error = an error of 2·0 per cent at 60°) for the angle error, and 1 per cent would have to be subtracted for the ratio error, making an effective alteration of 1·0 per cent added resistance, which is the algebraic sum of the two errors. This is effected on the right-hand element by subtracting resistance equivalent to 1·0 per cent.

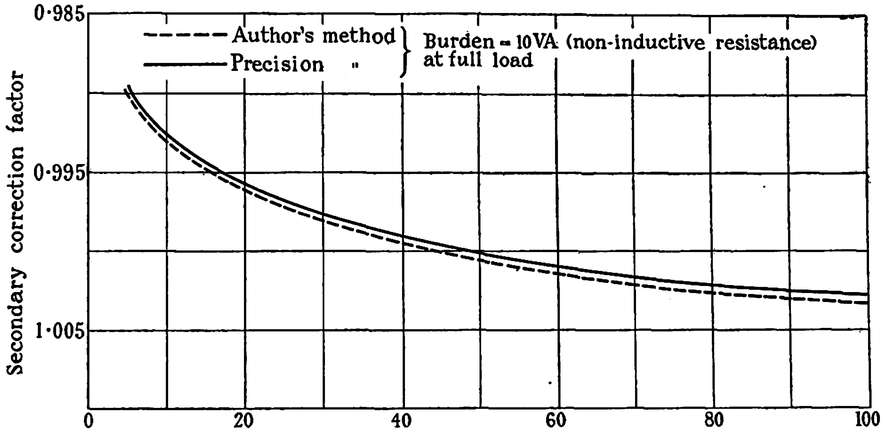

FIG. 11.

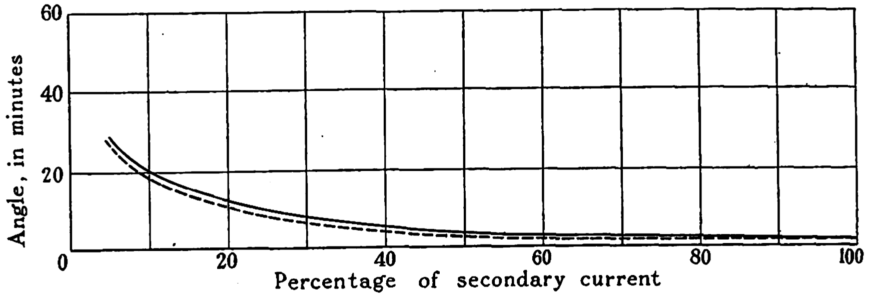

FIG. 12.

In the case of deriving the angle of the unknown transformer the same reasoning holds good, except that the reverse procedure is made, since the indication on the dials at the 60° test gives the combined ratio and phase-angle error, the percentage error due to angle being then the algebraic difference between the combined ratio and phase-angle error and the ratio error at the 0° test, from which value the phase angle is derived as follows:—

Phase angle, in minutes = (Percentage algebraic difference at 60°) × 20 (since 20 minutes = 1·0 per cent error at 60° phase angle).

The following examples are given, illustrating the extraction of ratio and phase angles for current transformers with various characteristics, from dial readings taken at the two tests:—

(1) Test (1) Ratio error = + 0·5 per cent.
Test (2) Combined ratio and phase-angle error = + 3·0 per cent.
Algebraic difference = (Test 2) — (Test 1)
= (+ 3·0 per cent) — (+ 0·5 per cent)
= + 2·5 per cent.
Angle = + 2·5 per cent × 20 = + 50 minutes.

(2) Test (1) Ratio error = — 0·5 per cent.
Test (2) Combined ratio and phase-angle error = + 3·0 per cent.
Algebraic difference = (Test 2) — (Test 1)
= (+ 3·0 per cent) — (— 0·5 per cent)
= + 3·5 per cent.
Angle = + 3·5 per cent × 20 = + 70 minutes.

(3) Test (1) Ratio error = + 1·0 per cent.
Test (2) Combined ratio and phase-angle error = + 0·5 per cent.
Algebraic difference = (Test 2) — (Test 1)
= (+ 0·5 per cent) — (+ 1·0 per cent)
= — 0·5 per cent.
Angle = — 0·5 per cent × 20 = — 10 minutes.

(4) Test (1) Ratio error = — 0·5 per cent.
Test (2) Combined ratio and phase-angle error = — 1·0 per cent.
Algebraic difference = (Test 2) — (Test 1)
= (— 1·0 per cent) — (— 0·5 per cent)
= — 0·5 per cent.
Angle = — 0·5 per cent × 20 = — 10 minutes.

It will be noted that the method is quite simple, and if due notice is taken of the sign the rest of the calculation is only a case of simple mental arithmetic.

Case (2).—*Potential-Transformer Testing.*

(*a*) *Ratio Test.*—This is identical with current-transformer testing, and the derivation of error is the same, a positive sign of percentage error meaning that the secondary voltage is higher than nominal, and vice versa for a negative sign.

(*b*) *Angle Test.*—In order to obtain the same sign notation, viz. a positive angle means that the reversed secondary leads the primary and a negative angle means that the reversed secondary lags relatively to the primary, it is necessary to make the current in the fixed coils lead with respect to the source of e.m.f. of the potential coils.

It will be noted, consequently, that since the current supply to the fixed coils is obtained from the small step-down transformer the primary of which is connected to the phase-shifter, then the phase-shifter is always rotated in the same direction (i.e. from 0° to 60° lead) both for current- and potential-transformer testing, to obtain the same sign notation.

It will be realized that this alteration in the relative vector relationship of the fixed and moving coils is due to the fact that a positive angle on a potential transformer produces a decrease in torque in a meter on a lagging power factor, which is the reverse of that of a current-transformer angle.

Accuracy of the Method.

No mention has yet been made of the accuracy of the method in practice, and as the only proof of this, from a practical point of view, is a comparison of results obtained by this method with those obtained by precision and other similar methods, comparison tests will be mentioned.

Figs. 9 and 10 show tests taken on a low-tension silicon-steel-core current transformer, comparing results obtained by the author's method with those obtained by a British standardizing institution. It will be seen that as regards the angle-error tests there is practically no difference between the results, but as regards ratio tests there is a slight difference of about 0·2 per cent at $\frac{1}{4}$ load. Unfortunately, the lowest point available from the standardizing institution is the $\frac{1}{4}$-load value.

Figs. 11 and 12 show comparison tests taken on a silicon-steel current transformer which was tested by the non-inductive shunt precision method, the shunts of which had been calibrated by the American Bureau of Standards. As will be seen, the comparison is extremely good both on ratio and phase-angle tests, there being a maximum error of 1 part in 2 000 on ratio test and 1 minute on phase-angle test.

Figs. 13 and 14 show comparison tests taken on a mumetal-core current transformer by the author's method, against a non-inductive shunt precision method at a standardizing institution, and by a manufacturer's method. It will be observed that there is very little difference between the results, both on ratio test and phase-angle test. It should, however, be noticed that the burden imposed in the author's test was slightly different from that imposed in the other tests. The

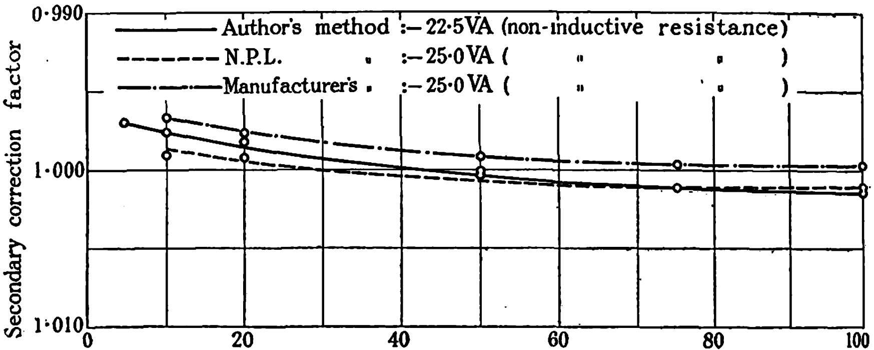

Fig. 13.

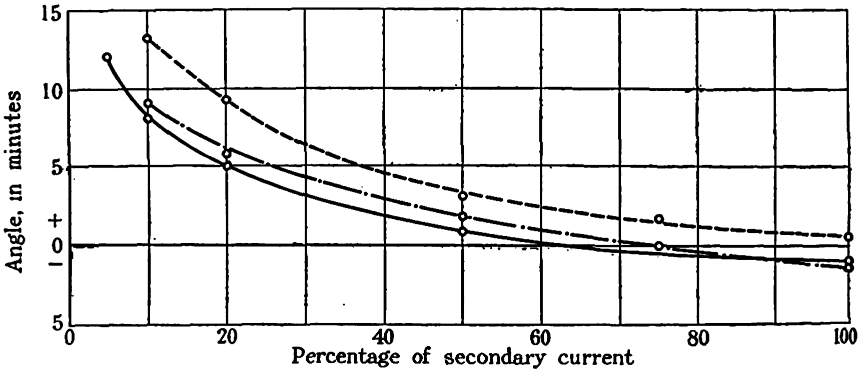

Fig. 14.

manufacturer's and the author's tests on ratio would have been brought more into line if the burden values had been equal.

STANDARD CURRENT TRANSFORMERS OF THE "HOLE" TYPE.

It is of interest to point out that all the above comparison tests were carried out by the author using a standard transformer of the "hole" type, the errors of which, ascertained by the method of calibration as a 1 : 1 ratio transformer outlined in Fig. 3, and exhibited in Figs. 4 and 5, had been compensated for by appropriate setting of the resistance values. Theoretical considerations, however, showed that it would be advisable to ensure that the same characteristics which were obtained when the transformer was wound for 1 : 1 ratio should apply for all other ratios. This involves keeping a constant radius for the primary turns and ensuring that these turns are always in the same position in the "hole."

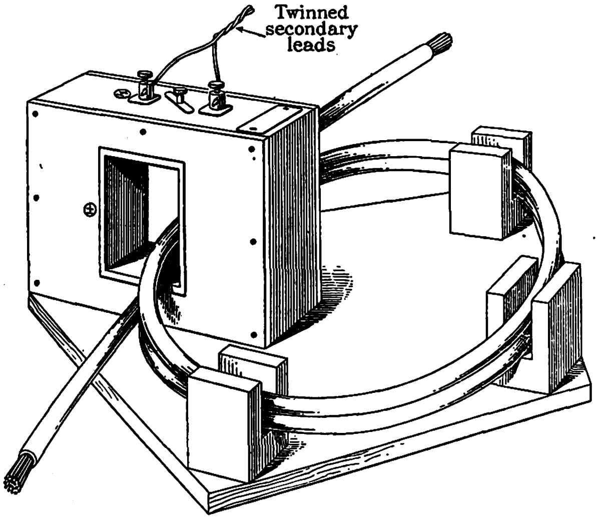

FIG. 15.

Fig. 15 illustrates a winding frame used in conjunction with one of the author's standard transformers, which ensures that the above conditions are fulfilled. Although from experiment it does not appear that this is very necessary in the type of standard transformer illustrated, which has two secondary windings on either side of the "hole," yet it is essential with transformers which have only one secondary winding.*

Incidentally, a necessary precaution which is often neglected when testing current transformers, is to use twinned wires from the transformer secondaries to the instruments.

An interesting series of tests was carried out by the author on the effect of the disposition of the primary winding on a "hole" type transformer, the results being shown in Fig. 16. The core of the transformer tested was of circular form with a distributed secondary, and the primary was wound in five different ways. From the curves it will be observed that there is very little difference between the results.

The disposition shown in (E) appears to give the best accuracy for ratio, but is the least satisfactory for angle. The maximum difference, however, between any of the results on the angle test is only approximately 5 minutes.

The explanation of the differences may be the variation of the leakage fluxes between the primary and secondary windings under the different conditions.

STANDARD TRANSFORMERS REQUIRED TO DEAL WITH ALL RATIOS OF TRANSFORMERS.

A point which often arises in connection with a comparison method is that of the multiplicity of standards which would be required to test all British standard ranges of current transformers. Consider a "hole" type standard current transformer the nominal ratio of which with one primary turn is 1 200/5 A. The ranges that can be tested by a standard of this size by suitably varying the number of primary turns are as follows:—

5/5, 10/5, 15/5, 20/5, 30/5, 40/5, 50/5, 60/5, 80/5, 100/5, 150/5, 200/5, 300/5, 400/5 and 600/5 A.

Two difficulties arise from this: (1) the tedious process of winding a large number of primary turns for the smaller ratios, and (2) that the following ratios, up to 2 000/5 A, cannot be tested:—

250/5, 500/5, 800/5, 1 000/5, 1 500/5 and 2 000/5 A.

A simple solution in the first case and one which is frequently carried out at the present day is to make use of a wound primary (in addition to the "hole" for the smaller ratios). If this is done, in the case cited, viz. 1 200/5 A ratio, it is possible to test the following ratios by winding the primary:—

60/5, 80/5, 100/5, 150/5, 200/5, 300/5, 400/5 and 600/5 A.

With the addition of a standard transformer the nominal ratio of which with one primary turn is 2 000/5 A, of the remaining British standard ranges from 5/5 to 2 000/5 A the following can be tested:—

250/5, 500/5, 1 000/5 and 2 000/5 A.

This leaves two ratios which have not yet been catered for, viz. 800/5 and 1 500/5 A. In order to include these ratios and to avoid purchasing two more standard transformers, an interesting modification of the method may be adopted. This consists of adding impedance to the potential element of the detector not incorporating the testing-dial resistances, viz. the left-hand element, which impedance must have theoretically the same time-constant as the left-hand potential element in order to produce a torque on that element equal to that which would be produced by a standard transformer having the same nominal ratio as the transformer under test, the standard transformer being wound for a ratio nearest to that of the transformer under test, i.e. to give a greater secondary current.

Considering the case of 800/5 A and 1 500/5 A ratio transformers to be tested, the standard transformer used to test the 800/5 A transformer would be the 1 200/5 A

---

* H. W. PRICE and C. K. DUFF: "Current Transformers," *University of Toronto Bulletin*, 1921, No. 2, Section 4.

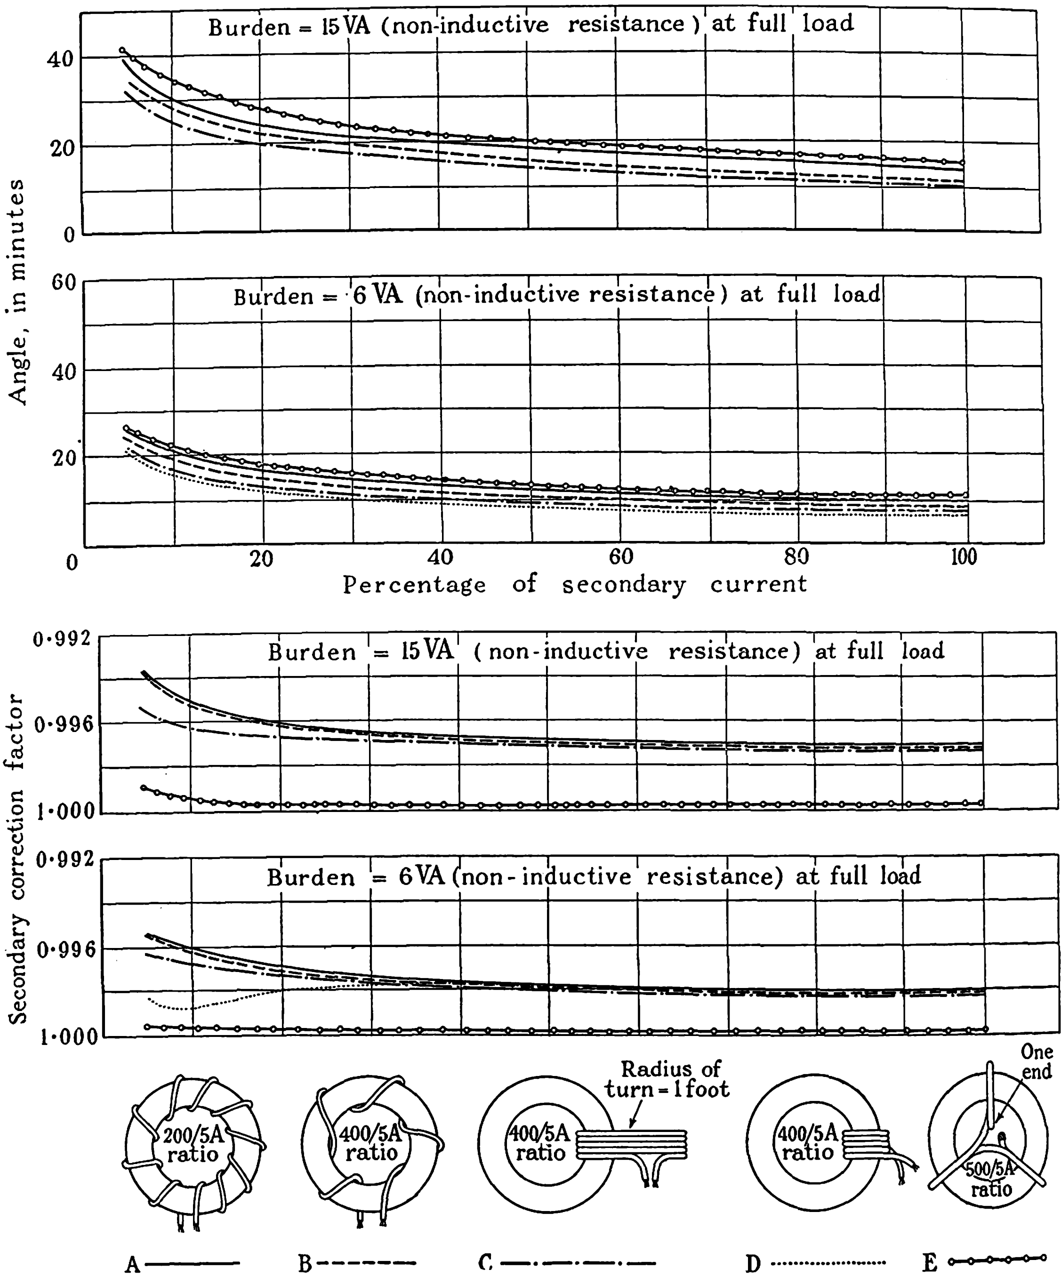

FIG. 16.—Curves showing effect of disposition of primary winding of cu rent transformer.

type wound for a ratio of 600/5 A. The impedance which would have to be added would be equal to:—

$$\frac{800}{600} \times \text{original impedance of left-hand element.}$$

In the case of the 1 500/5 A transformer, the standard transformer used would be the 1 200/5 A type wound as a 1 200/5 A instrument.

The impedance which would have to be added would be equal to:—

$$\frac{1\,500}{1\,200} \times \text{original impedance of left-hand element.}$$

As the reactance of the potential circuit of the detector is very small compared with the resistance, the impedance added can generally take the form of a resistance, with negligible error.

CONCLUSIONS.

The advantages which can be claimed for the method may be summed up as follows:—

(1) It reduces calculation to a minimum.

(2) It is a null method and can therefore be operated by non-technical testers.

(3) The error is read directly from the testing-box dials.

(4) It is accurate and sufficiently sensitive for most commercial requirements.

(5) It is the only method, so far as the author is aware, which with the same apparatus can be used for testing both current and potential transformers.

SUGGESTED APPLICATIONS OF THE METHOD.

(1) *The Measurement of Ratio and Determination of the Regulation Curve of a Power Transformer.*—An interesting application of the method is the testing of power transformers for ratio and the determination of the regulation curve, as shown in Fig. 17. A little consideration will show that if the characteristics of the potential transformers are identical, then no allowance will have to be made for their characteristics. If there is a difference, then the algebraic difference between the characteristics of the two potential transformers can be allowed for on the testing-box dials.

In carrying out such a test, the phase angle between the current supply to the fixed and moving coils of the detector is set at 0° by means of the phase-shifter.

The error read on the testing-box dials, after balance has been obtained, is proportional to the ratio between the primary and secondary voltages of the power transformer.

By loading the secondary of the power transformer, a regulation curve can be taken at various loads and power factors, and by obtaining values on a 60° phase angle between the fixed and moving coils the angular displacement of the secondary of the power transformer with respect to its primary can be deduced.

(2) *The Measurement of Iron Losses of a Power Transformer.*—A possible application of the method is for testing the losses of power transformers. This is outlined in Fig. 18, which is a fundamental diagram of such a suggested scheme. In this case, again, if the errors of the two current transformers are identical, then no corrections for these are necessary; whilst, if there is a difference, the algebraic difference between the two characteristics must be corrected for on the testing box.

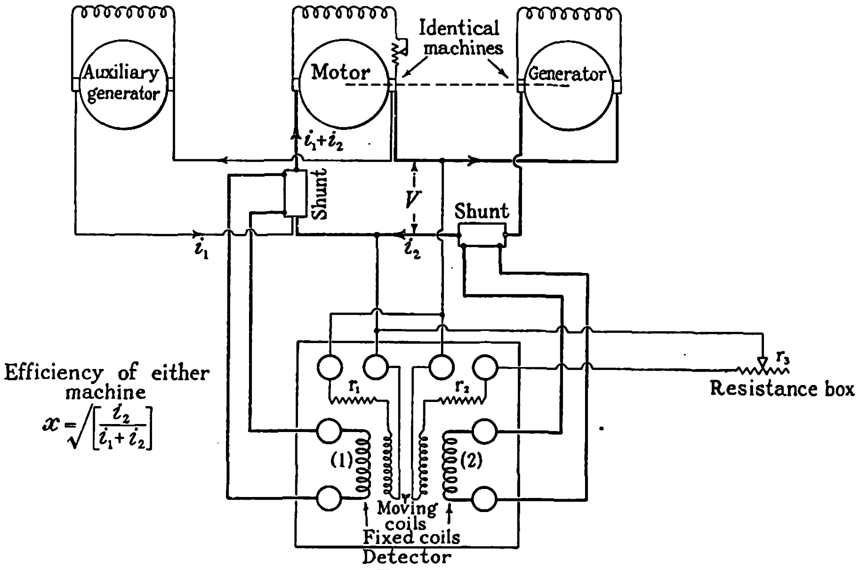

Fig. 19.

Using this method it seems possible to obtain, by means of a 0° test (i.e. 0° between the fixed and moving coils of the detector, established by means of the phase-shifter) and a 60° test (60° between the fixed and moving coils), the iron and copper losses of a power transformer by deduction from the phase angle so ascertained between the reversed secondary vector and the primary vector of the power transformer.

If several loads are taken on the power transformer, and ratio and angle tests are also taken, the complete characteristics of a power transformer can be analysed. This, however, the author leaves for further development to those interested in the testing of power transformers.

(3) *The Application of the Method to Hopkinson's Efficiency Tests on D.C. Machines.*—As a matter of interest, another suggested application of the method is its use in conjunction with the Kapp modification of the Hopkinson efficiency tests on d.c. machines, which is shown outlined in Fig. 19.

Shunts are used for the supply of current to the fixed coils of the detector, and the combined losses of the two identical machines are read directly from the testing box.

The efficiency of either machine can readily be deduced by applying the usual formula.

Other applications of the method might be developed, e.g. its use for determining the efficiency of a rotary convertor.

Finally, the author would like to thank the chief engineer of the North Metropolitan Electric Power Supply Co.—Captain J. M. Donaldson—for permission to publish results of tests taken in the company's laboratory. He is also indebted to Mr. W. Casson for assistance in the preparation of the paper and for suggestions as to other applications of the method, and to Mr. E. W. Hill for valuable suggestions.

APPENDIX.

LIST OF SYMBOLS.

I_p = primary current;
I_1 = secondary current of standard current transformer;
I_2 = secondary current of unknown current transformer;
ϕ = angle of lead or lag between I_p and V;
V = applied voltage to pressure coils of detector;
θ_1 = angle error of standard current transformer;
θ_2 = angle error of unknown current transformer;
γ_1 = angle of left-hand potential element;
γ_2 = angle of right-hand potential element;
r_1 = resistance of left-hand potential element;
r_2 = resistance of right-hand potential element;
r_3 = resistance added or subtracted on right-hand potential element in 0° test;
r_4 = resistance added or subtracted on right-hand potential element in 60° test;
L_1 = coefficient of self-induction of left-hand potential element;
L_2 = coefficient of self-induction of right-hand potential element.

CURRENT-TRANSFORMER TESTING.

(1) *Balance Test.*—Let the fixed coils be connected in opposition and in series with a source of e.m.f. so that a current I flows through the coils.

Let the potential coils be connected to a source of e.m.f., V, in phase with current I.

When balance conditions are obtained

$$I\frac{V}{\sqrt{[r_1^2 + (\omega L_1)^2]}}\cos\gamma_1 = I\frac{V}{\sqrt{[r_2^2 + (\omega L_2)^2]}}\cos\gamma_2$$

If $L_1 = L_2$ and $\gamma_1 = \gamma_2$

then $r_1 = r_2 = r$

(2) 0° *Test.*—Let the fixed coils be connected to the secondaries of the standard and unknown current transformers respectively.

Let the potential elements be connected in parallel to a source of e.m.f. in phase with the primary current.

Assume, for simplicity, that the standard current transformer has no errors.

Then $I_1\dfrac{V}{r_1}\cos\phi = I_2\dfrac{V}{(r_2 \pm r_3)}\cos(\phi \pm \theta_2)$ for balance.

Since $\phi = 0°$ and θ_2 is small, $\cos(\phi \pm \theta_2)$ can be expressed as unity.

$$\therefore \frac{I_1}{I_2} = \frac{r_1}{(r_2 \pm r_3)}$$

and, since from balance test $r_1 = r_2 = r$,

then $\dfrac{I_1}{I_2} = \dfrac{r}{(r \pm r_3)}$

(3) 60° *Test.*—Let the fixed and potential coils be connected as in the 0° test and let a phase difference of 60° between I_1 and V be imposed. Assume that the standard current transformer has no angle error. Then

$$I_1\frac{V}{r}\cos\phi = I_2\frac{V}{(r \pm r_4)}\cos(\phi \pm \theta_2) \text{ for balance}$$

Therefore $\dfrac{\cos\phi}{\cos(\phi \pm \theta_2)} = \dfrac{r}{(r \pm r_4)} \times \dfrac{I_2}{I_1}$

But from the 0° test $\dfrac{I_2}{I_1} = \dfrac{(r \pm r_3)}{r}$.

Substituting, we obtain

$$\frac{\cos\phi}{\cos(\phi \pm \theta_2)} = \frac{r}{(r \pm r_4)} \times \frac{(r \pm r_3)}{r}$$

and

$$\frac{\cos\phi}{\cos(\phi \pm \theta_2)} = \frac{(r \pm r_3)}{(r \pm r_4)} = \text{angle correction-factor}$$

Therefore the angle correction-factor equals the resistance of the potential element and the resistance added or subtracted at the 0° test, divided by the resistance of the potential element and the resistance added or subtracted at the 60° test. (The same method applies to the allowance for the errors of the standard current transformer.)

(4) *Effect of Standard Current-Transformer Angle Error.*—The phase-shifter setting for zero power factor is made on the left-hand element of the detector.

Assume that the standard current transformer has an angle error of + 1° (i.e. the reversed secondary vector leads the primary vector), then conditions are as follows:—

The left-hand element is connected to the secondary of the standard current transformer and has exactly 60° phase difference between the fixed and moving coils.

On the right-hand element, due to the standard current-transformer angle, the phase difference between the fixed and moving coils is only 60° − 1° = 59°, i.e. the angle between I_p and V; and although this has no effect on the 0° test, on the 60° test a slight error may be introduced.

The standard current-transformer angle is compensated for by adding resistance to the right-hand element potential circuit.

Hence

$$I\frac{V}{r}\cos 60° = I\frac{V}{(r + 3{\cdot}0\,\%\,r)}\cos 59° \text{ for balance,}$$

where 3 per cent is the figure which would be given as the correction for 60 minutes for the standard current transformer.

Now if the unknown transformer is connected to the right-hand potential element with an angle of, say, + 3°, then

$$I\frac{V}{r}\cos 60° = I\frac{V}{(r \times 1{\cdot}0309 \times F_c)}\cos 62° \text{ for balance,}$$

where F_c = correction factor of the percentage resistance added or subtracted for the angle error of the unknown transformer.

Therefore

$$F_c = \frac{\cos 62°}{\cos 60° \times 1{\cdot}0309} = 0{\cdot}911$$

If the standard current transformer had no angle error, then the correction factor (calculated) of the unknown transformer for an angle of + 3° would be derived as follows:—

$$I\frac{V}{r}\cos 60° = I\frac{V}{r \times F_c}\cos 63°$$

$$\therefore F_c = \frac{\cos 63°}{\cos 60°} = 0{\cdot}908$$

If the angle error of the unknown current transformer were calculated on a basis of 60°, then from the correction factor derived in the case when the standard current transformer had an error of + 1° there would be an error of 0·3 per cent; but, if necessary, the calculations for derivation of the angle could be based on 59° or (60° ∓ the standard current-transformer angle) to give absolute values.

When it is considered, however, that a good standard current-transformer angle error only varies from a few minutes at full load to 30 minutes at 1/20th full load, the calculations can be made on a basis of 60° for most commercial purposes.

The simpler method, however, is, after setting for 90° on the left-hand element between I_1 and V, to set the phase-shifter minus the standard angle error for positive angles, and vice versa for negative angles, at both the 0° and the 60° tests. This will give a setting of 0° and 60° respectively between I_p and V for the two tests.

(5) *Effect of Reactance in Potential Circuit of Detector.*—Provided the angles are identical in both elements, no error can accrue, since the angular difference between the fixed and moving-coil currents is fixed by the phase-shifter.

If there is an angular difference, this can be compensated for by adding or subtracting resistance at a 60° balance test.

The same reasoning applies to the testing of potential transformers.

[The discussion on this paper will be found on page 906.]

SOME ACCESSORY APPARATUS FOR PRECISE MEASUREMENTS OF ALTERNATING CURRENT.

By R. S. J. Spilsbury, B.Sc., and A. H. M. Arnold, Ph.D., Associate Members.

[From the National Physical Laboratory.]

(*Paper received* 25*th November*, 1929; *read before the* Meter and Instrument Section 7*th February*, 1930.)

Summary.

The paper describes apparatus for obtaining for purposes of measurement a voltage proportional to, and in phase with, a given alternating current. The Introduction outlines defects in the water-cooled tube resistors which have been in use at the National Physical Laboratory for this purpose; these defects have led to the construction of air-cooled resistors for moderate currents, and current transformers with nickel-iron cores for heavy currents. Section (1) deals with the requirements for the air-cooled resistors, and with theoretical and practical points in their design; tests showing very satisfactory performance are described. Section (2) outlines the construction of the special current transformers, and deals at some length with the method of calibrating them. Finally, the effects of a number of variables on the transformer performance are investigated: the characteristics are shown to be very good, and no sign of instability is found.

Introduction.

In the measurement of alternating current and power by electrostatic methods, it is generally necessary to employ apparatus capable of providing a voltage of the order of 2 volts, proportional to, and in phase with, the current to be measured. Usually a "non-inductive" resistor is used, and the design of such resistors has been given considerable attention.

At the National Physical Laboratory air-cooled resistors have been used for currents up to 20 amperes. Beyond this value, and up to 2 000 amperes, manganin tubes, internally water-cooled and specially compensated for self-inductance, have been employed. An account of the latter type has been published in the *Journal*.*

The experience gained with the tube resistors during the last 20 years has shown that they have certain disadvantages. In the first place the resistance tends to increase, owing to cracking of the film of enamel which covers the internal surface, and subsequent corrosion by the water. This effect is only serious in the smaller sizes, but necessitates their adjustment by shunting at rather frequent intervals. A second difficulty is that the residual inductance of the larger tubes is neither as small nor as constant as is desirable. The reduction of this quantity was, of course, one of the main objects of the design, and it does not appear possible to improve much on the figures obtained, which correspond to a phase angle of about 3 minutes at 50 cycles per sec. for the 2 000-ampere size. A phase error of this magnitude could be tolerated if it were satisfactorily constant; but it has been found, using a method due to Hartshorn,* that variations of the order of 2 minutes can be made by varying the disposition of the connecting leads.

Further difficulties were introduced a few years ago by the necessity for measuring currents in excess of 2 000 amperes. It had originally been intended to build resistors of similar design for 5 000 amperes. In order to keep down the phase angle, the manganin tube for such resistors should be about 12 cm in diameter and about 1 mm thick; but it does not appear possible to procure such tubing commercially. Even if it were possible to build the resistors, the amount of power which they would dissipate would be a serious problem; a 3-phase set-up, in which three resistors are used to preserve balance, would absorb 30 kW at 5 000 amperes.

The smaller sizes of water tubes have recently been eliminated by the design and construction, at the Laboratory, of air-cooled resistors to carry currents of 50, 100 and 200 amperes. These are described in the next Section. Air-cooled resistors are, naturally, larger than water-cooled resistors of equal capacity, and it has not been thought advisable to adopt this type for currents above 200 amperes, on account of the extreme bulk entailed. While this matter was being considered, however, the remarkable properties of nickel-iron alloys of high nickel content became known, and it was at once seen that current transformers with cores of such materials might solve at one stroke all the difficulties in the design of heavy-current resistors. Assuming that transformers could be obtained with satisfactory characteristics, it would merely be necessary to connect an accurate resistor of 0·4 ohm, the construction of which presents no difficulty, in the secondary circuit of, say, a 5 000/5 transformer, when the assembly would be the equivalent of a 5 000-ampere non-inductive resistor giving a 2-volt drop, except that the power loss would be of the order of 50 watts instead of 10 kW. Everything, of course, depended on the accuracy and stability of the transformer, and it was decided to make a detailed investigation of these points; the provision of a 5 000-ampere measuring device being the most urgent problem, transformers of this range were selected for the work. For this purpose a specification was drawn up, and three 5 000/5 transformers, in accordance therewith, were obtained from Messrs. Everett, Edgcumbe and Co., Ltd. Section (2) gives an account of the results obtained with these transformers.

(1) AIR-COOLED NON-INDUCTIVE RESISTORS.

(*a*) *Requirements*.—The purposes for which these resistors are used are:—(i) for testing ammeters; (ii) for testing wattmeters and watt-hour meters; (iii) for use with a.c. potentiometers; (iv) for testing current transformers; and (v) for standards of resistance and phase angle in a.c. bridges.

It has been found that, in order to obtain sufficient sensitivity for certain of these tests, a voltage-drop of the order of 2 volts is required. A range of resistors is therefore required, of such values that it is possible to obtain a p.d. of 1 or 2 volts for any current. Air-cooled resistors have been designed and constructed at the Laboratory to give a voltage-drop of 2 volts when carrying currents of 1, 2, 5, 10, 20, 50, 100 and 200 amperes respectively. The same general principles of design have been followed in all these resistors. The difficulties involved increase with an increase in current, and it is proposed, therefore, to describe in detail the design of the 200-ampere resistor only.

For the tests (i), (ii) and (iii) referred to above, an accuracy of 0·1 per cent is usually required; and it is desirable to be able to obtain this accuracy without the necessity for applying corrections to the nominal value of the resistance. Bearing in mind the possibility of similar errors in the determination of the voltage component in power measurements, it is probably necessary, in order to obtain an accuracy of 0·1 per cent, that the actual value of the resistance should not deviate more than 2 parts in 10 000 from its nominal value under all conditions of loading and room temperature, and that the residual phase angle should not introduce an error of more than 2 parts in 10 000. The residual phase angle will not introduce appreciable error into measurements of current or of power at unity power factor, but an error which reaches a maximum at zero power factor is introduced into the measurement of power at low power factors. Power factors under 0·5 are not often required in routine test work: at this power factor a residual phase angle of 0·4 minute causes an error of 2 parts in 10 000 in the power measurement, and this value, therefore, should not be exceeded. The residual phase angle is proportional to the frequency, which is now standardized in this country at 50 cycles per sec. For this frequency, a phase angle of 0·4 minute corresponds to a time-constant (inductance ÷ resistance) of 4×10^{-7}.

For tests (iv) and (v) above it is sometimes necessary to attain the greatest accuracy possible, and for this purpose the true value of the resistance should be used and a correction should be made for the residual phase angle. The temperature-rise of the larger sizes of these resistors is considerable, but it has been found possible, by using selected constantan wire, to keep the resistance constant to within 1 part in 10 000 for any current not exceeding rated current. The true resistance may, therefore, be determined to this limit. The residual phase angle of a resistor may be determined to within 0·05 minute at 50 cycles per sec., but, unless the resistor is carefully designed, this phase angle will be altered by stray magnetic fields produced by currents in neighbouring conductors. If large loops in the current circuit are avoided, the phase angle of the air-cooled resistors remains constant to within 0·05 minute.

(*b*) *Principles of Design*.—The main principle of the design was to construct a single non-inductive circuit of comparatively high resistance which will be referred to as a " unit." Lower-resistance circuits were then obtained by the simple multiplication of units in parallel. Resistances of this type, designed by Mr. C. C. Paterson and Dr. E. H. Rayner, have been in use at the Laboratory for many years. Provided that the mutual inductance between units is negligible, the time-constant of the whole resistor is substantially independent of the number of units. This conclusion is modified in practice by the inductance of the busbars which connect the units in parallel.

The " unit " resistance adopted was 2 ohms, with a rated current of 1 ampere.* The material of which it is made consists of 2 constantan wires which are separately double-silk-covered, and then laid flat and single-silk-covered over all. A length of about 40 in. of this bifilar wire constitutes the unit. The two individual wires are soldered at one end to a busbar, which forms the mid-point of the resistor. The free ends are connected respectively to the two main busbars, by means of which the current is led in and out of the resistor. The time-constant of this unit may be estimated very easily, and is found to be approximately 2×10^{-7}, that is, one-half the value which, in the last Section, was decided to be reasonable. In the light-current resistors the inductance of the busbars adds little to this figure, but, as the number of units in parallel is increased, the busbars increase both in length and in section, until, finally, the inductance of the busbars becomes the dominating factor.

Now, all these resistors are constructed as 4-terminal resistors; that is to say, the current is led in and out through one pair of terminals, and the voltage-drop across the resistor is measured between another pair of terminals which are connected to suitable points in the busbars. The points on the busbars to which the voltage terminals are connected will be referred to as the " voltage points." The impedance of the resistor is defined as the ratio of the voltage across the voltage terminals to the current entering and leaving the current terminals. The phase angle of the resistor is defined as the phase angle between the voltage across the voltage terminals and the current entering and leaving the current terminals. It is clear, therefore, that if the impedance of the busbars is an appreciable part of the impedance of the whole resistor, the impedance of the latter will depend on the position of the voltage points. The selection of suitable voltage points is of the greatest importance for heavy-current resistors. If the number of units connected in parallel to the busbars is large, the problem is analogous to that of determining the voltage at any point across a transmission line, with inductive leakage, and inductance and resistance in the line. The busbars constitute the line and the units connected to it constitute the leakage. Capacity effects may be neglected. The problem is solved on this basis in e Appendix, and it is there found that if the voltage points are at the opposite end of the busbars to the current terminals, the inductance of the resistor will be equal to the inductance of the units * minus one-sixth of the inductance of the busbars. If the inductance of the busbars is more than 6 times the inductance of the units, the resistor will have a leading phase angle. On the other hand, if the voltage points are at the same end of the busbars as the current terminals, the inductance of the resistor will be equal to the inductance of the units plus one-third of the inductance of the busbars. Provided, therefore, that the inductance of the busbars is greater than 6 times the inductance of the units, it is possible to select voltage points so as to make the resistor non-inductive. The results of this analysis are slightly modified in practice by the finite number of units connected to the busbars and also by the relative magnitudes of the section and length of the busbar. The selection of the correct voltage points is therefore carried out experimentally. Thus the time-constants of the light-current resistors are approximately 2×10^{-7}, and this figure can be reduced still further in the heavier-current resistors by the selection of suitable voltage points. The time-constants of these resistors will to some extent be affected by magnetic fields. It is of little use to adjust the voltage points carefully to give zero phase angle, if the magnetic fields produced by the currents in the conductors in other parts of the circuit disturb this phase angle. The magnetic fields which these resistors may encounter are proportional to the current in the circuit, and it is evident that far more attention must be given to the effect of these magnetic fields in the case of heavy-current resistors than is necessary for the smaller sizes.

---

* In some of the light-current resistors constructed, a unit of 4 ohms was adopted in order to make the adjustment of the resistance to its nominal value more easy.

Magnetic fields may affect the resistor in two ways. In the first place, the effective inductance of the resistor may be altered. It may be safely assumed that magnetic fields will have little, if any, effect on the effective inductance of the units. The wires of each unit are not twisted up together, but the disposition of the wires carrying currents in reverse directions in the different units is sufficiently haphazard to ensure that any small e.m.f. induced in one unit will be offset by other e.m.f.'s in other units. On the other hand, the busbars consist of two rectangular bars side by side, and it is possible for an appreciable e.m.f. to be induced between them by a magnetic field. The solution of this problem was found in duplicating the busbars and connecting one-half of the total number of units to each pair of busbars (see Fig. 2). The four bars were arranged side by side, and the two outer bars were connected to one current terminal and the two inner bars to the other current terminal. Thus a uniform magnetic field would induce equal and opposite e.m.f.'s in each pair of busbars, and the inductance of the whole resistor would be unaffected.

Secondly, magnetic fields may induce an e.m.f. in the leads between the voltage points and the measuring instruments. Such an e.m.f. would alter the effective phase angle of the resistor. These leads are carefully twinned together so as to avoid trouble from this cause. The leads are, however, in two sections, first from the voltage points to the voltage terminals fixed to the side of the box enclosing the resistor, and, secondly, external leads, which do not form part of the resistor, from these terminals to the measuring instrument. An ordinary pair of terminals would be separated by an appreciable amount, and, in the loop thus formed, it would be possible for a magnetic field to induce an e.m.f. A special voltage connector which is free from this defect has therefore been designed, and is described later.

The temperature-rise of these resistors is a factor which requires consideration, since in the 200-ampere size the energy dissipated amounts to 400 watts. It is found experimentally that if provision is made for a natural circulation of air, the temperature-rise of the units is practically independent of the spacing between them. A natural circulation is ensured by leaving openings in the resistor box at the top and the bottom: the spacing between units varies from ½ in. for the light-current resistors to ⅙ in. in the 200-ampere size, where the spacing is reduced to the minimum practicable in order to keep the size of the whole resistor moderate. The actual temperature-rise of the units in the 200-ampere resistor is from 40 deg. C. to 50 deg. C., and it is therefore essential that the temperature coefficient of the wire employed should be very small. The temperature coefficient of commercial constantan is very variable, and samples from different melts may vary from a few parts in 100 000 per deg. C. positive to as much as 8 parts in 100 000 per deg. C. negative. The wire used in the construction of these resistors was obtained by selection, and has a temperature coefficient per deg. C. of a few parts in a million.

The adjustment of the resistances of these resistors to their nominal values is a point of importance. The resistors are wound in the first place so as to have approximately the correct resistance. Suitable voltage points are then selected, experimentally, to give the smallest phase angle attainable. The resistance is then adjusted to its nominal value by the adjustment of one or more units. Usually this final adjustment will not have an appreciable effect on the phase angle. If the resistance is higher than its nominal value, the adjustment is very easily made by short-circuiting the two wires of a unit some distance from the mid-point busbar. This lowers the resistance of this unit below 2 ohms, and, therefore, increases its temperature-rise. To avoid this each resistor, in the heavier-current sizes, has one unit with a resistance of rather more than 2 ohms, and adjustment is carried out on this unit. In the 200-ampere size there are 200 units in parallel, and a considerable alteration of the resistance of one unit will have very little effect on the value of the total resistance. It is therefore very easy to adjust the total resistance to any desired accuracy. In the lighter-current resistors, where there are fewer units in parallel, the adjustment requires more care.

A few words may be said about the mid-point of the resistor. The mid-point is used for wattmeter measurements, with a fictitious load. One terminal of the voltage circuit is connected to the mid-point of the current resistor, while the other terminal is connected to the needle of the electrostatic wattmeter. The

---

* By the inductance of the units is meant their total inductance when connected in parallel; i.e. if inductance of 1 unit = L_1 and there are 200 units, combined inductance of 200 units = $L = L_1/200$, neglecting mutual inductance between units.

voltage connector on each resistor has therefore three points, one to each current busbar and the third to the mid-point busbar. It is desirable to keep all three leads twisted together to avoid trouble from magnetic fields; but, as the needle voltage of the wattmeter is 100 volts, little error is introduced by small departures of the nominal mid-point of a resistor, with 2 volts drop, from its actual mid-point.

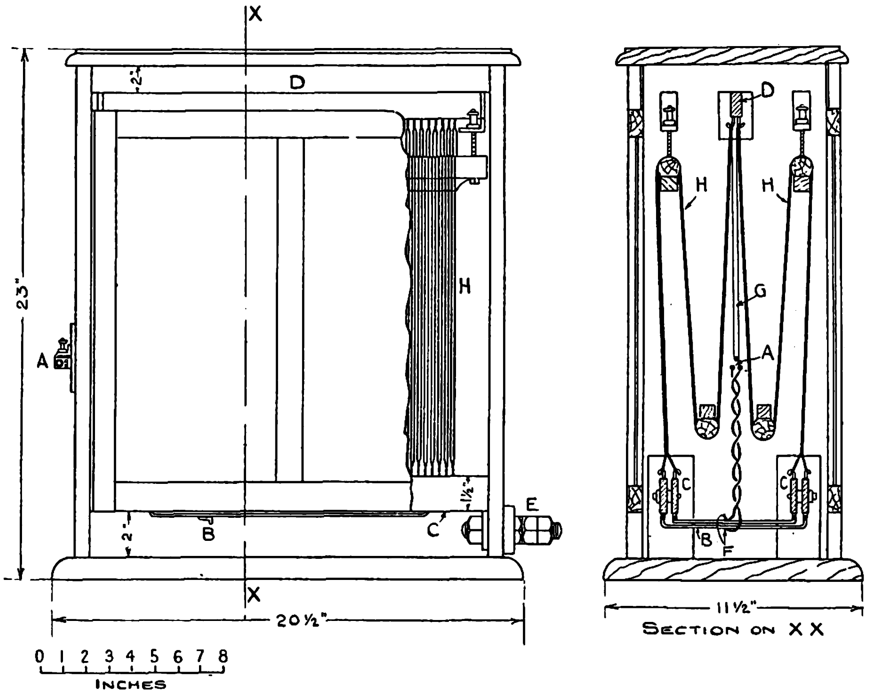

Fig. 1.—Elevation and section of 200-ampere resistor.

A = 3-point voltage connector (detail drawings shown in Figs. 3 and 4).
B = Paralleling conductors at voltage points, 0·104 in. diameter copper.
C = Current busbars.
D = Mid-point busbar.
E = Current terminals.
F = Voltage points (" twinned " copper leads of 0·048 in. diameter from these points to voltage connector A).
G = Copper lead, 0·104 in. diameter, from mid-point busbar to voltage connector A.

Note.—Separate low-resistance voltage connections with terminals were provided for measuring the resistance with direct current on the Kelvin double bridge. These are omitted from the diagram for the sake of clearness.

(*c*) *Design Details of the 200-Ampere Resistors.*—The resistor is mounted in an oak framework, which is shown in Fig. 1. The two side-panels are removable and the top is hinged. The current busbars are fixed near the bottom of the box in a horizontal position. The current terminals are at one end of the box, and the voltage connector is at the other end. Thus the voltage leads need not be taken near the heavy-current conductors, and the danger of induced e.m.f.'s from the magnetic fields of the latter is minimized. The busbars are constructed of brass and have a cross-section of $1\frac{1}{2}$ in. × $\frac{5}{16}$ in. They are shown in plan in Fig. 2. Copper hooks are soldered into the tops of the busbars at intervals of $\frac{1}{3}$ in., and the ends of two units are soldered to each hook. The units are carried over wooden supports to the mid-point busbar, which is fixed at the top of the box. An elevation showing the arrangement of two units, one going to each pair of current busbars, is shown in Fig. 1. The units were made up in pairs: that is to say, an 80-in. length of double wire was bent over at its mid-point, and this mid-point was soldered to a hook on the mid-point busbar. The ends of this double unit were then soldered to hooks on the current busbars. Since the exact voltage points were not known until the resistor was wound, a copper wire was fixed under each busbar running along the major portion of its length, and soldered into it near either end. The voltage terminals were soldered to suitable points on these wires. Since there were duplicate busbars, the wires underneath them were paralleled at the voltage point (see Fig. 1). The diameter of these wires was 0·104 in., so that small equalizing currents could flow between the busbars without much voltage-drop.

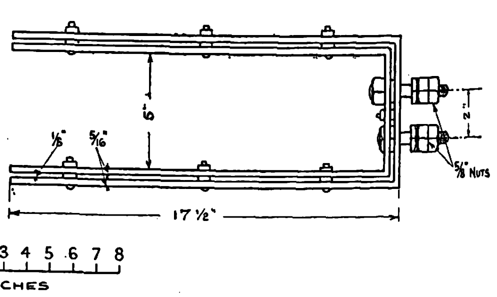

Fig. 2.—Plan of current busbars.

The design of the voltage connector is shown in Figs. 3 and 4. It may be seen from Fig. 4 that there are two loops, one in each half of the connector. Each of these loops is extremely small, and the method of cross-connecting the leads in one causes any e.m.f.'s induced in them to oppose each other. The complete connector is almost absolutely astatic to magnetic fields.

(*d*) *Performance of the* 200-*Ampere Resistor.*—The completed resistor was subjected to a series of tests in order to determine whether its performance reached the standard required. The change of resistance with rated current from the resistance when cold was less than **1 part in 10 000.** The change due to variation of ambient temperature was entirely negligible. The time-constant was experimentally adjusted to be less than $0 \cdot 5 \times 10^{-7}$, i.e. the phase angle at 50 cycles per sec. was less than 0·05 minute.

The resistor was then subjected to a test for stray magnetic field. The field produced at the centre of a circle, 1 metre in diameter, by the rated current of 200 amperes flowing round the circumference is equal to 2·5 C.G.S. units. This was adopted as the basis of tests. The resistor was subjected to a uniform alternating field of 2·5 C.G.S. units in various directions while carrying rated current: no change of phase angle greater than 0·1 minute was observed. The field was in time-phase with the resistor current. To determine the effect of non-uniform fields, a conductor carrying 200 amperes was placed in close proximity to the resistor, in various positions; again no change of phase angle greater than 0·1 minute was observed.

The resistor is mounted on a trolley, and the leads to it are normally taken downwards together, and then away from the resistor. Under normal conditions of use, therefore, the resistor will not be subjected to a field as strong as 2·5 C.G.S. units, and the phase angle may be assumed to be constant to within 0·05 minute.

(2) HIGH-RATIO CURRENT TRANSFORMERS.

(*a*) *Construction.*—The core of each transformer consists of jointless rings of mumetal, and carries a secondary winding of 999 turns: in order to minimize the effect of stray magnetic fields the winding was distributed as uniformly as possible round the core. The transformer was supplied uncased, and was mounted at the Laboratory in a substantial teak housing approximately 11 in. × 11 in. × 6 in., care being taken to avoid mechanical strains on the core material. In the centre of the casing is a circular hole $3\frac{1}{2}$ in. in diameter through which cables can be passed to form the primary winding. With a single cable through this aperture the ratio of the transformer is 5 000/5 amperes, the ratio compensation obtained by the omission of one secondary turn being almost exact.

(*b*) *Calibration.*—It has been mentioned that these transformers have been developed in order to provide means of measuring currents for which resistance standards are not available; it is therefore at once obvious that the usual method of direct calibration against water-cooled manganin standards is not applicable. Experience suggested that the characteristics of the transformer were likely to be practically independent of the number of turns in the primary winding, more especially in view of the uniform distribution of the secondary winding: evidently if this proved to be the case the calibration could be made with a number of primary turns such that full ampere-turns were obtained with a relatively light current. This would allow the use of the very satisfactory 200-ampere resistance standard already described.

To determine whether the characteristics of the transformer are actually independent of the number of primary turns, measurements were first made using the 200-ampere air-cooled resistors and the 1 000- and 2 000-ampere water-cooled manganin tubes as standards. Since it was desired to push the investigation to the limit of accuracy which the transformers would allow, somewhat elaborate precautions were taken to ensure that the phase angles of the standards could be determined accurately. Long copper extensions were attached to the current terminals of the tube resistors, so as to ensure that the stray field due to the current circuit should be constant, whilst special attention was given to the disposition of the apparatus and leads. The phase angles of all the standards used were measured by a bridge method immediately after the tests.

Observations were made with 1, 2, 5, 10 and 25 primary turns. In the cases of 1- and 2-turn primaries the calibration could not, of course, be carried up to the full ampere-turns of the transformer, since the largest resistance standard carries only 2 000 amperes. The measurements showed that under any given set of conditions the characteristics of the transformer were the same for 25, 10 and 5 primary turns, within 0·01 per cent for ratio and 0·1 minute for phase angle, i.e. within the limit of accuracy of the difference measurements. The values for two turns and one turn showed a similar agreement for ratio, but differences of 0·2 minute in phase angle occurred.

These latter values were, of course, obtained with the large tube resistors, and it was not known whether they were due to genuine "turn effects" or to uncertainties in the measurements of the phase angles of the resistors. The figures for 25, 10 and 5 turns were obtained with the air-cooled standards, and are believed to be quite reliable. It was therefore decided to investigate the matter further by direct comparison of two similar transformers having different numbers of primary turns.

Two sets of tests were made. In the first set one transformer, referred to as A, had twice as many primary turns as the other transformer, referred to as B. In the second set A had 4 times as many turns as B. The results obtained are shown in Table 1, the ratio differences being given to 0·01 per cent, and the phase-angle differences to 0·05 minute.

TABLE 1.

Primary turns		Fraction of full ampere-turns		Ratio difference	Phase-angle difference
A	B	A	B	B–A	B–A
				per cent	minute
26	13	1/1	1/2	$0\cdot0_0$	$+0\cdot3_5$
8	4				$+0\cdot3_5$
4	2				$+0\cdot3_5$
2	1				$+0\cdot2_5$
26	13	2/5	1/5	$0\cdot0_0$	$+0\cdot3_5$
8	4				$+0\cdot3_0$
4	2				$+0\cdot3_5$
2	1				$+0\cdot4_0$
26	13	1/5	1/10	$0\cdot0_0$	$+0\cdot3_0$
8	4				$+0\cdot2_0$
4	2				$+0\cdot3_5$
2	1				$+0\cdot4_0$
24	6	4/5	1/5	$0\cdot0_0$	$+0\cdot5_0$
12	3				$+0\cdot3_5$
8	2				$+0\cdot4_5$
4	1				$+0\cdot5_0$
24	6	2/5	1/10	$0\cdot0_0$	$+0\cdot4_0$
12	3				$+0\cdot2_5$
8	2				$+0\cdot3_5$
4	1				$+0\cdot3_5$

It will be seen from these results that the ratio difference between the transformers is the same for any given ratio of primary turns, whatever may be the actual numbers of turns. It is already known from the comparison with resistance standards that there is no significant "turn effect" when the number of primary turns is 5 or more. The present results therefore show that no such effect occurs over the whole range of numbers of turns employed, and confirm the values obtained with the tube resistors.

For phase angle, differences up to 0·2 minute occur for a given turn-ratio. These differences are, however, not systematic, and are therefore not genuine turn effects. They are of exactly the same order as those found in the comparisons with resistance standards.

The explanation of the discrepancies was found to lie in small differences of phase angle which were produced by varying the distribution of the primary winding on the core. When only one or two primary turns are employed, there is a tendency for the primary magnetomotive force to be concentrated over a small region of the core, and under these conditions leakage of flux and slight lack of uniformity in the secondary winding produce small variations in phase angle. When the number of primary turns is large, the distribution is naturally more symmetrical and the trouble does not arise. A set of tests was made in which the distribution of a small number of primary turns was deliberately varied over a considerable range. The maximum resultant variation of phase angle was 0·2 minute.

TABLE 2.

Frequency	Burden	Fraction of full ampere-turns	True ratio* / Nominal ratio	Phase angle †
cycles/sec.	VA			minutes
50	5	1/1	$1\cdot000_0$	$+0\cdot{}_6$
		3/4		$+0\cdot{}_6$
		1/2		$+0\cdot{}_7$
		1/5		$+0\cdot{}_8$
		1/10		$+0\cdot{}_8$

		3/4		$+0\cdot{}_7$
		1/2		$+0\cdot{}_8$
		1/5		$+0\cdot{}_9$
		1/10		$+0\cdot{}_9$
50	25	1/1	$1\cdot000_0$	$+0\cdot{}_8$
		3/4		$+0\cdot{}_9$
		1/2		$+1\cdot{}_0$
		1/5		$+1\cdot{}_1$
		1/10		$+1\cdot{}_2$
25	12·5	1/1	$1\cdot000_0$	$+1\cdot{}_1$
		3/4		$+1\cdot{}_2$
		1/2		$+1\cdot{}_4$
		1/5		$+1\cdot{}_6$
		1/10		$+1\cdot{}_7$
100	12·5	1/1	$1\cdot000_0$	$+0\cdot{}_4$
		3/4		$+0\cdot{}_4$
		1/2		$+0\cdot{}_4$
		1/5		$+0\cdot{}_5$
		1/10		$+0\cdot{}_5$

It appears from the results discussed that the limits of accuracy which can be obtained with these transformers at maximum ratio without using very special precautions are 0·01 per cent for ratio and 0·2 minute for phase angle. Within these limits the characteristics are independent of the number of primary turns. When the number of primary turns is 5 or more, and these are reasonably well distributed, the phase angle is reproducible to 0·1 minute.

This conclusion cleared the way for the calibration of the transformers against the 200-ampere resistance standard: this was carried out at three burdens at a frequency of 50 cycles per sec., and at one burden at 25 and 100 cycles per sec., with 25 primary turns, and the results for one transformer are given in Table 2.

For the majority of the work of the Laboratory the secondary burden is 12·5 VA, consisting of a precision resistor of 0·4 ohm, giving the voltage-drop of 2 for the electrostatic instruments, and leads of 0·1 ohm resistance. (It is necessary to use long leads in order to avoid placing the resistor in the large magnetic fields produced by the 5 000-ampere circuit.)

TABLE 3.

Frequency	Burden	Fraction of full current	True ratio / Nominal ratio	Phase angle
cycles/sec.	VA			minutes
50	12·5	1/1	$1\cdot000_0$	$-0\cdot{}_1$
		3/4		$-0\cdot{}_1$
		1/2		$0\cdot{}_0$
		1/5		$+0\cdot{}_1$
		1/10		$+0\cdot{}_1$

It is possible to improve the performance of the transformer at any given burden and frequency by connecting a small condenser, which need not be of high quality or precisely known capacitance, across the secondary terminals. Such a condenser, if of suitable value, will compensate the magnetizing current of the transformer and reduce the apparent phase angle to zero. The compensation will, of course, be perfect for one value of current only, but where the variation of phase angle with current is small the results obtained are very good. Table 3 shows the characteristics obtained by connecting a condenser of 1·4 μF capacitance across the secondary of the transformer to which Table 2 refers.

(c) *Effect of Stray Fields.*—In the use of the transformers in 3-phase circuits it is hardly possible to avoid placing them in magnetic fields of considerable intensity, due to currents in other phases. Even in single-phase work stray fields due to other parts of the circuit are present, and, at 5 000 amperes, may be very strong. It has been mentioned that the phase angles of the water-tube resistors are seriously disturbed by such fields, and the effect on the transformers is therefore of special interest.

In order to investigate the point, a transformer was placed at the centre of a coil having five turns, 1 metre in diameter. A current of 1 000 amperes, of the same frequency as the transformer primary current, was passed through the coil, giving a field of approximately 63 C.G.S. units near the centre. Various orientations of the field were investigated, and it was found that the maximum effect on the transformer characteristics was produced when the axis of the coil was parallel to the axis of the transformer core. Under this condition the disturbing field caused a change of less than 0·01 per cent in ratio, and a change of 0·6 minute in phase angle. The effect was independent of the relative time-phase of the transformer and coil currents, and therefore of the sense of the disturbing field.

---

* Ratio is defined as the quotient of primary current divided by secondary current. The values of (True ratio/Nominal ratio) are given to 0·0001 (0·01 per cent).

† The positive sign indicates that the vector of reversed secondary current is in advance of that of primary current. The values of phase angle are given to 0·1 minute.

The change of phase angle was in such a direction as to tend to make the transformer secondary current lag behind the primary current. As, under the normal conditions of use, the secondary current leads the primary current by about 0·8 minute, the effect of the field is to reduce the phase angle nearly to zero.

In order to obtain a comparison with the 2 000-ampere tube resistors, one of these was subjected to the same test, the field being reduced in the ratio of the current ratings, i.e. to 25 C.G.S. units. The change of phase angle of the tube due to the disturbing field was 3·0 minutes. The stray-field effect on the 5 000-ampere transformer is therefore only one-fifth of that on the 2 000-ampere resistor, which is a very satisfactory result.

(*d*) *Effect of Permanent Magnetization.*—A permanent magnetization of the core might be produced by the opening of the secondary circuit of the transformer while current was flowing, or by accidentally passing a direct current through the winding. A test of the magnitude of the effect was made by passing a direct current of 7 amperes through the secondary winding (the rate of change of flux in the core being controlled by a short-circuited primary winding) and gradually reducing the current to zero. The change of ratio due to the resultant magnetization was less than 0·01 per cent; the change of phase angle was 0·4 minute, the secondary current increasing its lead on the primary current. It was found possible to remove the effect completely by re-applying the direct current, and reducing it to zero while subjecting it to a series of reversals. This operation takes less than a minute.

It should be emphasized that it would be very dangerous to open the secondary circuit of one of these transformers while current was flowing through the primary winding, as an extremely high voltage would be produced. It is proposed to connect a neon-tube "lightning arrestor" across the secondary terminals, so as to limit the open-circuit voltage to about 300 volts.

(*e*) *Effect of Temperature.*—The transformer was allowed to remain for 24 hours in air at a temperature of 40° C., and was then re-tested. The value obtained for the ratio was the same, within 0·01 per cent, as that obtained at 15° C.: the phase angle also was the same within 0·1 minute.

(*f*) *Stability.*—Observations of the ratio and phase-angle errors of the transformer at one current and burden have been made at intervals over a period of 6 months. During this time no change of ratio larger than 0·01 per cent, and no change of phase angle larger than 0·1 minute, have been detected.

To investigate further the stability of the characteristics the following test was made. The transformer was provided with a primary winding of 10 turns, clamped in position, and its ratio and phase-angle errors were determined, using a bridge of very high sensitivity. The observation was repeated twice daily for two weeks: the transformer was then given a severe jarring by striking a number of heavy blows on its case with a mallet, and observations were then made daily for a further two weeks.

The total range of variation of phase angle during the test was ± 0·02 minute, which was of the same order as the sensitivity of the bridge; the shock test produced no detectable effect. The ratio remained constant within 0·01 per cent throughout the tests.

In view of the doubts which have been expressed with regard to the stability of mumetal, these results are of considerable interest; they suggest that a transformer with a mumetal core can be at least as stable as one in which silicon iron is used.

APPENDIX.

THE EFFECTIVE IMPEDANCE OF A 4-TERMINAL DISTRIBUTED RESISTANCE WHEN THE POSITION OF THE VOLTAGE POINTS IS VARIED.

The busbars are represented in Fig. 5 by AB and A′B′, and it is assumed that there is a continuously distributed impedance between the busbars. The current is led in and out at A and A′, and the voltage points are at C and C′.

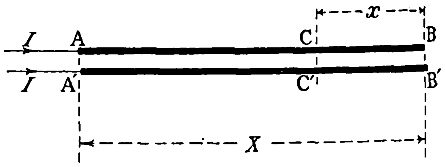

FIG. 5.

Let the length of the busbars = AB = X.

Let the length to the voltage points from the current terminals end = AC = $X - x$ or BC = x.

Let the impedance of the two busbars in series be $(r + j\omega l)$.

Let the impedance of the continuously distributed resistance between the busbars be $(R + j\omega L)$.

It will be assumed that r, ωl and ωL are small compared with R.

Let the current entering at A be I, and the voltage between C and C′ be E.

Then the effective impedance of the 4-terminal resistance = $Z = E/I$.

Impedance of busbars per unit length

$$= z = (r + j\omega l)/X$$

Admittance of continuously distributed resistance per unit length $= y = \left\{1/(R + jwL)\right\}/X$.

It is well known that the voltage (E) and current (I_x) at any point, such as C, along a pair of conductors, are given by

$$E = K_1\epsilon^{x\sqrt{(yz)}} + K_2\epsilon^{-x\sqrt{(yz)}}$$

$$I_x = \sqrt{\frac{y}{z}}\left\{K_1\epsilon^{x\sqrt{(yz)}} - K_2\epsilon^{-x\sqrt{(yz)}}\right\}$$

where K_1 and K_2 are constants.

Where $x = 0$ the current in the busbars is zero, i.e. the current at B $= 0$.

Let the voltage between busbars at B $= E_B$.

Then $E_B = (K_1 + K_2)$ and $(K_1 - K_2) = 0$.

$$\therefore K_1 = K_2 = \tfrac{1}{2}E_B$$

$$\therefore I = \tfrac{1}{2}E_B\sqrt{\frac{y}{z}}\left\{\epsilon^{X\sqrt{(yz)}} - \epsilon^{-X\sqrt{(yz)}}\right\}$$

and $$E = \tfrac{1}{2}E_B\left\{\epsilon^{x\sqrt{(yz)}} - \epsilon^{-x\sqrt{(yz)}}\right\}$$

$$\therefore Z = \frac{E}{I} = \sqrt{\frac{z}{y}}\left[\frac{\epsilon^{x\sqrt{(yz)}} + \epsilon^{-x\sqrt{(yz)}}}{\epsilon^{X\sqrt{(yz)}} - \epsilon^{-X\sqrt{(yz)}}}\right]$$

$$= \frac{1}{Xy}\left\{\frac{1 + \frac{1}{2}x^2yz}{1 + \frac{1}{6}X^2yz}\right\} \text{ approx.}$$

Let $(x/X) = a$.

Then

$$Z = \left\{R + j\omega L\right\}\left\{1 + \frac{a^2}{2R}(r + j\omega l)\right\}\left\{1 - \frac{1}{6R}(r + jwl)\right\}$$

$$= \left\{R + j\omega L\right\}\left\{1 + \frac{1}{6R}(3a^2 - 1)\,(r + j\omega l)\right\} \text{ approx.}$$

when $a = 1/\sqrt{3}$, i.e. $x = 0{\cdot}577X$

$$Z = R + j\omega L$$

Also $Z = \left\{R + \frac{1}{6}(3a^2 - 1)r\right\} + j\omega\left\{L + \frac{1}{6}(3a^2 - 1)l\right\}$

therefore Z is non-inductive when $L = \frac{1}{6}\,(1 - 3a^2)l$, i.e when $a = \sqrt{\left\{l - 6L/3l\right\}}$.

It is interesting to note the impedance when the voltage points are fixed at either end.

(i) *Voltage points at* A: $a = 1$.

$$Z = (R + \tfrac{1}{3}r) + j\omega\,(L + \tfrac{1}{3}l)$$

(ii) *Voltage points at* B: $a = 0$.

$$Z = (R - \tfrac{1}{6}r) + j\omega\,(L - \tfrac{1}{6}l)$$

From this last equation it may be seen that the resistance cannot be made non-inductive unless the inductance of the busbars is at least 6 times the inductance component of the impedance between the busbars. Since it is difficult to increase the inductance of the busbars without increasing the stray-field effect, the inductance of the resistance units should be the minimum possible.

[The discussion on this paper will be found on page 906.]

PRECISION TESTING OF CURRENT TRANSFORMERS.

By A. H. M. ARNOLD, Ph.D., Associate Member.

[From the National Physical Laboratory.]

(*Paper received 10th December, 1929; read before the* METER AND INSTRUMENT SECTION *7th February,* 1930.)

SUMMARY.

The paper describes in detail how the testing of current transformers may be carried out with speed and accuracy by means of a potential-divider bridge. The corrections to be made to the readings are deduced from the theory of the bridge; and it is shown that, by taking a few simple precautions, an accuracy of 0·01 per cent for ratio measurements, and of 0·1 minute for phase-angle measurements, is attainable if the transformer characteristics are stable to this limit.

A very sensitive and accurate bridge, which is not so convenient for general purposes as the potential-divider bridge, is then described. Results obtained with this bridge are compared with those obtained with the potential-divider bridge, and are found to be in close agreement.

LIST OF SYMBOLS.

I_1 = primary current of transformer under test.
I_2 = secondary current of transformer under test.
R_1 = resistance of primary resistor.
L_1 = inductance of primary resistor.
X_1 = reactance of primary resistor = $2\pi L_1 \times$ frequency.
R_2 = resistance of secondary resistor = $0 \cdot 1$ ohm.
L_2 = inductance of secondary resistor.
X_2 = reactance of secondary resistor.
r = resistance of potential divider = 200 ohms.
r_a = resistance of tapped portion of potential divider opposed to voltage-drop across R_2.
C = value of capacity shunt.

For circuit shown in Fig. 1:

r_c = resistance of portion of potential divider shunted by capacity $C = 136 \cdot 1$ ohms.
Z_c = combined impedance of potential divider and capacity.
Y = total admittance of primary resistor R_1 in parallel with impedance Z_c.
$\omega = 2\pi \times$ frequency.
$\theta = \omega C r_c$.
$a = (r_c/r) = 0 \cdot 6805$.

For circuit shown in Fig. 2:

r_b = resistance of portion of potential divider shunted by capacity $C = 72 \cdot 8$ ohms.
Z_b = combined impedance of potential divider and capacity.
Y_a = total admittance of primary resistor R_1 in parallel with impedance Z_b.
$\phi = \omega C r_b$.
$\beta = (r_b/r) = 0 \cdot 364$.

(1) INTRODUCTION.

In 1913–14, two papers were published in the German technical Press describing a bridge method of testing current transformers.* This method was simple to use, and had the further advantage that it could be made direct-reading. The accuracy attainable was of the order of 0·1 per cent for ratio. That attainable in the phase-angle measurement would depend to a large extent on the design of the component parts of the apparatus, and on the care taken in the set-up to avoid trouble from magnetic and electric fields. It would probably be of the order of a few minutes. For most work this accuracy is ample. The advent of high-precision current transformers with mumetal cores has, however, created a demand for testing to a higher degree of accuracy. An investigation was therefore carried out at the National Physical Laboratory in order to determine whether this method was capable of giving greater accuracy. It was found that, provided certain precautions were taken, it was possible to determine the ratio of transformers to 0·01 per cent, and their phase angles to 0·1 minute (0·00003 radian). It is, however, impossible to attain this accuracy and, in addition, to make the apparatus direct-reading. The direct-reading principle has not been entirely sacrificed, for it is possible by the use of a few small correction terms to correct the direct readings of ratio and phase angle in order to obtain the true values.

At the same time, a modification of this method was developed which has greater sensitivity and is capable of rather greater accuracy. The two methods are useful as a check on one another. The greater sensitivity of the modified method makes it very useful for studying small changes in the characteristics of transformers or for determining their stability. It is not direct-reading and is not quite as flexible as the original method. Both methods will be considered in this paper. The method, developed in Germany, which has been adopted by the National Physical Laboratory for routine test work will be referred to as the "potential-divider bridge" method. The modified method, developed at the National Physical Laboratory, which is used only for special work and as a check on the potential-divider bridge method, will be referred to as the "direct bridge" method.

---

* E. ALBERTI and V. VIEWEG: *Archiv für Elektrotechnik* 1913, vol. 2, p. 208; also H. SCHERING and E. ALBERTI, *ibid.*, p. 263.

The development of this apparatus to give the above-mentioned accuracy has shown that the characteristics of well-designed transformers are quite stable to this limit. In another paper [*] results are given which show that the characteristics of well-designed mumetal transformers are stable, at least to the limit of sensitivity of the testing apparatus. From this point of view, therefore, the increased accuracy is justifiable.

(2) The Potential-Divider Bridge.

(*a*) *Description.*—The circuit employed is shown in Figs. 1 and 2. The primary winding of the current transformer T, which is being tested, is connected, in series with the non-inductive resistor R_1 and any convenient current-measuring device, to the supply. The supply, for high-precision work, should be obtained from a separate generator, and should always be fed through an isolating transformer. The ratio of this transformer will depend on the primary current of the transformer to be tested. The primary current of the transformer under test is usually measured by means of an accurate current-transformer, M, and an ammeter, A. The secondary winding of the transformer under test is connected to a non-inductive resistor R_2. If the rated secondary current of the transformer is 5 amperes, R_2 is 0·1 ohm. In order to keep the primary current of the transformer well away from the galvanometer and from R_2, it is necessary to employ rather long leads from the secondary terminals of the transformer to the terminals of R_2. These are conveniently made exactly 0·1 ohm, and should be twisted together in order to make them non-inductive. The minimum external resistance in the secondary of the current transformer is therefore 0·2 ohm, corresponding to a burden of 5 volt-amperes at rated current. If it is desired to test the transformer on higher burdens than this, additional loading resistance may be inserted in the secondary circuit.

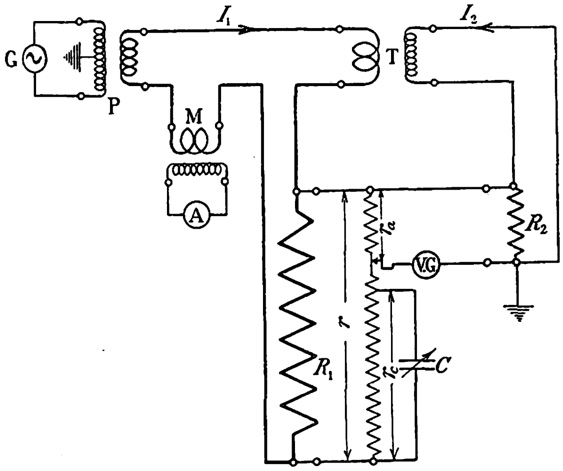

Fig. 1.—Diagram of connections of potential-divider bridge for testing a current transformer, the secondary current of which leads the primary current.

G = Generator.
P = Power and isolating transformer.
M and A = Current transformer and ammeter for measuring primary current of transformer under test.
T = Transformer under test.
V.G. = Vibration galvanometer.

A resistance of 200 ohms is connected in parallel with the resistor R_1. This resistance constitutes the potential divider of the apparatus. A suitable voltage is tapped off from this potential divider and opposed to the voltage-drop across R_2 through a vibration galvanometer.[*]

When the transformer under test is carrying its rated current, its secondary current will be 5 amperes and the voltage-drop across R_2 will be 0·5 volt. R_1 is of such a value that the voltage-drop across it, when carrying the rated current of the transformer under test, is 2 volts. If, therefore, the ratio of the transformer is correct, one-quarter of the voltage across the potential divider will have to be tapped off in order to balance the voltage-drop in R_2. The potential divider consists of two wound sections of 48 ohms and 148 ohms respectively, with a slide-wire of 4 ohms connected between them. A moving contact connected to the galvanometer moves over this slide-wire. Thus any ratio error up to ± 4 per cent may be measured on this bridge.[†] The slide-wire is calibrated to read ratio error directly. To balance the quadrature component of e.m.f., a variable condenser is connected across part of the potential divider. The capacity required to balance the quadrature e.m.f. is proportional to the phase angle of the transformer. In most transformers the reversed secondary current leads the primary

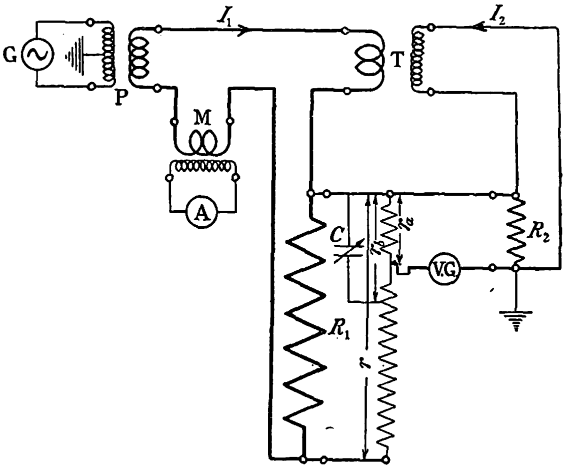

Fig. 2.—Diagram of connections of potential-divider bridge for testing a current transformer, the primary current of which leads the secondary current.

[*] R. S. J. Spilsbury and A. H. M. Arnold: "Some Accessory Apparatus for Precise Measurements of Alternating Current," *Journal I.E.E.* 1930, vol. 68, p. 889.

[*] In the actual apparatus used, a second potential divider is connected across R_2, so that only a fraction of the voltage-drop across R_2 may be used if required. This is simply for the sake of flexibility, as rather fewer values of R_1 are then required for testing transformers of different ratios. The theory is not affected by this second divider, and it has therefore been omitted from Figs. 1 and 2.

[†] If the ratio error exceeds ± 4 per cent, balance can only be obtained by altering the resistance of R_1 or R_2.

current, and for this case the condenser is connected as shown in Fig. 1. The resistance, r_c, across which it is connected is 136·1 ohms, so that, at a frequency of 50 cycles per sec., 0·01 μF corresponds to a phase angle of 1 minute, and the phase angle may be read directly from the value of the condenser shunt. If the reversed secondary current lags on the primary current, the condenser must be connected as shown in Fig. 2, and this is effected by means of a change-over switch. In this case it is connected across 72·8 ohms (r_b), and 0·02 μF corresponds to a phase angle of 1 minute at 50 cycles per sec., so that the phase angle may be deduced from the condenser reading almost as easily as in the normal case.

The double balance is very quickly attained in practice, but, in setting up the apparatus, care should be taken that the voltage-drop across R_2 is opposed to the voltage-drop across the tapped portion (r_a) of the divider, and is not in series with it.

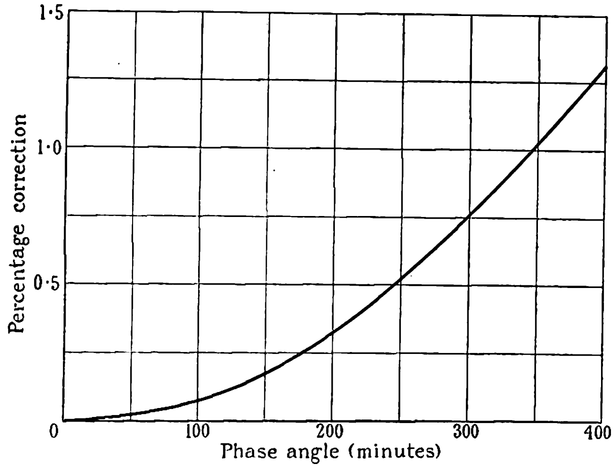

FIG. 3.—Percentage correction to be subtracted from apparent value of $\frac{\text{True Ratio}}{\text{Nominal Ratio}}$ to allow for the shunting effect of the capacity across r_c.

Percentage correction $= -44\cdot 9\theta^2$.

The accuracy of the ratio reading will depend on the accuracy of the adjustment of R_1 and R_2, and on the calibration of the potential-divider scale. The ratio reading will also be affected by the capacity shunt. For phase angles not exceeding 100 minutes, the shunting effect of the capacity will alter the ratio reading by less than 0·1 per cent. The shunting effect is proportional to the square of the phase angle, and for large phase angles the shunting effect becomes serious. Transformers with phase angles exceeding 100 minutes do not usually need to be tested to a very high degree of accuracy. At the same time, the shunting effect of the condenser increases so rapidly, as the phase angle increases above 100 minutes, that it is undesirable to neglect this effect. A curve showing the effect of the capacity shunt is given in Fig. 3.

The accuracy of the phase-angle reading depends first on the accuracy of r_c and of the condenser. Neither of these require to be known to a very high degree of accuracy, since the errors that they introduce are proportional to the phase angle measured. Thus, an error of 0·1 per cent in the value of the condenser would introduce an error of 0·1 per cent in the phase-angle measurement, i.e. 0·1 minute for a phase angle of 100 minutes. For phase angles of less than 100 minutes, the error would be proportionally less than 0·1 minute.

More serious errors may be introduced by the residual phase angles of R_1 and R_2, and by capacity and magnetic effects from other parts of the circuit.

The development of this apparatus for high-precision testing consists, therefore, of three parts:—(i) a theoretical consideration of the effect of the residuals and of the capacity shunt; (ii) the measurement of the residuals, and also the measurement of the resistances used in the circuit; and (iii) the elimination of stray magnetic and capacity effects from the circuit.

Two types of transformers are affected by the theoretical consideration. Firstly, it is desirable to test very good transformers, having small phase angles, to the highest possible degree of accuracy: the effect of the residuals must be considered, but the effect of the capacity shunt will be negligible. Secondly, it will not be necessary to test transformers with large phase angles to a high degree of accuracy: so that the residuals may be neglected, but the effect of the capacity shunt cannot be neglected. A single theoretical consideration is given in which both the effects of residuals and of the capacity shunt are considered, and a series of correction factors are deduced. In utilizing these correction factors, only those terms which are of importance in the case of the particular transformer tested need be considered.

(*b*) *The Effect of the Residuals and the Effect of the Capacity Shunt.*—In order to deduce simple correction-factors, it is necessary to neglect certain small terms. To determine phase angles to 0·1 minute, no term should be neglected which may introduce an error exceeding 3 parts in 100 000. Limiting values must, therefore, be assigned to the residuals and to the capacity shunt. The following terms will be neglected in comparison with unity:—

(i) All powers of X_1/R_1, X_2/R_2 and R_1/r, above the first power, and any products of two or more of these terms.
(ii) All powers of X_1/R_1, X_2/R_2, and R_1/r, multiplied by any power of θ or ϕ above the first power.
(iii) All powers of θ or ϕ above the third power.

The residual inductance of the potential divider will be completely neglected, as it can easily be made very small (under 0·1 minute).

The magnitude of R_1/r depends on the rated primary current of the transformer tested. It has a maximum value of 0·002 for a 5/5 transformer ($R_1 = 0\cdot 4$ ohm). It is convenient to fix the same upper limit for X_1/R_1 and X_2/R_2. This maximum value corresponds to a phase angle of about 7 minutes. This value should not be exceeded in well-designed resistors, even for very large currents. The value of θ (or ϕ) is proportional to the phase angle of the transformer under test, and has no definite limit. The highest precision will not be required in testing transformers with large phase angles, and it is possible, therefore, to fix a series of limits for θ with reduced accuracy as θ increases. The value of ϕ, which corresponds to a lagging secondary current, is never likely to be very large. For an accuracy of 3 parts in 100 000 (0·1 minute), θ should not exceed 0·07, corresponding to a transformer phase angle of 164 minutes. For an accuracy of 1 in 10 000 (0·3 minute), θ should not exceed 0·1, corresponding to a phase angle of 4 degrees. For an accuracy of 1 in 2 000 (2 minutes), θ should not exceed 0·15, corresponding to a phase angle of 6 degrees.

It is obvious that correction factors deduced on this basis will be amply accurate for all transformer tests. These correction factors will now be deduced.

Case (1)—I_2 *leading* I_1. *Circuit as shown in Fig.* 1.—

$$Z_c = r - r_c + \frac{r_c}{1+\theta^2} - j\frac{\theta r_c}{1+\theta^2}$$

$$= r\left\{1 - \alpha\theta^2 - j\alpha\theta(1-\theta^2)\right\}$$

$$Y = \frac{1}{R_1 + jX_1} + \frac{1}{r\left\{1 - \alpha\theta^2 - j\alpha\theta(1-\theta^2)\right\}}$$

$$= \frac{1}{R_1}\left\{1 + \frac{R_1}{r}\right\}\left\{1 + j\left(\alpha\theta\frac{R_1}{r} - \frac{X_1}{R_1}\right)\right\}$$

When the bridge is balanced (i.e. zero current in galvanometer)

$$I_1/I_2 = \left\{(R_2 + jX_2)Z_cY\right\}/r_a$$

$$= \frac{R_2 r}{R_1 r_a}\left\{1 + \frac{R_1}{r}\right\}\left\{1 - \alpha\theta^2 + \alpha\theta\left(\frac{X_2}{R_2} - \frac{X_1}{R_1}\right) + j\left(\frac{X_2}{R_2} - \frac{X_1}{R_1} + \alpha\theta\frac{R_1}{r} - \alpha\theta + \alpha\theta^3\right)\right\}$$

True ratio = Numerical value of (I_1/I_2)

$$= \frac{R_2 r}{R_1 r_a}\left\{1 + \frac{R_1}{r}\right\}\left[\left\{1 - \alpha\theta^2 + \alpha\theta\left(\frac{X_2}{R_2} - \frac{X_1}{R_1}\right)\right\}^2 + \left\{\frac{X_2}{R_2} - \frac{X_1}{R_1} - \alpha\theta\left(1 - \frac{R_1}{r} - \theta^2\right)\right\}^2\right]^{\frac{1}{2}}$$

$$= \frac{R_2 r}{R_1 r_a}\left\{1 + \frac{R_1}{r}\right\}\left\{1 - \tfrac{1}{2}\alpha\theta^2(2 - a)\right\}$$

$$= \frac{R_2 r}{R_1 r_a}\left\{1 + \frac{R_1}{r}\right\}\left\{1 - 0{\cdot}449\theta^2\right\} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

Tangent of phase angle

$$= \frac{\alpha\theta\left\{1 - (R_1/r) - \theta^2\right\} + (X_1/R_1) - (X_2/R_2)}{1 - \alpha\theta^2 + \alpha\theta\left\{(X_2/R_2) - (X_1/R_1)\right\}}$$

$$= \alpha\theta + \frac{X_1}{R_1} - \frac{X_2}{R_2} - \alpha\theta\frac{R_1}{r} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

The simple formulæ, on which the direct-reading scales are based, are:—

True ratio $= (R_2 r)/(R_1 r_a)$
Phase angle $= \alpha\theta$

There are two correction factors for the ratio measurement. The first, $\left\{1 + (R_1/r)\right\}$, is to allow for the shunting effect of the potential divider on the resistance R_1. This shunting effect is conveniently combined with any correction due to the fact that the true value of R_1 is not equal to its nominal value. The maximum value of this shunting effect is 0·2 per cent when $R_1 = 0{\cdot}4$ ohm, the value used when testing a 5/5 transformer. The second correction factor, $(1 - 0{\cdot}449\theta^2)$, is to allow for the shunting effect of the capacity. Fig. 3 shows the percentage correction to (True ratio/Nominal ratio) plotted against transformer phase-angle. The residuals do not appreciably affect the ratio reading.

The phase angle is equal to the tangent of the phase angle within the limits of accuracy required for this work, so that there are three simple corrections to be made to the phase-angle reading. The first two are of opposite sign and allow for the residuals of R_1 and R_2. The third term, which is negligible in practically all cases, allows for the fact that the capacity C alters the phase angle of the whole primary impedance $(1/Y)$ by a small amount.

Case (2)—I_1 *leading* I_2. *Circuit as shown in Fig.* 2.—

$$Z_b = r\left\{1 - \beta\phi^2 - j\beta\phi(1 - \phi^2)\right\}$$

$$Y_a = \frac{1}{R_1}\left\{1 + \frac{R_1}{r}\right\}\left\{1 + j\left(\beta\phi\frac{R_1}{r} - \frac{X_1}{R_1}\right)\right\}$$

For balance,

$$\frac{I_1}{I_2} = \frac{(R_2 + jX_2)Z_bY_a}{r_a}\left\{1 + j\phi\right\}$$

$$= \frac{R_2 r}{R_1 r_a}\left\{1 + \frac{R_1}{r}\right\}\left\{1 + \phi(1-\beta)\left(\frac{X_1}{R_1} - \frac{X_2}{R_2}\right) + j\left(\frac{X_2}{R_2} - \frac{X_1}{R_1} + \phi - \beta\phi + \beta\phi\frac{R_1}{r}\right)\right\}$$

True ratio—

$$= \frac{R_2 r}{R_1 r_a}\left\{1 + \frac{R_1}{r}\right\}\left\{1 + \tfrac{1}{2}\phi^2(1-\beta)^2\right\}$$

$$= \frac{R_2 r}{R_1 r_a}\left\{1 + \frac{R_1}{r}\right\}\left\{1 + 0{\cdot}202\phi^2\right\} \quad . \quad . \quad . \quad (3)$$

Tangent of phase angle

$$= -\phi(1-\beta) + \frac{X_1}{R_1} - \frac{X_2}{R_2} - \beta\phi\frac{R_1}{r} \quad . \quad . \quad (4)$$

Equations (1) to (4) thus show that very simple correction terms will enable the ratio and phase-angle readings to be corrected to their true values with a very high degree of accuracy, provided that there are no observational errors and that the constants of the circuit are known to an equal degree of accuracy. This aspect of the problem will be considered in the next section.

(*c*) *The Determination of the Constants of the Circuit.*—The accuracy of each observation will depend, in the first place, on the accuracy to which the primary current and the burden are known. The transformer characteristics will vary more rapidly with current and burden in a bad transformer than in a good one, and these variables will therefore have to be determined with more care in the former case. There is little difficulty in determining the burden sufficiently accurately for this work, but in the measurement of the primary current it is necessary, in order to get reasonable deflections on an a.c. ammeter over considerable current ranges, to employ transformers of different ratios. Transformers are usually tested at $\frac{1}{10}$, $\frac{1}{5}$, $\frac{1}{2}$, $\frac{3}{4}$ and full rated current. The last three values are set by means of a 5-ampere substandard ammeter (12-in. scale), in conjunction with a current transformer of ratio equal to that of the transformer under test. The first two currents are set by the same ammeter in conjunction with a current transformer of ratio equal to one-quarter of the ratio of the transformer under test. The frequency of the generator is adjusted to within 0·1 per cent of the required frequency.

Each observation involves five resistances and one capacity. For reasons already given the values of r_c and C need not be known to the highest degree of accuracy, so that there remain four resistances, R_1, R_2, r and r_a, which must be known to a sufficient degree of accuracy to give the required accuracy to the reading, and their residuals must also be determined. r_a is a variable resistance with a variation between 48 ohms and 52 ohms. A scale attached to the slide-wire indicates the value of r_a, and also the ratio error, for any position of the sliding contact.

For $r_a = 50$ ohms, the ratio error = 0, and as far as the divider is concerned this is correct, provided that, at this point, $r_a = \frac{1}{4}r$.

The scale calibration can be made sufficiently correct to show changes in r_a of 1 part in 10 000, but in general, when the sliding contact is at $r_a = 50$, r_a will not be exactly $\frac{1}{4}r$, so that there is a zero error in the scale calibration. The resistance of r includes the resistance of the leads from the terminals of coils constituting the main part of r to the voltage terminals of the resistor R_1. The zero error of the scale has therefore to be determined by measuring r, including appropriate leads, and by measuring r_a, with the contact set at $r_a = 50$. Owing to the contact resistance of the sliding contact, three measurements are necessary: r, (r_a + contact resistance), and ($r - r_a$ + contact resistance). From these three measurements the ratio of (r_a/r), and therefore the zero error of the scale, can be determined. R_2 is a 4-terminal resistance and can be measured by a Kelvin double-bridge with an accuracy of approximately 1 in 100 000. The difference between the nominal and actual value of R_2 may be combined with the zero error of the divider scale to form the "overall" error of the bridge. The difference between the nominal and actual values of R_1 is not included in this overall error, because R_1 is different for different transformers and its error must therefore be considered separately. For primary currents up to 200 amperes, R_1 is a 4-terminal resistor designed to give a 2-volt drop with rated current. Its resistance may be determined by the Kelvin double-bridge, and its change of resistance with any current up to its rated current is less than 1 part in 10 000. Above 200 amperes, R_1 consists of a current transformer, with a 4-terminal resistance of 0·4 ohm connected to its secondary terminals. The nominal ratio of this current transformer is equal to the nominal ratio of the transformer under test, so that, at rated current, a current of 5 amperes passes through the 0·4-ohm resistance and gives a 2-volt drop between the voltage terminals. The potential divider is connected across the voltage terminals (Fig. 4). To determine the difference between the nominal and actual values of this "primary resistor," it is necessary to measure the resistance of the 0·4-ohm resistor on the Kelvin double-bridge, and to determine the ratio of the current transformer accurately. The characteristics of the transformer should be determined on a burden of 12·5 volt-amperes, consisting of a 0·4-ohm resistor and secondary leads of resistance 0·1 ohm. Current transformers are now available the ratios of which are constant to within 1 part in 10 000 for any current between rated current and 1/20th of rated current.*

The difference between the nominal and actual values of R_1 is combined with the shunt effect of the potential divider to give the overall error of the primary resistor.

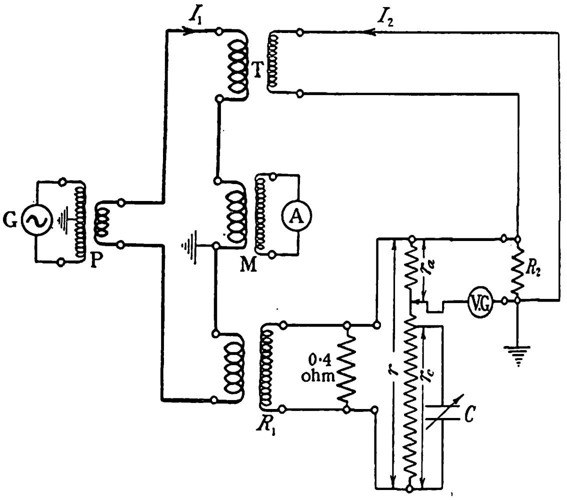

FIG. 4.—Diagram of connections of potential-divider bridge.

Standard current-transformer, with 0·4 ohm non-inductive resistance connected in secondary circuit, used as primary resistor (R_1) to provide the voltage for the potential divider.

It may be observed that, when the primary resistor consists of a current transformer in conjunction with a 0·4-ohm resistance, the shunting effect of the potential divider is 0·2 per cent for a current transformer of any ratio. The residual phase angles of R_2 and R_1 may be determined to within 1/20th of a minute by Hartshorn's double-bridge method.† If R_1 is a 0·4-ohm resistance combined with a current transformer, the phase angle of the current transformer must be added to (or subtracted from) the residual phase angle of the 0·4-ohm resistance. It is not at present possible to build current transformers the phase angles of which are constant to within 0·1 minute for all currents down to, say, 1/20th of rated current. For work of the highest precision it is therefore necessary to use a different correction term for different currents.

The primary resistor is, essentially, the standard against which the transformer is tested, and, except in the case of a 5/5 transformer, the characteristics of the transformer under test cannot be determined to a greater accuracy than the accuracy to which the constants of the primary resistor are known. On the other hand, the divider and the resistor R_2 are the bridge arms, and it is possible, by a method to be described, to determine the overall error of the bridge without knowing the errors of its component parts. This method is a most valuable check on the direct method of calibrating each component part.

---

* R. S. J. SPILSBURY and A. H. M. ARNOLD, *loc. cit.*

† L. HARTSHORN: "Measurement of the Inductances of Four-Terminal Resistance Standards," *Proceedings of the Physical Society of London*, 1927, vol. 39, p. 377.

The test is carried out by means of two similar current transformers of any convenient ratio.* The transformers will be referred to as A and B. The characteristics of transformer A are determined, assuming the overall error of the bridge to be zero. The primary resistor used in this case is a simple resistance. The characteristics of transformer B are then determined similarly, first against the same primary resistor, and then against a primary resistor consisting of transformer A in conjunction with a 0·4-ohm resistance. If the overall error of the bridge is not zero the two calibrations of transformer B will not agree, and the difference between these two calibrations will be exactly equal to the overall error of the bridge. An example of this test is given in the Appendix, and it may be seen that the agreement between this method of determining the overall error of the bridge and the direct calibration method is within 1 part in 10 000 for ratio and within 1/20th of a minute for phase angle.

(*d*) *Stray-field Effects and Earthing.*—The reliability of measurements made may be considerably reduced unless care is taken to avoid trouble from stray fields. Electromagnetic fields are produced mainly by the primary-current circuit and will affect the phase-angle reading only. Capacity effects, which may be caused by capacity currents from the high-tension side of the power transformer, may affect the ratio or the phase-angle reading or both. Earth-current effects also may affect either or both readings.

If a moving-iron vibration galvanometer is used, it is very difficult to shield it effectively from magnetic fields, and it is recommended, therefore, that a moving-coil galvanometer should always be used for this work. With properly twinned galvanometer leads, no trouble need be experienced as a result of e.m.f.'s induced in the galvanometer circuit.

Magnetic fields may, however, induce e.m.f.'s in any of the resistances R_1, R_2 or r, and these e.m.f.'s will result in a change of the effective phase angle of the resistance involved. The elimination of trouble from this source is achieved by designing the resistor R_1 to be as nearly astatic as possible, by placing the bridge and galvanometer at least 1 yard, and preferably 2 yards, away from the primary circuit, and by avoiding large loops in the primary circuit. A suitable lay-out for a test is shown in Fig. 5.

Unfortunately, a large number of current transformers are of the " inserted " primary type, and it is customary in testing these to keep the return lead a considerable distance, say 1 yard, away from the transformer. This creates a large inductive loop which may introduce error into the measurements if the primary current is large. In this case it is necessary to make two observations at each point. The leads to the resistors R_1 and R_2 are reversed between the two observations. The mean of the two observations will be free from error due to electromagnetic or capacity effects. It is important to note that if the primary resistor consists of a current transformer in conjunction with a resistance, the mean of these two observations will not eliminate any change of phase angle in the current transformer. The phase angles of transformers are altered by magnetic fields, but the change of phase angle is not reversed when the magnetic field is reversed. A well-designed mumetal transformer will be very little affected by magnetic fields, but in cases where the primary current is very large, say over 1 000 amperes, the standard current-transformer should be placed at least 2 yards away from the transformer under test.

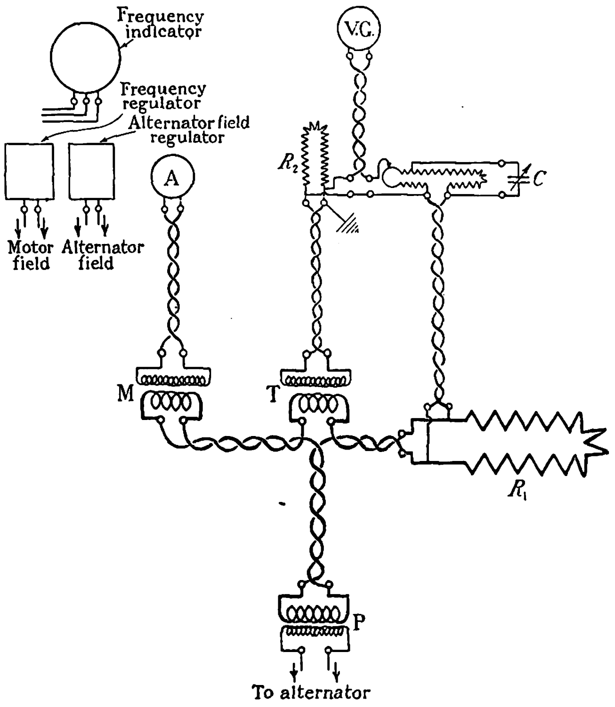

FIG. 5.—Diagram showing convenient lay-out for the potential-divider bridge circuit to minimize stray capacity and electromagnetic effects.

Capacity effects are best avoided by placing the power transformer as far as possible from the bridge. If possible, the mid-point of its primary winding should be earthed. It is essential to earth the bridge circuit and it is, therefore, very important that the insulation resistance between the primary and secondary windings of the power transformer should be high.

It has been found experimentally that one terminal of R_1 or R_2 should be earthed. Provided that the galvanometer is connected to the sliding contact of the divider, and not to the end of the divider, it is immaterial which of the four possible terminals is earthed. The terminal of R_2 to which the galvanometer is connected has been selected, so that the galvanometer is always at earth potential. If the primary resistor includes a current transformer, the primary circuit should be separately earthed (see Fig. 4).

---

* Transformers with 5/5 ratio are most convenient, but the test can be carried out satisfactorily with other ratios.

(3) The "Direct Bridge."

The circuit is shown in Fig. 6. In this method the potential divider is eliminated, and the whole of the voltage-drop across R_1 is opposed to the voltage-drop across R_2. The adjustment for ratio error is obtained by shunting a high resistance, r, across R_1 or R_2, and the phase-angle adjustment is obtained by shunting a condenser across R_1 or R_2. Owing to the high capacitance required, it is impracticable to test transformers with large phase angles by this method. The capacity C and the high resistance r need not be known to a high degree of precision, so that only two resistances, R_1 and R_2, have to be measured. R_1 and R_2 are chosen of such values that the voltage-drops in them are approximately equal. If the voltage-drop across R_1 and R_2 is 2 volts at rated current, it is possible to detect changes of phase angle of 0·01 minute at one-fifth of rated current, using a moving-coil galvanometer of 8 ohms resistance.

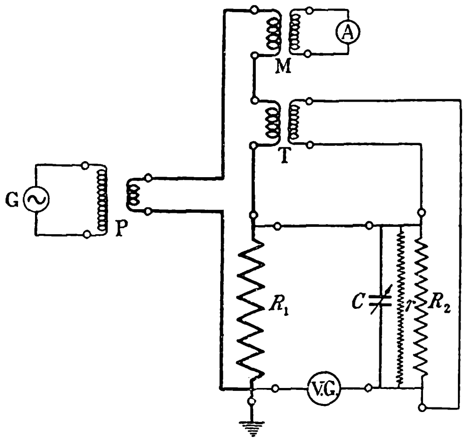

Fig. 6.—Diagram of connections of direct bridge for testing a current transformer, the secondary current of which leads the primary current.

The equations for balance are given below, for a case where both the resistance and capacity shunts are connected across R_2.

$$I_1(R_1 + jX_1) = I_2R_2\left\{1 - \frac{R_2}{r} - j\left(\omega CR_2 - \frac{X_2}{R_2}\right)\right\}$$

$$\therefore \quad \frac{I_1}{I_2} = \frac{R_2}{R_1}\left\{1 - \frac{R_2}{r} - j\left(\omega CR_2 + \frac{X_1}{R_1} - \frac{X_2}{R_2}\right)\right\}$$

$$\text{True ratio} \qquad = \frac{R_2}{R_1}\left\{1 - \frac{R_2}{r}\right\}$$

$$\text{Phase angle} \qquad = \omega CR_2 + \frac{X_1}{R_1} - \frac{X_2}{R_2} \text{ radians.}$$

APPENDIX.

Determination of the Overall Error of the Bridge in the Potential-Divider Bridge Method.

The test was carried out with a primary current of 100 amperes, using two transformers, A and B, with ratios of 200/5. Transformer A was tested on a burden of 12·5 volt-amperes, as this was the burden required when using it as the primary resistor. Transformer B was tested on a burden of 5 volt-amperes.

Test of transformer A.—Primary resistor R_1 = resistor of 0·01-ohm nominal resistance.

Corrections to ratio reading:—

Resistor, 8 in 100 000 (high).
Shunting effect of potential divider = 5 in 100 000.
Total ratio-correction = − 3 in 100 000.

The phase angle of the resistor R_1 was approximately nil, hence there was no phase-angle correction.

Ratio-error reading = $+ 0{\cdot}03_7$ per cent.
Condenser shunt = $+ 0{\cdot}013_8$ μF.

∴ Apparent ratio-error = $+ 0{\cdot}03_4$ per cent.*
Apparent phase angle = $+ 1{\cdot}3_8$ minutes.†

First test of transformer B.—Primary resistor the same as for test on transformer A.

Ratio-error reading = $+ 0{\cdot}04_1$ per cent.
Condenser shunt = $+ 0{\cdot}001_7$ μF.

∴ Apparent ratio-error = $+ 0{\cdot}03_8$ per cent.
Apparent phase angle = $+ 0{\cdot}1_7$ minute.

Second test of transformer B.—Primary resistor = resistor of 0·4-ohm nominal resistance connected in secondary circuit of transformer A. Primary of transformer A in series with primary of transformer B.

Corrections to ratio reading:—

0·4-ohm resistance = 26 in 100 000 (high).
Shunting effect of potential divider = 200 in 100 000.
Ratio error of transformer A = + 34 in 100 000.
Total ratio-correction = + 208 in 100 000.

Corrections to phase-angle reading:—

Phase angle of 0·4-ohm resistance = $+ 0{\cdot}1_2$ minute.
Phase angle of transformer A = $+ 1{\cdot}3_8$ minutes.
Total phase-angle correction = $+ 1{\cdot}5_0$ minutes.
Ratio-error reading = $- 0{\cdot}15_5$ per cent.
Condenser shunt = $- 0{\cdot}024_2$ μF.

∴ Apparent ratio-error = $+ 0{\cdot}05_3$ per cent.
Apparent phase angle $= (-1{\cdot}2_1 + 1{\cdot}5_0) = +0{\cdot}2_9$ minute.

Comparing the results of the two tests on transformer B, the overall errors of the bridge are:—

Overall ratio-error $= (+ 0{\cdot}05_3 - 0{\cdot}03_8) = + 0{\cdot}01_5$ per cent.
Overall phase-angle error $= (+ 0{\cdot}2_9 - 0{\cdot}1_7) = +0{\cdot}1_2$ minute.

---

* Plus sign indicates that the primary current is high.
† Plus sign indicates that the reversed secondary current leads the primary current.

The corrections to be applied to readings are of opposite sign to the errors; thus the corrections to be made are as follows:—

Ratio correction for bridge error = $- 0{\cdot}01_5$ per cent.
Phase-angle correction for bridge error = $- 0{\cdot}01_2$ minute.

If these corrections are now applied to readings taken in these tests, the following results are obtained:—

Ratio error of transformer A = $+ 0{\cdot}01_9$ per cent.
Phase angle of transformer A = $+ 1{\cdot}2_6$ minutes.
Ratio error of transformer B = $+ 0{\cdot}02_3$ per cent.
Phase angle of transformer B = $+ 0{\cdot}0_5$ minute.
} by both tests.

Direct calibration.—

Total resistance of r, including leads, = $200{\cdot}16_4$ ohms.
Resistance of r_a, with contact set at "r_a = 50 ohms," = $50{\cdot}01_7$ ohms.
Zero error of scale = $200{\cdot}16_4 - (4 \times 50{\cdot}01_7)$ parts in 200 = + 48 parts in 100 000.
Secondary resistor, R_2, nominal resistance 0·1 ohm, = 67 parts in 100 000 (low).
∴ Ratio correction for bridge error = (+ 48 − 67) parts in 100 000 = $- 0{\cdot}01_9$ per cent.
Phase angle of secondary resistor R_2 = $+ 0{\cdot}1_5$ minute.
∴ Phase-angle correction for bridge error = $- 0{\cdot}1_5$ minute.

It may be seen that the corrections deduced by the two methods are in very close agreement. A final check was obtained by calibrating transformer A by the direct bridge method.

Primary resistor = 0·01-ohm resistance, 8 parts in 100 000 (high). Phase angle, nil.
Secondary resistor = 0·4-ohm resistance, 26 parts in 100 000 (high). Phase angle, $0{\cdot}1_2$ minute.

For bridge balance,

Shunt resistance across primary resistor = 221 ohms.
Shunting effect = $0{\cdot}00_5$ per cent.
Shunt condenser across secondary resistor = 3·22 μF.
Phase-angle effect of capacity = $(3{\cdot}22 \times 0{\cdot}4 \times 1{\cdot}08) = 1{\cdot}3_9$ minutes.
∴ Ratio error of transformer A = $(+ 0{\cdot}00_5 - 0{\cdot}00_8 + 0{\cdot}02_6) = + 0{\cdot}02_3$ per cent.
Phase angle of transformer A = $(+ 1{\cdot}3_9 - 0{\cdot}1_2) = + 1{\cdot}2_7$ minutes.

These results, also, are in very close agreement with the calibration of transformer A by the potential-divider bridge. For comparison, the results are tabulated below.

Calibration of transformer A *at half rated-current on a burden of* 12·5 *volt-amperes at a frequency of* 50 *cycles per second.*

Ratio error			Phase angle		
Direct bridge method	Potential-divider bridge method		Direct bridge method	Potential-divider bridge method	
	(1)	(2)		(1)	(2)
per cent $+ 0{\cdot}02_3$	per cent $+0{\cdot}01_9$	per cent $+0{\cdot}01_5$	minutes $+ 1{\cdot}2_7$	minutes $+1{\cdot}2_6$	minutes $+1{\cdot}2_3$

The results for the potential-divider bridge are given, using the correction for the bridge error deduced by both methods. The columns marked (1) show the calibration of transformer A, using the corrections deduced from the results of the tests on the two transformers. The columns marked (2) show the calibration, using the corrections deduced from the direct calibration of R_2, r and r_a.

The agreement between all three methods is within 1 part in 10 000 for ratio, and within 1/20th of a minute for phase angle.

[The discussion on this paper will be found on page 906.]

DISCUSSION BEFORE THE METER AND INSTRUMENT SECTION ON THE PAPERS BY MR. SHOTTER (SEE PAGE 873), MESSRS. SPILSBURY AND ARNOLD (SEE PAGE 889), AND DR. ARNOLD (SEE PAGE 898), 7TH FEBRUARY, 1930.

Dr. C. V. Drysdale: The great value of instrument transformers was obvious from the moment of their introduction, but the errors in their ratio and especially in their phase were at first too great to commend them to lovers of accuracy. With the advent of better design, methods of compensation and, above all, the use of nickel-iron alloy, the situation is now entirely changed, and precision instrument transformers can be employed without appreciable error for all commercial tests, and even for the majority of standardizing measurements. It is no exaggeration to state that such transformers are now effecting a revolution in a.c. measurement. These improvements have, however, accentuated the need for accurate tests of the transformers themselves, and the papers now before us are valuable contributions to this subject. Mr. Shotter's paper interests me greatly, as I believe that I was the first to make accurate measurements on the ratio and phase displacement of potential and current transformers, using a wattmeter method.* My methods were practically equivalent to Figs. 2 and 3 of the paper, but instead of using a null method by varying the resistance in one of the wattmeter shunts, I observed the wattmeter deflection and found the quadrature or phase-displacement component by replacing the series resistance in the moving-coil circuit by a condenser. This method worked well, and gave measurements which were consistent to about ± 0·05 per cent in ratio and ± 1 minute in phase angle. Mr. Shotter's null method is ingenious, convenient and probably rather more accurate, if the symmetry of the double wattmeter is sufficiently perfect, and care is taken to secure the correct phase relations. His theory of the method does not, however, seem to me to be very lucid, and a simple vector diagram (Fig. A) makes it more easily understandable. A wattmeter may be regarded either as an ammeter which measures the component of the current in phase with the potential or as a voltmeter which measures the component of the potential in phase with the current. Let OA be the primary vector current or potential, and OB the secondary current or potential, the latter generally being slightly smaller than OA and lagging behind it by a small angle. Assuming that the differential wattmeter is "excited" in phase with OA, it is evident that if OA could be reduced to OC (where BC is perpendicular to OA) there would be no deflection, and this effect can be produced by increasing the resistance in the corresponding wattmeter shunt, in which case it is evident that the percentage difference or loss of ratio:—(OA − OB)/OA × 100 = 100 CA/OA = the percentage increase of resistance required to produce balance. If we could measure the quadrature component BC, the phase displacement could be evaluated, as $\theta = BC/OA$ radians = 3 438 BC/OA minutes, approximately (assuming CA very small); in my own test this component was directly measured by changing the phase of the wattmeter shunt current or "excitation," to quadrature by the condenser. In order to measure it by a null method, Mr. Shotter causes the "excitation" to lag by 60° behind OA, in which case if the vector OA were increased to OD there would again be balance; and this can be effected by reducing the resistance in the wattmeter shunt. But CD = $\sqrt{3} \times$ BC, so that

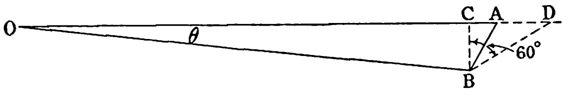

FIG. A.

$$\theta = (3\,438 \times CD)/\sqrt{3} \times OA = 1\,985\ CD/OA,$$

and if CD/OA is 1 per cent, $\theta = 19\cdot85$ or approximately 20 minutes. The phase-lag in minutes is therefore 20 times the percentage reduction of resistance from its previous value. Mr. Shotter's double resistance box enables these two changes of resistance to be made separately, and thus renders the method direct-reading. It should be observed, however, that the accuracy of the method depends materially upon the accuracy with which the wattmeter is "excited," firstly in phase with, and secondly lagging 60 degrees behind, the primary potential or current, as well as upon the accuracy of balance of the two sections of the wattmeter. If in setting up the apparatus great care is taken to secure accuracy in these respects, the method is convenient and accurate, but otherwise I should be inclined to adhere to my original deflectional method with a single wattmeter and condenser. Had I to make such measurements again, however, I should be inclined to use a bridge method such as that described by Dr. Arnold. Of the two methods which he describes I should employ his "Direct Bridge," but I should prefer to substitute a variable mutual inductance for the condenser shunt and to make the bridge direct-reading for a given frequency, as shown in Fig. B. In this diagram the primary and secondary coils of the transformer are connected in series with two non-inductive resistances R_1 and R_2, preferably of the Moore concentric form, the ratio R_1/R_2 being equal to the nominal ratio of the transformer. As the maximum secondary current is usually the standard 5 amperes, R_2 can be fixed, but it is made about 2 per cent higher than its nominal value, and has a second contact "b" at a point 2 per cent below the nominal value, a slide wire being connected between these two contacts "a" and "b" (the resistance should of course be adjusted with the slide wire connected). The main lead from "a" passes through the primary of an astatic shielded variable mutual inductance M to the load, and the vibration galvanometer is connected between R_1 and the slide-wire contact, through the secondary of M. If the transformer were perfect, balance would be obtained with the slide-wire contact at its centre or zero point and with zero inductance; the loss of ratio can be read directly from the slide-wire contact, and the phase displacement from the mutual inductance, since $\theta = 3\,438\ M\omega/R_2$. Allowing for a drop of $0 \cdot 5$ volt with 5 amperes (the secondary current), $R_2 = 0 \cdot 1$ ohm, and, for a frequency of 50 cycles per second, $\omega = 314$, so that $3\,438\omega = 1 \cdot 08 \times 10^6$. If the maximum phase displacement to be measured is $1 \cdot 5°$, or, say, 100 minutes, $M = R_2\theta/3\,438\omega = 0 \cdot 1 \times 100/1 \cdot 08 \times 10^6 = 10$ microhenrys approximately, and the scale of the mutual inductance can be marked off directly in minutes for that frequency. Dr. Arnold's shunting arrangement cannot be improved upon for accuracy, but the resistance shunt involves calculating reciprocals, and the mutual inductance should be cheaper than the variable condensers, and cover a greater range of phase angle. It should be pointed out that as the phase displacement produced by the condenser shunt is $\theta = 3\,438\ CR_2\omega \times 10^{-6}$ minutes if C is in microfarads, C must be approximately 10μF per minute of phase displacement for $R_2 = 0 \cdot 1$ ohm at 50 cycles per second, so that a very high capacity would be necessary for many commercial transformers. It would be more in conformity with other methods to connect the slide wire and mutual inductance in the primary rather than the secondary circuit, but the arrangement shown seems preferable on the ground that the maximum secondary current of transformers is generally fixed at 5 amperes, so that R_2 and M can be fixed, and different resistors can be used for R_1 according to the primary current. Mr. Spilsbury's form of resistor is probably as good a form as can be devised for the somewhat high drop of 2 volts for which it is designed, and his theory of correction by suitably tapping the p.d. points on the busbars is ingenious. Many years ago * I advocated the subdivision of low-resistance standards into a number of parallel circuits, in order to reduce their inductance, and he has now carried this method to perfection. Since the advent of Mr. Moore's concentric form of resistance, however, I have always felt this to be the best form to adopt wherever possible, and I do not think that it has received the appreciation which it deserves. On account of its tubular construction it is not suitable for resistances of a higher value than a few tenths of an ohm, but for this or any lower value I should use it in all precision measurements. For practical purposes, the oil-cooled double tubular form which Messrs. H. Tinsley have made to my designs for a.c. potentiometer work, seems to be more convenient, as it takes up less space and the low residual inductance can easily be calculated. I feel that the three papers which have been read have brought the important subject of instrument-transformer testing to a very satisfactory state, and that little further advance is now needed.

FIG. B.

Dr. E. H. Rayner: There are two things in this world which I had never expected to experience or see: one is transatlantic telephony, and the other is a perfect current transformer. I admit that the perfect current transformer has given me more trouble and worry than the telephony, because it has been one of the weak links in the chain of electrical measurements. It has been my experience to have to consider inquiries from almost all the large electrical manufacturing undertakings in this country as to how they can improve the accuracy of measurements of power in cases where power factors are very low; the light-load losses of large transformers which in these days are fixed by specification within closer limits than those between which it has been possible to measure them, are an example of this. The readings of the instruments are necessarily small when the power factor is of the order of 5 per cent, so that the errors, and especially the phase-angle error, make a very big percentage correction to the reading. The mumetal transformer has changed all this; and it has the advantage that whilst the phase angle, which has been largely the crux of the situation, has been reduced almost to zero, the ratio has also been kept constant. A new era of accurate electrical measurements has thus begun. It is rather peculiar that even now, as for many years past, the measurement of power and energy by alternating-currents has been simpler and more accurate than the measurement of direct current by wattmeters or watt-hour meters. A new stage in which the watt-hour meter is once more the focus of attention as regards the measurement of energy is just now beginning, and I hope that the development of the watt-hour meter will be stimulated by the perfection of the current transformer. These developments will make the measurement of the power and the energy produced by large plants and, indeed, of all kinds of electrical apparatus, more accurate. The designer will be able to obtain more accurate information as to the performance of his plant so that improvements will be facilitated. Eventually the effect will be felt throughout the whole field of alternating-current engineering, and it will stimulate the day-to-day improvements which are proceeding so rapidly all over the world. Mr. Spilsbury has mentioned the difficulty of measuring these large currents otherwise than by means of current transformers. These transformer methods have only recently become available, and he and Dr. Arnold have been working for months upon them. Many small details have cropped up and produced little anomalies which have been investigated at considerable pains; the work has, I believe, been carried to a greater accuracy than has ever before been achieved. Before the possibilities of mumetal had been explored, other methods of measuring power at currents upwards of 2 000 amperes had to be thought out, and I designed a non-inductive resistance for 5 000 amperes. The design has never been completed, partly on account of the introduction of mumetal. It is possible that, as the result of further investigation, this material may be applied to potential transformers. In my own experience we have already found it valuable in connection with potential transformers designed for certain specific purposes.

---

* "New Low-Resistance Standards," *Electrician*, 1916, vol 77, p. 629.

Mr. E. V. Newbery: The conclusions of Mr. Spilsbury and Dr. Arnold with regard to the stability of mumetal cores are certainly very interesting, but they do not agree with my own experience at Rugby. The investigations which are going on there have shown certain variations with regard to mechanical treatment and over-magnetization. Although these are comparatively small and do not affect the value of mumetal for many industrial applications, they tend to show that the concluding paragraph of the paper is rather too sweeping in its assertions. Mumetal cores have, no doubt, a great future, but further investigations are necessary.

With regard to Mr. Shotter's paper, I notice that he has been using a standard transformer with a square core; the author rightly stressed the fact that with a square core the primary must always be wound in the same position in the hole, and with the same radius of turns. Some years ago the firm with which I am connected carried out experiments on this subject, when large variations were discovered, and this led to the abandonment of the use of square cores for precision work. It is true that if the radius of the primary turns is kept constant and the turns are placed in the centre of the hole, fairly good agreement can be obtained. In the case of a standard transformer with a varying number of turns, however, these cannot be placed in the same space in the centre of the core. With a ring-core transformer the position and radius of the turns do not materially affect the ratio or the phase angle, if the secondary is evenly distributed. I refer, of course, not so much to the high-precision work of the National Physical Laboratory as to commercial testing. With regard to the applications which Mr. Shotter suggests, I do not feel that they will be of great value. The measurement of losses on power transformers is certainly a very difficult problem in view of the low power factor, but modern research in the building of wattmeters has produced instruments which are capable of very accurate work, provided that allowance is made for the phase-angle errors of the instrument transformers. In the latter the mumetal core is of value, but the lengthy calculations involved in the computation of the losses when using the author's apparatus will probably discount any advantage which may be claimed for it. The Hopkinson method of testing machines is now no longer used for measuring efficiencies, as the British Engineering Standards Association definitely lays down the method of segregation of losses. With regard to the actual methods of testing current transformers, I am concerned in an investigation which employs the N.P.L. method. The apparatus, which is at present being prepared, embodies the modification of using a standard current transformer not only for the heavier currents but right down to the 5·5 ratio. A current transformer with 7 200 ampere-turns is being built for the purpose; it will have an ordinary 5-ampere secondary winding with two primary windings wound upon it. One of these will have the same number of turns as the secondary winding, but will be wound in 20 sections for series or parallel connection. A 5·5 ratio which will make the transformer self-checking is thus obtained. The second primary winding is designed for 60 turns wound in 20 sections, and these two primaries, together with turns which can be wound through the hole, will give every ratio in the standard line; there will also be tappings on the secondary winding for that purpose. The instrument will be calibrated by the N.P.L. to give the standard of precision necessary for accurate commercial testing. This type of transformer enables the whole of the testing to be carried out without the use of shunts—an important advantage over the more usual form of equipment. The idea of eliminating errors due to the human element, which the same author has devised, by introducing the use of dials on the instrument for the corrections of the standard transformer, is of value from the point of view of commercial testing. The equipment can be used either for current or potential transformers, and although this feature does not present very great advantages to large concerns in which separate apparatus for each is provided, it is nevertheless a point in its favour.

Mr. W. Holmes: It is not many years ago since current transformers and potential transformers were placed in two different categories. Phase-angle errors were not much understood. It was considered to be sufficiently accurate to test a wattmeter with and without its current transformer, and to ascribe the difference to the phase angle. This became such a habit that 20 minutes per 1 per cent error at a power factor of 0·5 was always assumed without reference to a cosine table. The method was technically accurate, but the observational and other errors were great. Mr. Shotter, after patient investigation, has produced a practical way of eliminating the errors. We have been working with the Shotter method for current-transformer and the Silsbee method for potential-transformer testing, but I now consider that testing institutions should adopt the Arnold method for current transformers. The method due to Mr. Shotter is suitable for an ordinary electricity supply laboratory and test room which has to deal with an output of transformers for meter work, because this method will test both current and potential transformers. When using the bridge method in our works we experience considerable disturbance of the galvanometers as the result of mechanical vibration from surrounding machinery, and this may give trouble in the test room of a generating station. I have been looking for wave-form errors in Mr. Spilsbury's paper, because if such errors exist it must be difficult to define phase-angle error. We have observed differences between the test results obtained when using a wave with a steep front compared with those obtained when a sine wave is used. From this point of view the Shotter method should give a more practical result, as transformers are generally used on dynamometers or induction wattmeters. Mr.

Shotter should perhaps describe it as a "balanced torque" rather than as a "null" method, as he applies full current and full potential to the instrument. I am glad that Mr. Spilsbury finds the 5 000-ampere-turn mumetal current transformer to be stable. Owing to the high cost, we are used to limiting mumetal to the bushing type of about 500 ampere-turns, and thus the errors are necessarily larger. In Fig. 14 of Mr. Shotter's paper a difference of 4 minutes is recorded between the results of his own and the N.P.L. tests, while the manufacturer's test result lies between the two. Differences of this magnitude frequently occur between tests made by different authorities. Recently we made a slightly compensated potential transformer and found it to have a phase-angle error of — 8 minutes on our test. It was sent first to a southern testing institution, which found the error to be — 2 minutes, and then to a northern testing institution, which reported an error of — 11 minutes, whilst our own test can only repeat — 8 minutes. I am therefore glad to see that testing methods are being thoroughly investigated.

Mr. W. Phillips: For routine testing of instruments it is necessary to have a quick and accurate method which at the same time involves the minimum of expense in the way of special plant and instruments. In this respect the Shotter apparatus is almost ideal; it requires only a sensitive differential wattmeter and a potential divider adjusted in percentages. Each of these pieces of apparatus has been designed as a separate unit, so that any instrument can be used with any resistance box. This, of course, tends to cheapness of production and ease of repair and replacement. Special transformers can evidently be dispensed with and any transformer of which the errors are known can be employed as a standard. This is, I think, a valuable feature. It is further stated that the errors can be estimated on the apparatus itself, provided that the transformer has a hole through the centre so that a primary winding giving a 1 : 1 ratio can be employed. The only other accessory, apart from the apparatus for phase-shifting to be found in every laboratory which deals with accurate testing of wattmeters and watt-hour meters, is a small transformer to supply the current coils of the indicator for testing potential transformers. This can be constructed in the test room or can be purchased for a few shillings. The method of test is quick and accurate; when the apparatus has been installed and permanent connections have been made, the complete testing of a current transformer for ratio and phase angle at one secondary burden takes about 5 minutes. The errors are usually not in excess of 0·02 per cent in ratio and 2 minutes in phase angle at full load. The only point that requires care is the application of the corrections, and this is largely a matter of experience. While the Shotter method is all that is required for use in industrial testing rooms, it is recognized that an absolute or precision method is necessary for ultimate standardizing work. The method in use at the N.P.L. and on the Continent incorporates a standard resistance, a potential divider, a balance indicator in the form of a vibration galvanometer and some means of balancing the quadrature component of the current. This latter consists of a subdivided condenser, in the equipment which has been described. Although rapid and accurate, the apparatus is expensive, as I found some time ago when I investigated the methods of precision measurement of current transformers and made an especial survey of this type. I found that the cost of the apparatus for testing current transformers up to a primary current of 100 amperes was between £250 and £300, and that if potential transformers were to be tested up to a voltage of 25 000 an additional £330 was necessary. These prices were quoted by a German company. It is evident, therefore, that this apparatus is beyond the reach of almost all testing rooms except those supported by a Government department. I cannot see why this scheme was chosen in preference to an older but equally accurate one of the type similar to that described by Dr. Drysdale, with the exception that the quadrature component is compensated by a phase-shifter or double generator. The method, which is due to P. de la Gorce,* employs standard resistances. It is very accurate and requires no special additional apparatus such as a standard condenser—most engineers regard these with doubtful enthusiasm, particularly when they are subdivided to such low values as 0·001 microfarad. One of the necessary accessories for current transformers is the standard resistance, and that described by Mr. Spilsbury seems to be an accurate and comparatively cheap instrument which overcomes all the difficulties involved in the design of standard resistances for large currents. I should like him to amplify his method of testing the resistance for phase angle. Referring to the use of mumetal current transformers as standards, my experience, extending over some 5 years, has convinced me that they offer a means of accurate current and power measurement hitherto unequalled. I have found no appreciable variations in phase angle or ratio and can endorse all the evidence that Mr. Spilsbury and Dr. Arnold have brought in their favour; in fact I consider a mumetal current transformer, used in conjunction with a 5-ampere wattmeter, to be the most accurate means of industrial power measurement in existence. In connection with the use of mumetal current transformers, it must be remembered that for the most accurate work the secondary burden should be kept low in order that the density in the core may remain at a value such that advantage can be taken of the high permeability of the metal.

Mr. R. S. J. Spilsbury: Mr. Shotter mentions the Silsbee method of testing current transformers, and suggests that his own is simpler. Actually there is not much to choose between the two from this point of view, the phase shifter and other auxiliary apparatus being common to both; the Silsbee method, however, uses only a single-element wattmeter instead of a double-element instrument, and it dispenses with the resistance box. The calculation of the phase angle is also rather simpler, because the auxiliary voltage is in quadrature with the current, so that no account has to be taken of the ratio error of either transformer. The secondary burden of 4 volt-amperes imposed by Mr. Shotter's method may be somewhat inconvenient when it is desired to make a test at a definite burden. It is suggested in the paper that this difficulty is easily overcome by making tests with two or more burdens and extrapolating the results to zero burden: it should be mentioned that the added burdens must have the same time-constant as the detector current coil, so that it would be of advantage to supply one or two accurately matched dummy coils with the equipment. The Silsbee method shows to advantage here, since the burden imposed is much less. Using the special instrument to which Mr. Shotter refers in the paper to test a current transformer having a ratio error of 1 per cent and a phase-angle error of 60 minutes (the limits for Class B accuracy), the added burden due to the detector is only 0·3 volt-ampere at full current, which is practically negligible. The points in the author's method which appeal most to me are the versatility of the equipment, and the ingenious method of compensating for the errors of the standard transformer on a separate set of dials; this latter feature will, I think, prove to be very valuable when the apparatus is used by relatively unskilled staff.

---

* "Note sur L'Essai des Transformateurs de Mesure de Courant au Laboratoire Centrale d'Électricité," *Bulletin de la Société International des Électriciens*, 1916, vol. 6, p. 299.

Mr. G. W. Stubbings (*communicated*): Mr. Shotter's method for the determination of the phase error of a current transformer depends upon the fact that the fractional error of a wattmeter, due to this phase error, is approximately equal to $\alpha \tan \phi$, where α, the phase error, is expressed in radian measure. Tan $60° = \sqrt{3}$, and the radian measure of 20 minutes is very nearly $1/\sqrt{3}$ per cent. If, therefore, a wattmeter reads inaccurately, owing to the phase error of a current transformer with a circuit power factor of 0·5, the percentage error multiplied by 20 gives this phase error in minutes. Had the more rational method of specifying phase errors in percentages of a radian been adopted, the test could have been simplified by balancing the double wattmeter with a phase difference of 45 degrees between the current and voltage. Since $\tan 45° = 1$, the difference between the tests at power factors of unity and 0·707 gives the phase error directly in radians. The degree measure of small phase errors has to be converted to radian measure for correcting wattmeter readings, and it therefore seems best to record these errors in the form in which they will be used. A further advantage of carrying out the second balance test at a power factor of 0·707 is that the torque on the wattmeter is nearly half as much again as it is with a power factor of 0·5, and the sensitivity of the instrument is correspondingly increased.

Mr. G. F. Shotter (*in reply*): As Dr. Drysdale points out, it is essential that the phase relationship between the current and potential supplies to the detector must be accurately set. I, myself, experience no difficulty in this direction since I use a Tinsley-Drysdale phase-shifter.

Mr. Newbery confirms the precautions necessary when using a "hole" type current transformer. I am indebted to him for his remarks about the other applications of the method. They were only referred to from the point of view of interest, although I feel that the application of the method to the testing of power transformers would not be so complicated as he states.

I quite agree with Mr. Holmes's suggestion that "balanced torque" would be a more suitable title for the method than "null," as the theory of the method, as developed in the paper, is based on those lines.

I agree with Mr. Spilsbury regarding the inconvenience of the 4-VA burden of the detector in certain cases, although for commercial testing the errors introduced by this burden would be negligible. I think his suggestions as to accurately matched dummy burdens is a valuable one. However, it might be possible to decrease the burden imposed by the series coils if this was found to be necessary.

I agree with Mr. Stubbings that in the cases where the phase-angle errors of instrument transformers have to be applied to wattmeter or watt-hour meters at any power factor (e.g. when testing *in situ*) his method of correction is undoubtedly the right one, but when testing equipments in the laboratory at the British Engineering Standards test of unity and 0·5 power factors, I think the method of correction as outlined in the paper is much simpler, since the percentage errors (read directly on the testing box) obtained in the 60° test are the combined ratio and phase-angle errors of the instrument transformers at 0·5 power factor (lag), and can be directly applied to the wattmeter or watt-hour meter.

Mr. R. S. J. Spilsbury and **Dr. A. H. M. Arnold** (*in reply*): In reply to Dr. Drysdale we do not suggest the use of the "direct bridge" for general testing: it is used purely for work of the highest accuracy on transformers having very low errors, and for these the value of the capacitance required is not unduly large. We think that the method suggested by him has several disadvantages as compared with the "potential divider bridge." In the first place it is much less flexible and requires a different heavy-current resistance for each transformer ratio. A more serious objection is the use of a variable mutual inductor. Though such instruments are described as astatic, they are in reality appreciably affected by stray magnetic fields, and in testing bar-type current transformers such fields cannot be avoided. In our view the perfect astaticism of the condenser is a great advantage. The capacitance required at 50 cycles for a phase angle of 100 minutes is 1 μF, which is a convenient value. The method is direct-reading for ratio and phase angle. It is possible that Dr. Drysdale's method might be a little more rapid, but the saving in time could only be small. The Moore type of non-inductive resistor should be very satisfactory for low values of resistance and moderate currents, provided that a uniform distribution of current in the tube can be secured: for large power dissipations cooling would probably be difficult. We have, however, never seen a resistor of this type or any account of measurements of its characteristics. With Dr. Drysdale's own double tubular form we are more familiar: the residual inductance of this type is fairly low and is calculable. Owing to the method of cooling adopted it becomes rather bulky where large powers have to be dissipated, but the stability of the resistance should probably be better than that of the Paterson-Rayner type. For large voltage-drops at high currents this latter form appears still to hold the field, except in so far as the mumetal transformer replaces it.

We agree with Dr. Rayner that the mumetal-core transformer will make revolutionary changes in methods of precise electrical measurements. It is an interesting fact that one of the first effects of the introduction of mumetal, an alloy produced for quite different purposes, has been to extend indefinitely the range of powers which can be easily and accurately measured by the electrometer.

Mr. Newbery has doubts as to the stability of the mumetal-core transformer: we think, however, that if he will re-read the paragraph in our paper to which he refers he will see that it is a statement of fact. We entirely agree with him that very much more work will be necessary before the stability of commercial transformers using this material is established, but we feel that our results show that such stability is not impossible to attain. We think that the standard current transformer which Mr. Newbery describes should be a most valuable piece of apparatus.

Mr. Holmes mentions difficulties due to mechanical vibration. Such troubles are serious where precise testing has to be done near running machinery. Probably Mr. Holmes is already using a moving-coil vibration galvanometer: if not, the substitution of an instrument of this type for the moving-iron pattern will reduce the disturbance. With regard to wave-form errors it is, we believe, general experience that a normal current transformer reproduces the primary wave-form to a high degree of accuracy, even when this wave-form is badly distorted. The methods we have described, employing a vibration galvanometer, give the ratio and phase angle corresponding to the fundamental wave: this is, in general, what is required. Certain special types of transformer do give wave-form distortion, and for these no precise figures of ratio or phase angle can be obtained by any method. Mr. Holmes's figures with regard to voltage transformers are interesting, though hardly within the scope of our papers: we may, however, mention that discrepancies of this order can very easily occur unless great care is taken to eliminate or allow for the effects of earth capacitance in the voltage divider employed in the tests.

The cost of the complete apparatus for the "potential divider bridge" which Mr. Phillips mentions seems very high. The cost of the heavy-current resistances is a serious item for all "absolute" methods, but is actually lower than usual for the "potential divider bridge," since only a few values are required. Apart from the variable condenser, which would cost about £40, it should be possible to construct the apparatus quite cheaply. De la Gorce's method, which Mr. Phillips advocates, seems to us to have several disadvantages. Our main reason for abandoning the electrometer method which we had previously used was to enable current-transformer testing to be carried out on any single-phase supply, so that the de la Gorce method, which requires a phase-shifter or double-alternator set, was inadmissible. Apart from this, however, the method requires an additional setting (that of the phase of the auxiliary voltage) beyond the normal double adjustment of the bridge. The standard condenser used in the "potential divider bridge" is a very reliable piece of apparatus: if a change of value of one section were to occur it would make itself obvious, since the phase-angle values obtained for a transformer at various currents would no longer lie on a smooth curve. The method used for measuring the phase angles of the 200-ampere resistors was that described by L. Hartshorn in the *Proceedings of the Physical Society of London* (1926–7, vol. 39, p. 377). Another method, more suitable for use at power frequencies, is now being developed, and will probably be described shortly. We are very glad to learn Mr. Phillips's opinion, based on a much larger experience than our own, with regard to the stability of mumetal-core transformers: we agree with him that the days of the "straight-through" heavy current wattmeter are over.

AN ANALYSIS OF HEATING TESTS ON ELECTRICAL MACHINES.[*]

By EDWARD HUGHES, Ph.D., B.Sc., Member.

(*Paper first received* 20*th August, and in final form* 27*th November*, 1929.)

SUMMARY.

The factors governing the temperature-rise of electrical machines are so interwoven that the only satisfactory method of separating them is to test actual machines with different distributions of losses, different speeds, etc.; conclusions derived from tests on models must be accepted with caution. In this paper are given the results obtained on two electrical machines, one with a rotating armature and the other with a rotating field, which were tested with different load and field currents, different speeds, etc. The machines were also tested when totally enclosed and when cooled by an induced draught. Temperature-rises were measured by thermometer, by thermo-junction and by the increase of resistance. In the case of the machine with the rotating armature it was found possible to follow the temperature variation of the latter by placing a thermo-junction a short distance away from the armature, and it is suggested that this method might be used for shortening the duration of heat-runs.

INTRODUCTION.

An enormous amount of work has been done on various aspects of the rise and distribution of temperature in electrical machines. Many investigators—notably G. E. Luke in the United States—have endeavoured to analyse the various factors governing the temperature-rise of a machine by studying each factor separately on suitable models. This method simplifies the procedure and often results in important discoveries being made; but it must be borne in mind that the effect of two factors in combination may be different from their effects when acting separately. For instance, Luke[†] found that the heat dissipation from a rotor was increased (*a*) by increasing the peripheral speed with no forced axial ventilation, and (*b*) by increasing the forced axial ventilation when the rotor was stationary; but with a combination of peripheral speed and forced axial ventilation he found that, under certain conditions, less heat was dissipated with the rotor revolving than when it was stationary for the same rise of temperature and the same quantity of air through the air-gap per minute. Hence, if we are to separate the factors that determine the temperature-rise of various parts of an electrical machine and to find their interaction upon one another, the first step is to carry out an exhaustive series of tests on *one* machine, the losses in which have been measured accurately for the different test conditions. It is, of course, realized that the conclusions deduced from such an analysis cannot be applied indiscrimately to all types of dynamos and motors, but they do assist in elucidating the problem of heat dissipation.

In this paper the test-results on two machines have been investigated. Machine A was a standard d.c. machine except that the commutator was replaced by 3 slip-rings and, for this reason, was chosen for these tests. Its rated 3-phase output was 3·5 kVA, at 50 periods per sec. and 1 500 r.p.m. Machine B was also a 3-phase alternator with a revolving field and a stator winding of the concentric 2-plane type. Its rated output was 5 kVA at 60 periods per sec. and 1 200 r.p.m.

Test Procedure.—The machines were tested at different load currents, different exciting currents and different frequencies, each test being continued until the temperature became practically steady. Many of the tests were carried out with the field and output currents maintained constant throughout any one test. Other tests were performed by overloading either the field or the armature or both for the first half-hour or so, the currents being then adjusted to the correct values. The latter method is referred to in greater detail on page 922.

The temperature-rise of the field winding was determined by a bridge arrangement described in a previous paper,[*] whilst those of the armature and stator windings of machines A and B respectively were measured by noting the p.d. required for a known direct current, the machine being stopped occasionally for the few seconds required to take readings. In the case of machine A, the p.d. was determined by auxiliary copper-gauze brushes bearing on two of the rings.

Other temperature-rises were also measured; thus, on machine A, a copper-constantan thermo-junction was fixed midway between the uppermost pole-tips at a radial distance of 2·5 mm from the armature core. The object of this arrangement was to see whether it was possible to obtain externally an indication of the core temperature without having to stop the machine, and thus enable the heating test to be shortened, as discussed on page 921. Also, the temperature of the armature core was determined by thermometer at the completion of each test. With machine B, one thermo-junction was placed under the head of a screw inserted radially into the stator core on the external surface and midway along one batch of laminations. Another thermo-junction was rigidly fixed in the middle of the centre vent-duct at a point half-way between the internal and external surfaces of the stator core. The object of this junction was to investigate the temperature of the cooling air passing through the duct.

The iron losses corresponding to the various loads, speeds and excitations were determined by measuring the input power to the d.c. motor that was directly coupled to the alternator, and also the output power of the latter. Allowance was made for the copper loss in the armature winding, the contact-resistance loss at the slip-rings and the small increase of copper loss in the motor armature.

(1) TESTS ON MACHINE WITH REVOLVING ARMATURE.

Temperature-Rise of the Field Winding.—Figs. 1 and 2 * show the variation of the temperature-rise per watt with the total armature loss for different exciting currents and different peripheral speeds. It will be seen that the temperature-rise per watt is a linear function of the armature loss, but that the effect is greatly influenced by the temperature-rise of the field relatively to that of the armature. In a previous paper † the author suggested that the temperature-rise per watt for the field could be represented in the form

$$\frac{\theta_f}{W_f} = \frac{k(1 + mW_a)}{1 + nv}$$

where W_a is the armature loss, v the peripheral speed, and k, m and n are constants for a given machine. The data then available were not sufficient to check the general applicability of this expression. From Figs. 1 and 2, however, it is evident that the coefficient m, namely the slope of the lines, varies with every variation of the exciting current and of the speed, and that no general expression for the temperature-rise of the field is complete if it does not take into account the speed and either the loss in, or the temperature-rise of, the armature.

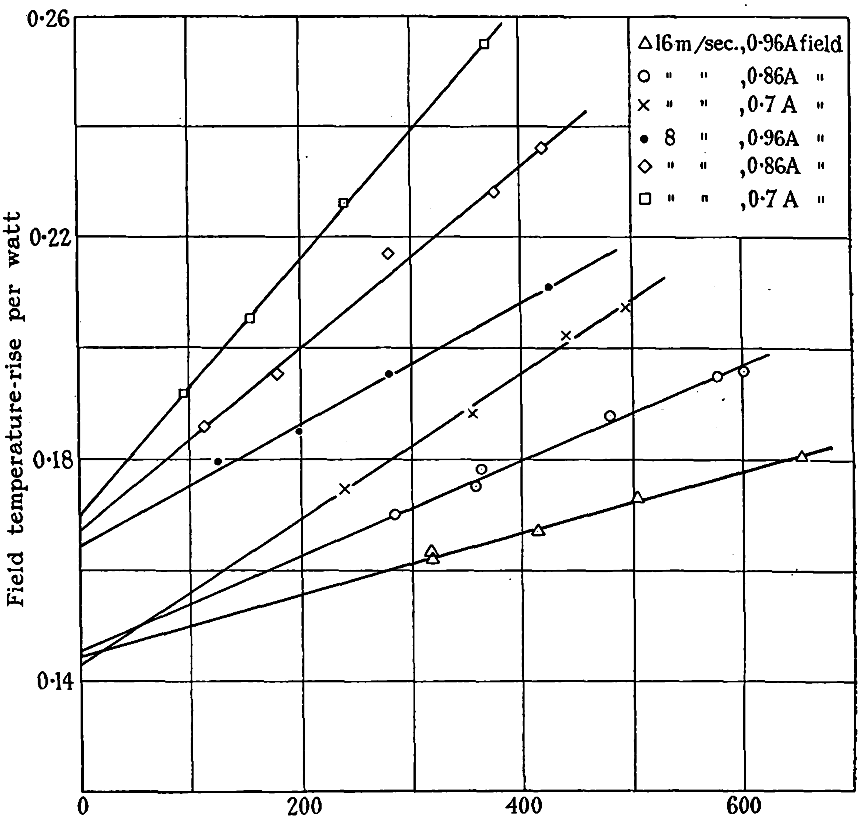

FIG. 1.

By producing the graphs of Figs. 1 and 2 back to the vertical axis, the temperature-rise per watt for zero armature loss can be determined for the various speeds and excitations. Graphs obtained by plotting the field temperature-rise per watt against the armature temperature-rise (by resistance) were of almost identically the same character as those of Figs. 1 and 2, and the values of θ_f/W_f for no temperature-rise of the armature winding agreed very closely with the corresponding values for no armature loss. The mean values of W_f/θ_f for no armature loss and for no armature temperature-rise, derived from these two sets of graphs, have been plotted in Fig. 3. If the curve through the mean of these points be represented by $A(1 + Bv^x)$, the value of x is found to decrease from 0·93 for a range of 0 to 5 metres per sec. down to 0·52 for a range of 11 to 16 metres per sec. These figures indicate that after the influence of armature heating has been eliminated, the effect of the speed upon the field is very similar to that found by Luke * for a cylinder rotating in air. From an analysis of Luke's curve the author finds that, up to a peripheral speed of 20 metres per sec., the watts dissipated per degree rise of temperature is represented by $A_1 + B_1v^{0\cdot 93}$, whilst for peripheral speeds of 25 to 50 metres per sec. it becomes $A_1 + B_2v^{0\cdot 6}$. It will be noticed that the *variation* of *x* is surprisingly similar to that found for the field coils above, and appears to be due to the air at the dissipating surface not being removed in proportion to the velocity.

---

* The lines through the points corresponding to 1·86 metres per sec. have been drawn parallel to the respective lines for 3·73 metres per sec.

* *Loc. cit.*, p. 646.

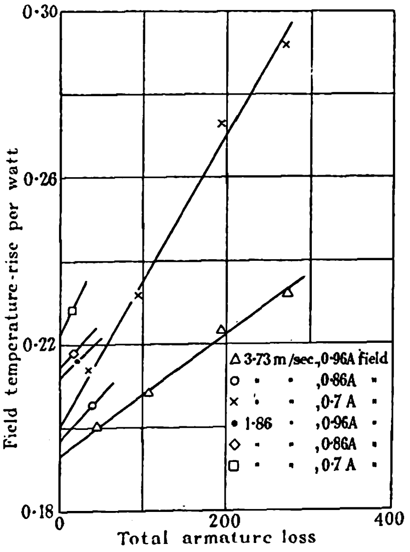

FIG. 2.

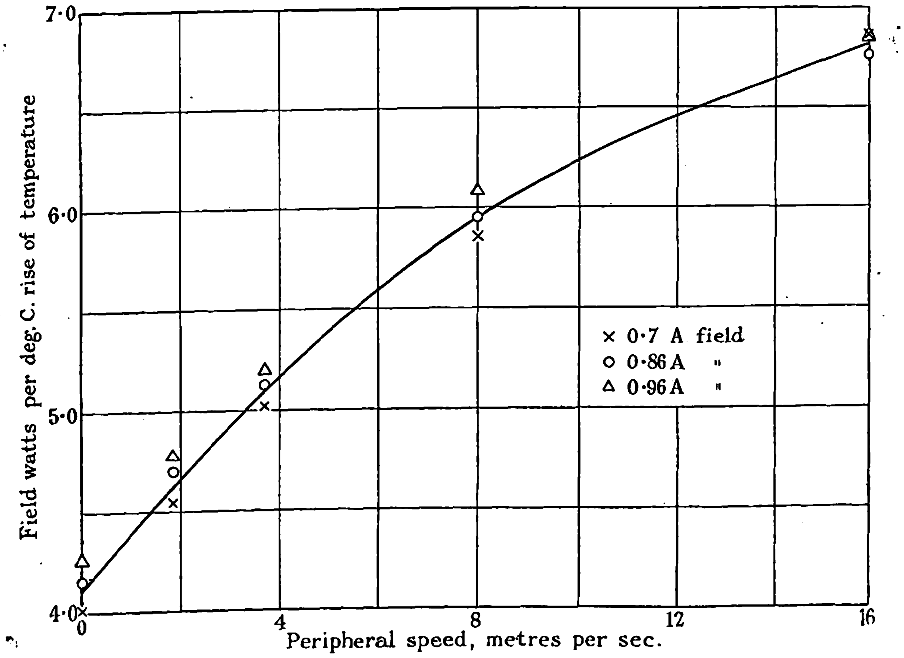

FIG. 3.

A simple mathematical expression giving a fair approximation to the graph of Fig. 3 is

$$W_f/\theta_f = 4\cdot 1(1 + 0\cdot 16\sqrt{v}) \quad . \quad . \quad . \quad (1)$$

A more cumbersome expression, but one which is in closer agreement with this graph, is

$$W_f/\theta_f = \frac{(v + 3\cdot 75)^{\frac{1}{3}}}{0\cdot 385} \quad . \quad . \quad . \quad . \quad (2)$$

Table 1 shows how the values calculated from expressions (1) and (2) compare with those obtained experimentally.

It will be evident from Table 1 that expression (1) underestimates the temperature-rise at low speeds.

16·0	6·82	6·72	7·01

Effect of Armature Heating upon Field Temperature.—In any electrical machine working under normal conditions there is a rise of temperature of the armature—even on no load. It is therefore desirable to determine whether the effect of speed upon the field temperature is the same when the armature is hot as when it is at the room temperature, and, if possible, to derive an expression taking the temperature-rise of the armature into account.

In Fig. 4 the temperature-rise per watt of the field winding has been plotted against the difference between the temperature-rises of the field and armature windings (both measured by resistance) for different currents and different speeds. From these graphs it will be obvious that θ_f/W_f is almost independent of the field excitation and of the actual temperatures of the field and armature windings—as apart from the difference between their temperatures. The values of θ_f/W_f for the different speeds and for *equal* temperature-rises by resistance of the field and armature windings have been derived from these graphs and are indicated by crosses in Fig. 5. For purposes of comparison, curve A, showing the values of θ_f/W_f for no temperature-rise of the armature, has been included in this figure.

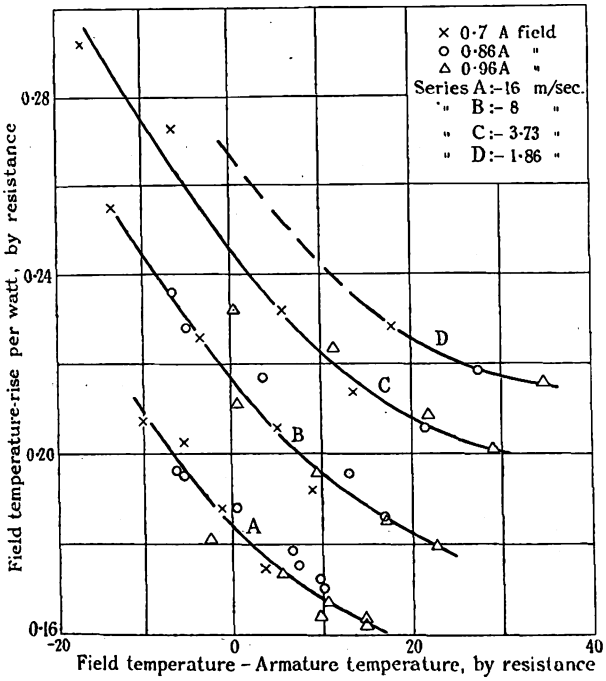

FIG. 4.

Since the more common practice is to measure the temperature-rise by thermometer, it is of interest to ascertain whether a similar result can be derived from such temperatures. Unfortunately, only a few thermometer readings had been taken for the field winding. From these readings, however, it was found that the temperature-rise by resistance was about 1·4 times that by thermometer, and the author had previously * found that this ratio was practically independent of speed and of excitation. By the aid of this ratio, the difference between the temperature-rises by thermometer of the field winding and armature core was estimated, and the results have been plotted against θ_f/W_f in Fig. 6. These curves again demonstrate that the effect of the armature heating upon the temperature-rise of the field is dependent upon the difference of temperature and is practically independent of the excitation.

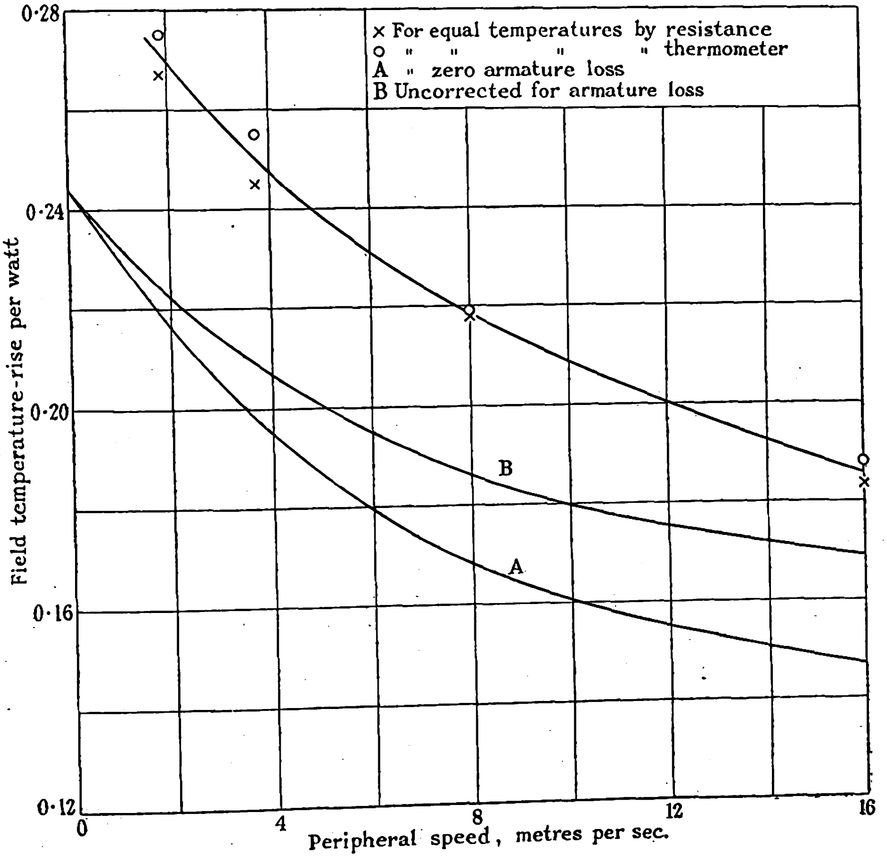

FIG. 5.

---

* *Loc. cit.*, p. 646.

The values of θ_f/W_f for equal temperatures by thermometer are indicated by circles in Fig. 5 and are in close agreement with those derived from resistance measurements. The average of these two sets of points is represented very closely by

$$W_f/\theta_f = 2\cdot7(1 + 0\cdot25\sqrt{v}) \quad . \quad . \quad . \quad (3)$$

A comparison of expressions (1) and (3) shows that the speed is relatively much more important when the armature is hot than when it is cold; also, that the relationship between θ_f/W_f and speed, derived for no armature losses, does not apply when armature losses are present. That the relationship derived from the no-load tests, without any allowance for armature heating, is even more inaccurate—as far as speed is concerned—is evident from an inspection of curve B in Fig. 5, this curve being the mean for the three exciting currents with the armature on open circuit.

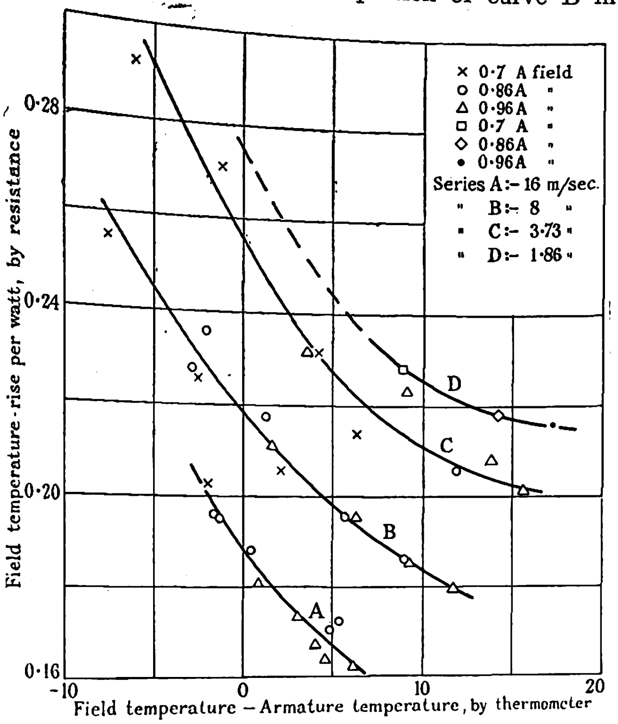

FIG. 6.

From Figs. 4 and 6 it will be obvious that the coefficient 2·7 in formula (3) requires to be modified whenever there is a difference of temperature between the field and the armature. Thus, in Fig. 4, a change from − 5 to + 5 deg. C. in the relative temperatures at a peripheral speed of 16 metres per sec. reduces θ_f/W_f from 0·1955 to 0·1745, a reduction of 10·7 per cent; whilst a change from − 10 to + 10 deg. C. results in a decrease of 20·3 per cent. The corresponding values for 8 metres per sec. are 10·6 and 20·2 per cent respectively, and those for 3·73 metres per sec. are 10·1 and 19 per cent. It therefore follows that a very close approximation may be made by allowing 1 per cent variation of θ_f/W_f for every 1 deg. C. variation between the temperatures of the field and armature windings when the temperatures are measured by resistance. For temperature-rises measured by thermometer (Fig. 6) it is found that the field temperature-rise varies about 1·4 per cent for every 1 deg. C. variation in the difference of the field and core temperatures.

These relationships may now be utilized for calculating the temperature-rise of the field under all conditions of load, speed and excitation, in the following manner:—

Let θ_f and θ_a = temperature-rises of the field and armature respectively;

c = percentage decrease of θ_f/W_f per degree increase of $(\theta_f - \theta_a)$;

d = value of θ_f/W_f when θ_f and θ_a are equal;

W_f = field loss at the final temperature.

Then

$$\theta_f/W_f = d\left\{1 - \frac{c}{100}(\theta_f - \theta_a)\right\} \quad . \quad . \quad . \quad (4)$$

If W = field loss at room temperature, which can be assumed to be about 15° to 20° C., and a = temperature coefficient of resistance at room temperature—for instance, about 0·004 for the above range—then $W_f = W(1 + a\theta_f)$.

Should θ_f be the temperature-rise by thermometer, it is necessary to make allowance in this expression for the ratio of temperature-rise by resistance to that by thermometer.

Substituting for W_f in (4) and solving for θ_f, we have

$$\frac{acdW\theta_f^2}{100} + \theta_f\left\{1 + dW\left(\frac{c}{100} - a - \frac{ac\theta_a}{100}\right)\right\} - dW\left(1 + \frac{c\theta_a}{100}\right) = 0 \quad . \quad (5)$$

For the machine under discussion, the value of c is about 1 per cent for temperature measured by resistance. Also, from (3), we have

$$d = \frac{0\cdot37}{1 + 0\cdot25\sqrt{v}}$$

At this stage it was felt desirable to check the temperature-rises calculated by the above formulæ against the test values over wide ranges of load and of speed. The results are given in Table 2.

Comparison of the last two columns shows that the agreement between the calculated and the observed temperature-rises of the field is very close—especially in view of the numerous factors that are involved. It is realized that the values of c derived above are only applicable to this particular machine, and that in most machines the field and armature windings are designed for the same temperature-rise. There are a few cases, however, such as variable-speed motors, where there may be considerable difference between the field and armature temperatures. In such machines, expression (5) can be of considerable assistance in determining the influence of the armature heating upon the temperature-rise of the field winding.

Temperature-Rise of the Armature.—The temperature-rise was determined both by resistance and by a thermometer placed on the core after the machine was shut down, as already detailed on page 912. In Fig. 7 the temperature-rise by resistance has been plotted against the total armature loss, and it will be seen that the two quantities are practically proportional to each other and that the relationship is independent of the field temperature but is greatly influenced by the speed.

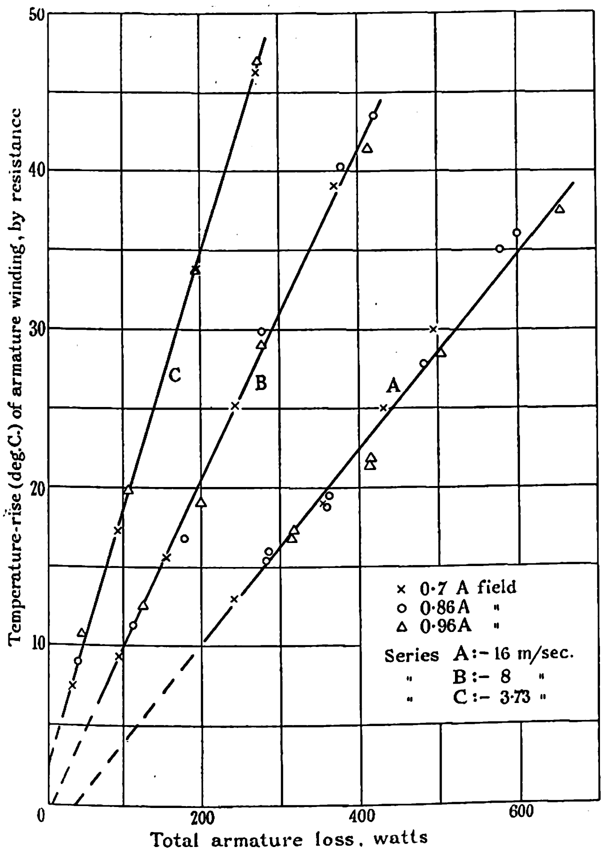

FIG. 7.

Attempts were made to find whether the temperature-rise by resistance could be related to any other quantity such as the armature copper loss, but none was found so satisfactory as the total armature loss.

In the same way, it was found that the temperature-rise of the core was most closely related to the sum of the iron and slot I^2R losses.

A thermo-junction was fixed midway between the uppermost pole-tips and 2·5 mm from the core, as mentioned on page 912, and the temperature-rises noted on this junction were also found to be more closely related to the iron and slot I^2R losses than to any other quantity. This relationship is seen in Fig. 8.

The simplest method of analysing these results so as to deduce a general expression involving losses and speed, was to calculate from Figs. 7 and 8 the watts

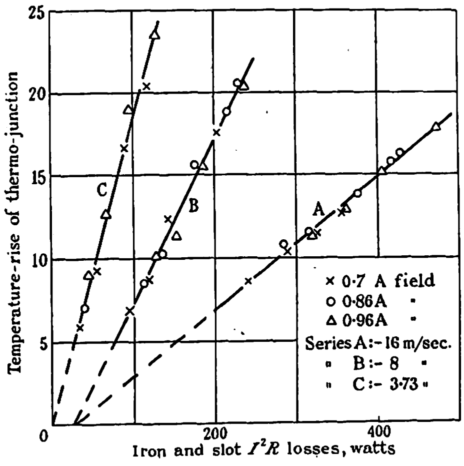

FIG. 8.

per deg. C. rise of temperature for various temperature-rises and then to plot these values against speed, as in Figs. 9 and 10.

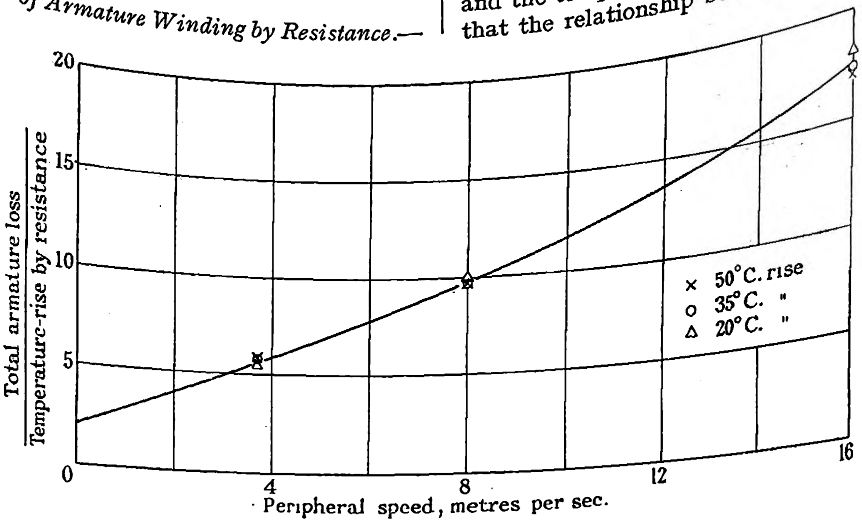

FIG. 9.

Temperature-Rise of Armature Winding by Resistance.—From Fig. 9 it will be seen that the armature loss per deg. C. is a linear function of the speed and is expressed by

$$W_t/\theta_r = 2(1 + 0\cdot485v)$$
$$\doteqdot 2(1 + 0\cdot5v)$$

where W_t and θ_r represent the total armature loss and the temperature-rise by resistance, respectively. The above approximation gives a round figure for the coefficient of v and is within the limits of experimental error. The external cylindrical area of the winding was 15·33 dm²; hence

$$\text{Watts/dm}^2\text{/deg. C.} = 0\cdot13(1 + 0\cdot5v) \quad . \quad (6)$$

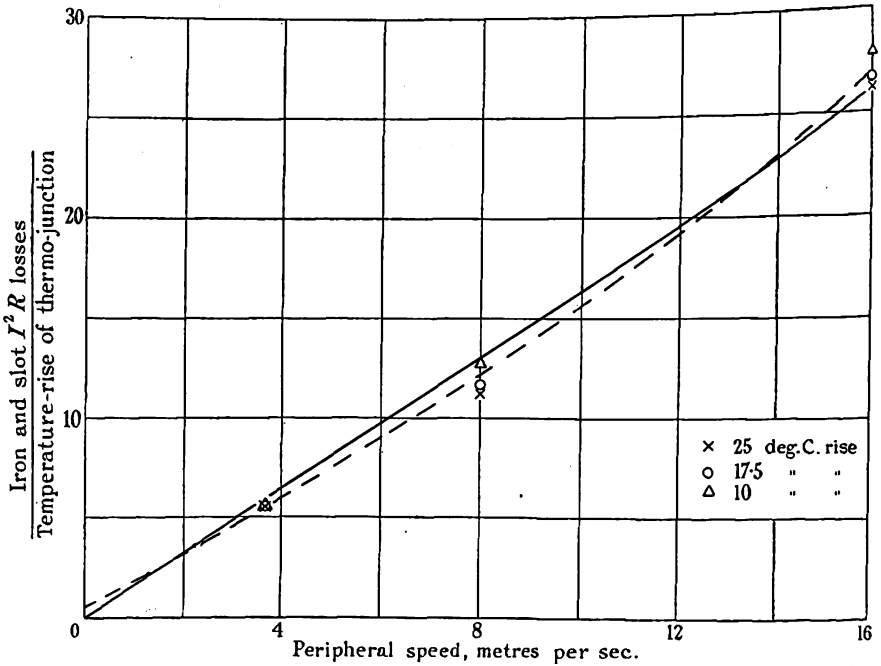

FIG. 10.

Temperature-Rise of Armature Core by Thermometer.—If the iron and slot I^2R losses be represented by W_c and the temperature-rise of the core by θ_t, it was found that the relationship between W_c/θ_t and the peripheral speed was very similar to that derived from the thermo-junction and represented in Fig. 10. The nearest mathematical representation of the curve through the mean of the points appeared to be given by

$$W_c/\theta_t = 1\cdot4 + 0\cdot65v + 0\cdot03v^2$$

but a close and simple relationship was given by

$$W_c/\theta_t = 1\cdot17v$$

Since the temperature-rise by thermometer is proportional to the iron and slot I^2R losses, the most reasonable surface to be taken into account is the external cylindrical area of the armature core, namely, 5·6 dm² for the present machine. Hence,

$$\text{Watts/dm}^2\text{/deg. C.} = 0\cdot 18v \quad . \quad . \quad . \quad (7)$$

Temperature-Rise by Thermo-junction Outside Armature Core.—The relationship between W_c/θ_j and the peripheral speed in Fig. 10 is expressed very closely by

$$W_c/\theta_j = 0\cdot 5 + 1\cdot 25v + 0\cdot 0246v^2$$

and fairly closely by

$$W_c/\theta_j = 1\cdot 64v$$

From the latter we have

$$\text{Watts/dm}^2\text{/deg. C.} = 0\cdot 252v \quad . \quad . \quad . \quad (8)$$

Comparison of the Above Results with those of Other Investigators.—It is of interest to compare expressions (6) and (7) with the two that are most commonly employed for estimating temperature-rise, namely

$$\text{Watts/dm}^2\text{/deg. C.} = A(1 + 0\cdot 1v)\ [*] \quad . \quad (9)$$

$$\text{Watts/dm}^2\text{/deg. C.} = B(1 + 0\cdot 097v^{1\cdot 3})\ [†] \quad (10)$$

where A and B are constants.

TABLE 3.

Peripheral speed	Relative values of temperature-rise/watt/dm².			
	From (6):— $\frac{8\cdot 5}{1 + 0\cdot 5v}$	From (7):— $\frac{15}{v}$	From (9):— $\frac{2\cdot 5}{1 + 0\cdot 1v}$	From (10):— $\frac{4\cdot 27}{1 + 0\cdot 097v^{1\cdot 3}}$
m/sec.				
0	8·5	—	2·5	4·27
5	2·43	3·0	1·67	2·39
10	1·42	1·5	1·25	1·45
15	1·0	1·0	1·0	1·0
20	0·773	0·75	0·833	0·743
25	0·63	0·6	0·71	0·583
30	0·532	0·5	0·625	0·473

Since our purpose just now is to examine the way in which the velocity enters into the various expressions for temperature-rise and to compare the results obtainable from them, the coefficients of expressions (6), (7), (9) and (10) will be so chosen as to give the same value, say 1·0, for the temperature-rise per watt per dm² at 15 metres per sec. On this basis Table 3 has been calculated.

From Table 3 it will be seen that at low peripheral speeds expression (9) considerably underestimates the temperature-rise, whilst at high speeds it tends to overestimate the rise; but if this formula be used only over a limited speed range it may be sufficiently satisfactory for most practical purposes. It is also evident from Table 3 that expressions (6) and (10) are in sufficiently close agreement between 5 and 30 metres per sec. as to be equally satisfactory. At very low speeds, however, even expression (10) may be in considerable error. A comparison of the values for (6) and (7) shows that, though they were derived from resistance and thermometer measurements respectively, they are in reasonably good agreement except at speeds below about 5 metres per sec.

Formulæ of the type represented by (9) and (10)—especially the former—have been so widely used by designers that the author would hesitate to suggest the modified forms (6) and (7) without other evidence. It is therefore of interest to note that both Luke [*] and Hinlein [†] found the temperature-rise per watt per dm² to fall very rapidly with increase of peripheral speed between 0 and 5 metres per sec. The values given in column (*a*) of Table 4 were obtained on a rotor, 25 in. diameter and 36 in. long, made of 0·875 in. bare monel-metal strip wound on the outside of a micarta drum, the strip acting as the heater. The drum was rotated in air with no housing surrounding it. The values in column (*b*) were obtained on an experimental model of end-windings, 25 in. diameter and 22 in. long. This was also rotated in air without any housing. The data by Hinlein were derived from a revolving cylinder coated with dynamo varnish. To facilitate the comparison of these results with one another and with the values given in Table 3, columns 5, 6 and 7 in Table 4 have been calculated on the basis of unity at 15 metres per sec.

TABLE 4.

30	1·12	1·34	3·22	0·644	0·736	0·74

In view of the figures given in Table 4 and of the results embodied in expressions (6) and (7), the author has no hesitation in suggesting that the formula

---

[*] After KAPP.

[†] C. C. HAWKINS: "The Dynamo," 6th ed., vol. 2, p. 210.

[*] *Loc. cit.*

[†] H. D. SYMONS and M. WALKER: "Heat Paths in Electrical Machinery," *Journal I.E.E.*, 1912, vol. 48, p. 689.

$A(1 + 0 \cdot 1v)$, so commonly employed for calculating temperature-rise, does not attach adequate importance to the velocity term. Formula (10) is more satisfactory than (9) but is much clumsier than either (6) or (7) above.

There is one other point of interest in Luke's results, namely the variation in the exponent of v. It has already been mentioned on page 914 that the watts/dm²/deg. C. for his rotating drum were represented by $(A_1 + B_1v^{0 \cdot 93})$ up to 20 metres per sec., and by $(A_1 + B_2v^{0 \cdot 6})$ above 25 metres per sec. For his rotating winding the expressions were of the form $(A_2 + B_3v^{0 \cdot 75})$ up to about 15 metres per sec. and $(A_2 + B_4v^{0 \cdot 54})$ between 15 and 50 metres per sec. On the machine tested by the author there was no indication of the exponent decreasing below unity; in fact, a curve drawn through the mean of the experimental points in Fig. 10 and the corresponding curve for the temperature-rise by thermometer have gradually increasing slopes corresponding to an exponent of about 1·1. The difference in behaviour between Luke's models and the actual machine may be due to air turbulence caused by the pole-tips of the machine; whereas with the models the air tends to be carried round with the rotor, there being nothing except centrifugal force tending to displace it. In other words, the results go to show that relationships derived from incomplete models must not be applied indiscriminately to actual machines.

Comparison of Temperature-Rises Measured by Resistance, Thermometer and Thermo-junction.—It has already been pointed out that both the thermometer and the thermo-junction gave readings that were proportional to the iron and slot I^2R losses, whilst the resistance measurements gave a temperature-rise that was proportional to the total armature loss. It has also been shown that, for the particular machine tested:—

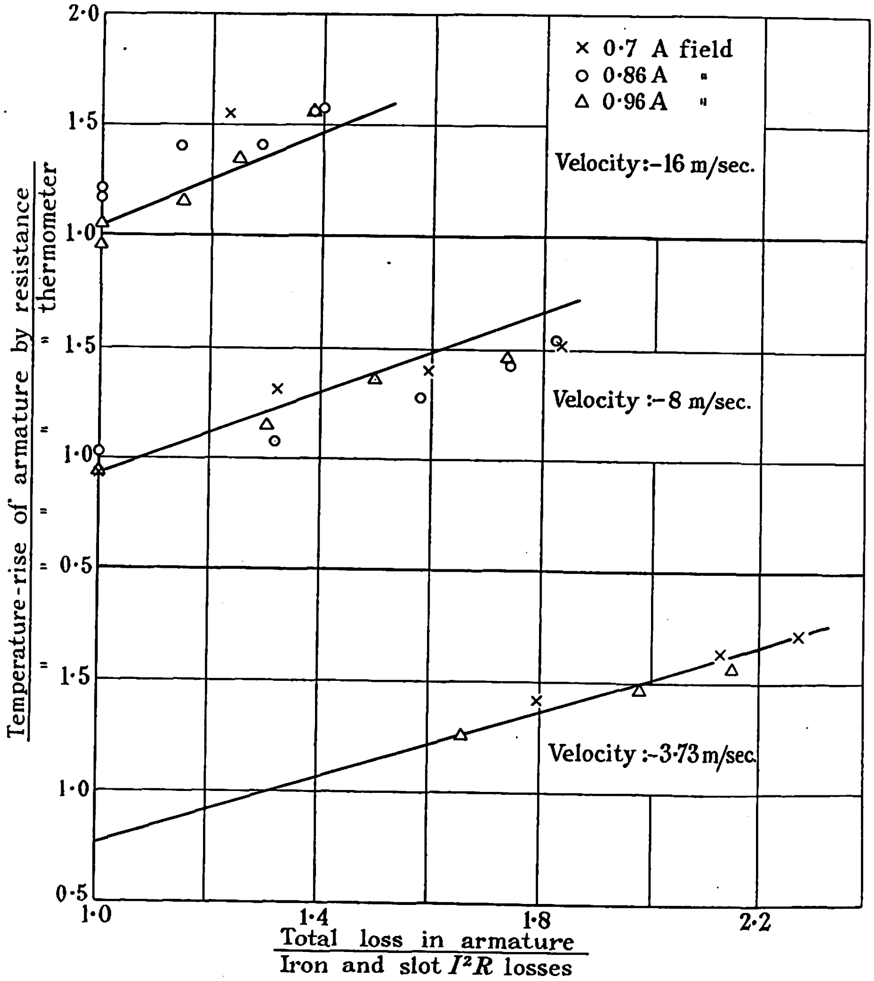

FIG. 11.

$$\frac{\text{Total armature losses}}{\text{Temp.-rise of winding by resistance}} = 2(1 + 0 \cdot 5v)$$

$$\frac{\text{Iron and slot } I^2R \text{ losses}}{\text{Temp.-rise of core by thermometer}} = 1 \cdot 17v$$

and

$$\frac{\text{Iron and slot } I^2R \text{ losses}}{\text{Temp.-rise by thermo-junction}} = 1 \cdot 64v$$

Hence

$$\frac{\text{Temp.-rise by resistance}}{\text{Temp.-rise by thermometer}} = \frac{\text{total armature losses}}{\text{iron and slot } I^2R \text{ losses}} \times \frac{0 \cdot 585}{(1/v) + 0 \cdot 5}$$

$$\frac{\text{Temp.-rise by resistance}}{\text{Temp.-rise by junction}} = \frac{\text{total armature losses}}{\text{iron and slot } I^2R \text{ losses}} \times \frac{0 \cdot 82}{(1/v) + 0 \cdot 5}$$

and

$$\frac{\text{Temp.-rise by thermometer}}{\text{Temp.-rise by junction}} = 1 \cdot 4$$

In Figs. 11, 12 and 13, the ratios of the temperature-rises obtained experimentally have been plotted against the ratio of the total armature losses to the iron and slot I^2R losses; and the straight lines in these diagrams represent the values calculated from the above expressions. The agreement between the calculated and the experimental values in Fig. 11 is sufficiently good to show that the ratio of the temperature-rise by resistance to that by thermometer is mainly dependent upon the ratio of the total losses to the iron and slot I^2R losses.

An attempt was made to apply Karapetoff's two-chunk theory * to the above results, but without any satisfaction.

Suggested Application of the Thermo-junction Method.—It will be seen from Fig. 13 that the temperature-rise indicated by the thermo-junction bears practically a constant ratio to that of the armature core as measured by thermometer, and that this ratio is almost independent of the distribution of losses, of speed and of excitation. It is therefore suggested that such a thermo-junction can with advantage be used for following the rise of temperature of the armature core during a heat test and for determining when the temperature attains a

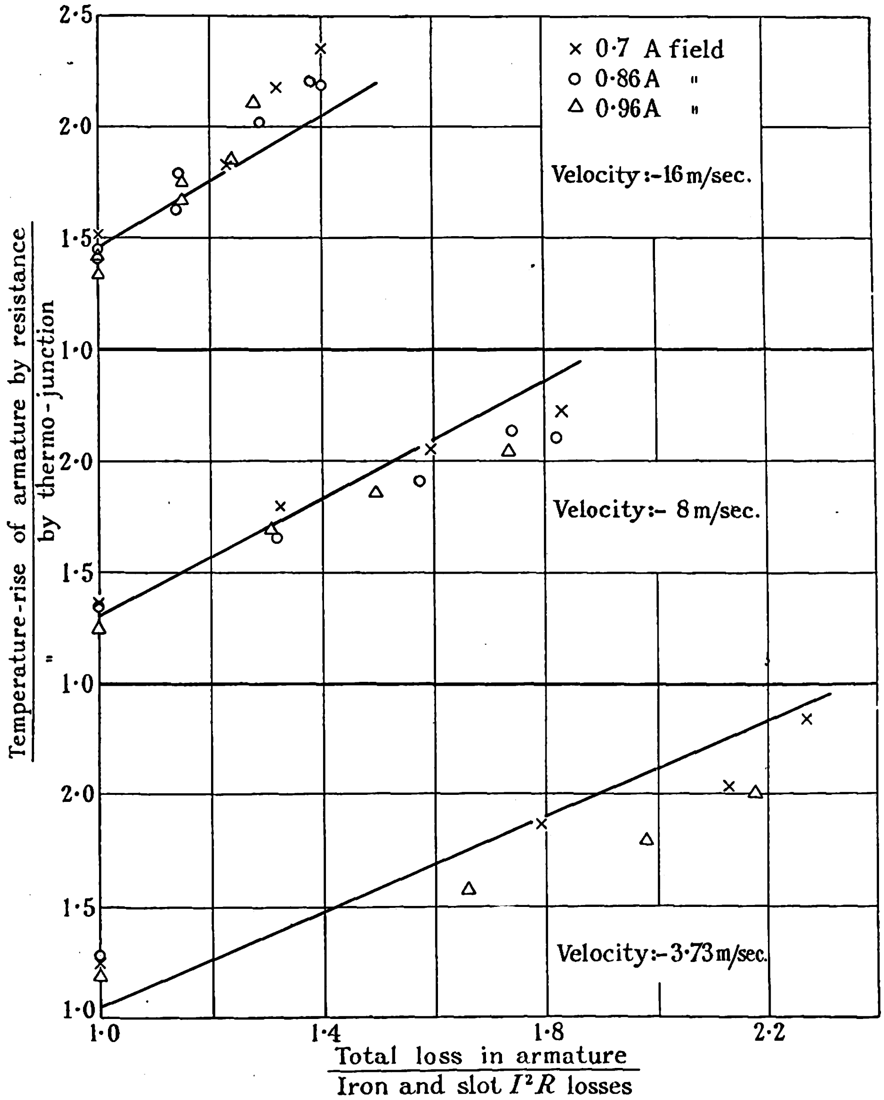

FIG. 12.

---

* "Parameters of Heating Curves of Electrical Machinery," *Transactions of the American I.E.E.*, 1926, vol. 45, p. 349.

steady value. It will be granted that the heating time-constant of the armature is usually shorter than that of the field and that if the heating test be continued with a *constant* load until the field temperature is steady the temperature of the armature will also have attained its maximum value. By means of a thermo-junction, however, it is possible to shorten * the heat test considerably by overloading the armature and field until their temperatures have attained approximately their anticipated values. The load and exciting currents are then re-adjusted to the correct values and the changes in the temperatures of the field and thermo-junction noted.

The curves in Fig. 14 are typical of the results obtained under these conditions. In this particular test the armature and field currents were kept at 10·5 and 0·96 amperes respectively for 76 minutes and then reduced to 9·22 and 0·86 amperes. The curves obtained with this method of loading all exhibited the peculiarity that, after readjustment of the currents, the temperatures first of all fell and then increased again to their final values. This phenomenon appears to be due to the time-lag in the temperature-rises of the armature and pole-cores, and was much more marked for the armature winding than for the thermo-junction.

In view of this possible application it is desirable to investigate how the temperature of the junction varies with its radial distance from the armature core. The curves in Fig. 15 show the results obtained on two machines. The latter were run on load until the temperature became steady, and readings were taken with the junction at different radial distances from the core, the load being maintained constant. Curve A applies to the machine on which all the preceding tests were performed, and curve C was obtained on a 7·5-b.h.p. shunt motor. Further particulars of these tests are given in Table 5.

It will be seen that the temperature of the thermo-junction falls very rapidly near the surface and then becomes fairly constant. The greater radial distance over which the temperature fell in machine C was probably due to the longer air-gap allowing a greater thickness of air to be carried round with the armature; and the slight rise in curve C between 1 and 5 cm may be due to the comparatively small clearance between the field coils in this particular machine.

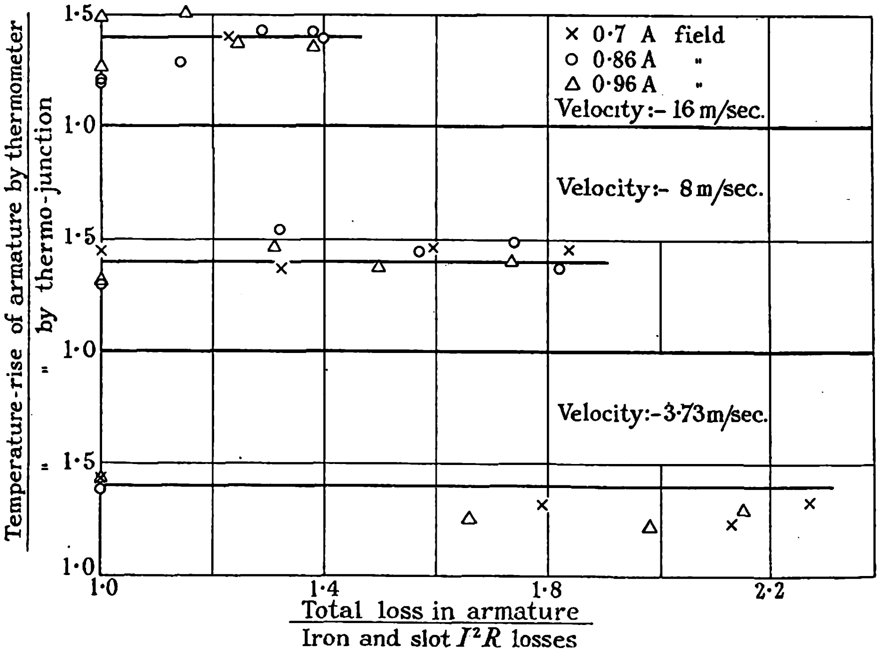

FIG. 13.

These tests appear to indicate (*a*) that so long as the thermo-junction is at a distance greater than the gap length from the core, its temperature is fairly constant for a relatively large variation of that distance; and

TABLE 5.

Machine	Curve A	Curve C
Temp.-rise of armature core by thermometer ..	28 deg. C.	20·8 deg. C.

Temp.-rise of field winding by resistance	35·2 deg. C.	34·6 deg. C.
Peripheral speed, metres per sec.	8	12·6
Radial length of air-gap, mm.	1·8	2·6

---

* It has often been suggested that the final temperature-rise can be computed from short heat-runs by assuming the heating curve to be exponential. This problem is fully discussed by the author in another paper (see page 932), where it is shown that the steady temperature-rise of windings calculated from the initial portion of the heating curves plotted from carefully observed readings is less than the actual value.

(*b*) that the temperature-rise of the core as measured by thermometer is about 1·4 to 1·5 times that indicated by the thermo-junction under these conditions.

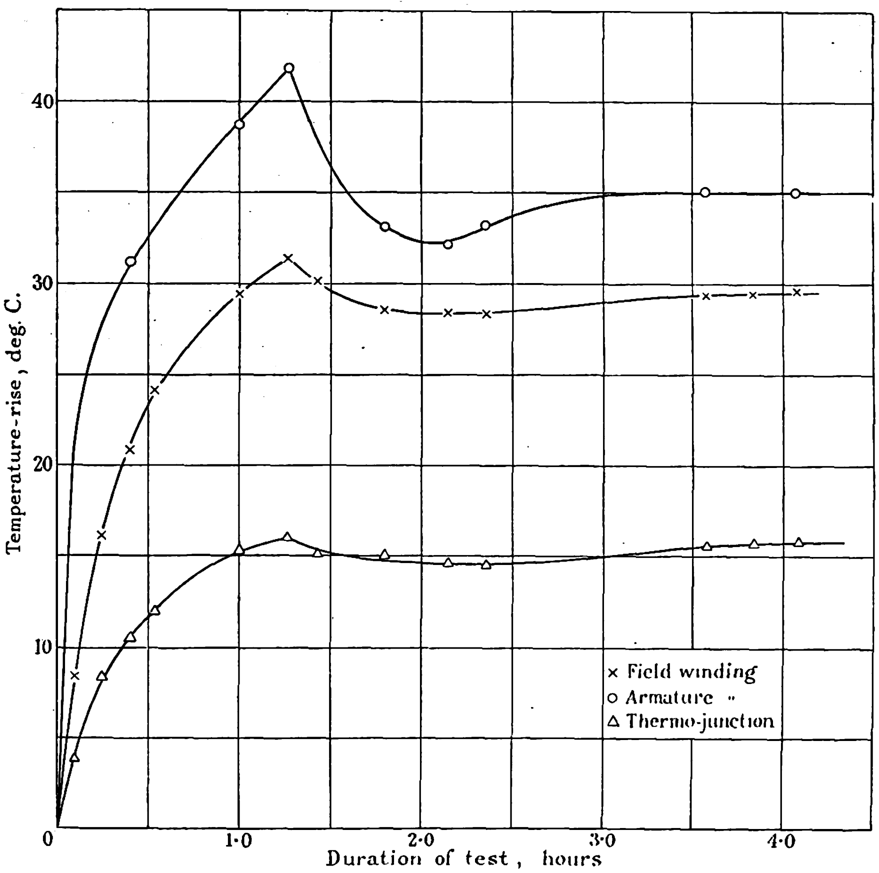

FIG. 14.

(2) TESTS ON MACHINE WITH REVOLVING FIELD.

Temperature-Rise of Field Winding.—The variation of the field temperature-rise per watt with speed, excitation and total stator losses was somewhat similar to that already found for the stationary field winding of machine A and represented in Figs. 1 and 2. From the graphs, the watts per deg. C. rise for *no* stator loss have been derived for different speeds and are represented by curves C and D in Fig. 16. These curves are represented very closely by

$$W_f/\theta_f = 2\cdot4 + 0\cdot71\sqrt{v} \text{ for C}$$

and

$$W_f/\theta_f = 2\cdot7 + 0\cdot71\sqrt{v} \text{ for D}$$

In view of the results obtained with machine A when the values of θ_f/W_f were plotted against the difference of field and armature temperatures, the same procedure was tried with machine B, the values being shown in Fig. 17. It will again be seen that the temperature-rise per watt of the field winding is a function of the difference between the temperature-rises of the field and stator windings and is practically independent of the exciting current. From Fig. 17 the values of W_f/θ_f at different speeds for equal temperature-rises of the field and stator windings have been determined and plotted in Fig. 16. These points lie very closely to a curve representing the formula

$$\begin{aligned} W_f/\theta_f &= 2 + 0\cdot57\sqrt{v} \\ &= 2(1 + 0\cdot285\sqrt{v}) \quad . \quad . \quad . \quad . \quad (11) \end{aligned}$$

It did not appear possible to develop a general expression in any way comparable with (5) for machine A. The main conclusions, however, are that the value of the temperature-rise per watt is considerably influenced by the stator temperature and a function of the square root of the speed.

It is interesting to compare the thermal behaviour of a rotating field with that of the rotating armature previously investigated. Thus, we find that:—

(*a*) The temperature of the rotating field is influenced by that of the stator, whereas the temperature of the rotating armature is independent of that of the field winding. This difference seems to be due to the insulating cheeks of the field winding, together with the pole-tips in the latter case preventing any radiation towards the armature; whilst, in the former case, heat is radiated inwards partly from the end windings towards the field winding and partly from the internal surface of the stator core.

(*b*) The effect of speed upon the temperature-rise of the rotating field is not nearly as great as in the case of the rotating armature, as will be evident from a comparison of (11) and (6). This difference would appear to be due to the relatively smaller loss by convection from the rotating field than from the rotating armature.

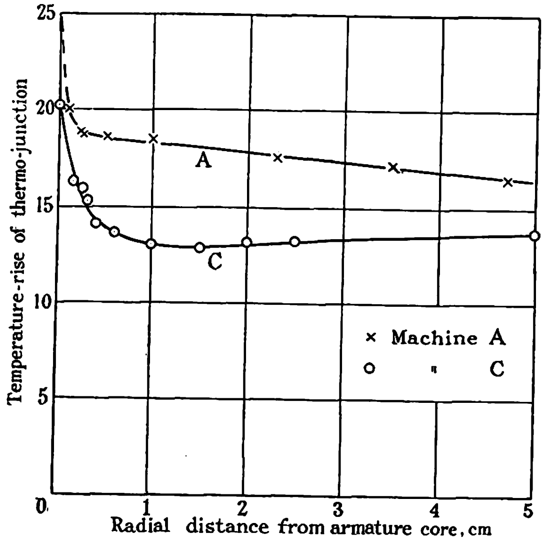

FIG. 15.

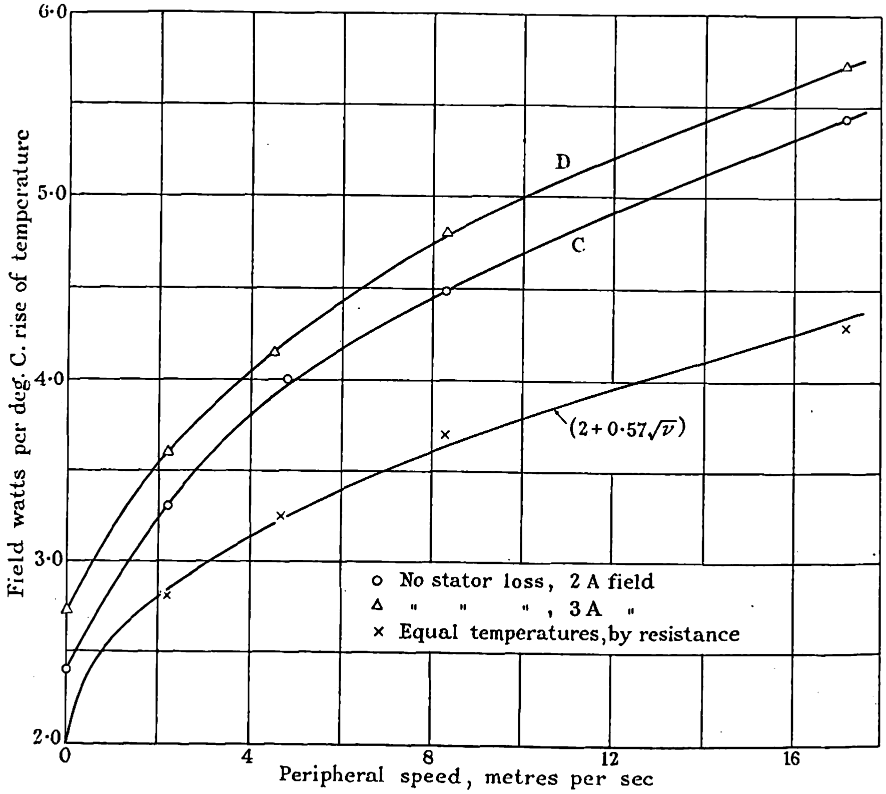

FIG. 16.

(*c*) A comparison of (3) and (11) shows that the variation of the temperature-rise per watt with speed for the rotating field is surprisingly similar to that for the stationary field.

Temperature-Rise of Stator.—Temperatures were measured by (*a*) increase of resistance of the winding, (*b*) thermo-junction attached to the outer surface of the core, and (*c*) thermo-junction inserted in the radial duct, as described on page 912. Difficulty was at first experienced in deciding whether the temperature-rise of the winding, for instance, was a function of the total stator loss or of the I^2R loss only, as both relationships gave good linear graphs. This difficulty was overcome by plotting the corresponding values for excitations of 2 and 3 amperes on the same axes. If the curves thus obtained were reasonably parallel, as in Figs. 18 and 19, the particular temperature concerned could be taken as a linear function of the quantity plotted as abscissa. On the other hand, if the curves intersected so that some of the temperature-rises for 2-ampere excitation were greater than those for 3 amperes, such relationships could not be accepted even if the points did give straight-line graphs. In this way it was found:—

(*a*) That the temperature-rise of the stator winding, measured by resistance, was a linear function of the stator I^2R loss (Fig. 18). This conclusion is conceivable from the fact that 63 per cent of the winding was accounted for by end-connections. Furthermore, most of the heat due to the iron loss probably flows outwards to be dissipated by the external surface of the core.

(*b*) That the temperature-rises of the core and duct were linear functions of the total stator losses (Fig. 19). It had been anticipated that these temperatures would have been more closely related to the iron and slot I^2R losses; but this was not supported by experimental evidence. On the other hand, the ventilating air on its way outwards would tend to convey some heat from the end connections to the core.

The next problem was to investigate the effect of speed upon the stator temperature. It will be seen from Fig. 18 that the temperature-rise of the winding at a given speed can be regarded as being due to (*a*) the interception the vertical axis—a quantity that appears to be mainly a function of the excitation—and (*b*) to a component that is proportional to the stator copper loss;

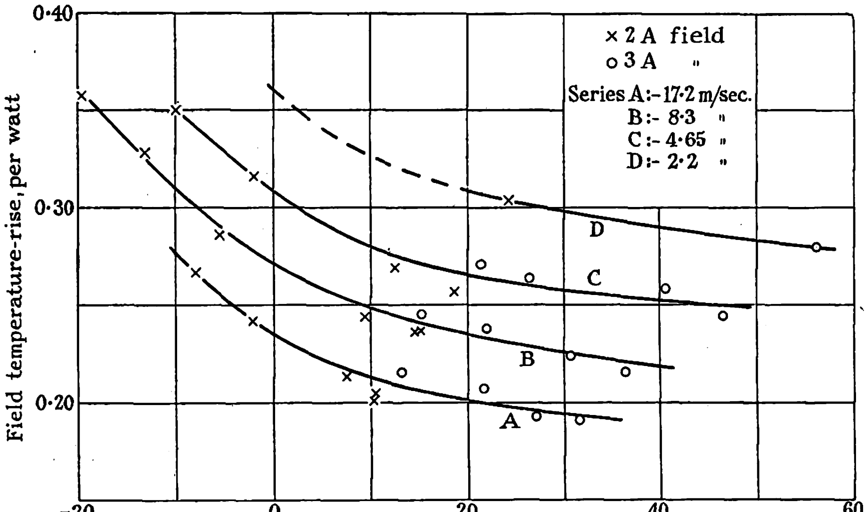

FIG. 17.

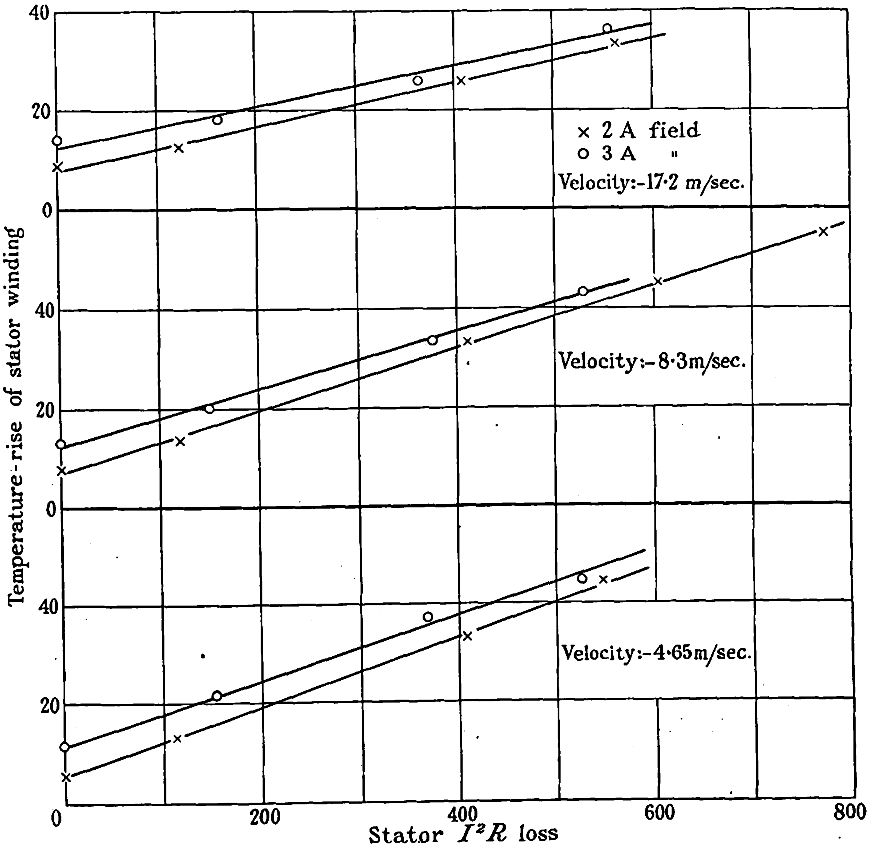

FIG. 18.

i.e. the temperature-rise by resistance can be represented approximately by

$$\theta_r = a_r\theta_f + b_r W_c$$

where W_c = total copper loss,
b_r = a coefficient that is a function of the speed,
and $a_r\theta_f$ = temperature-rise due to the excitation.

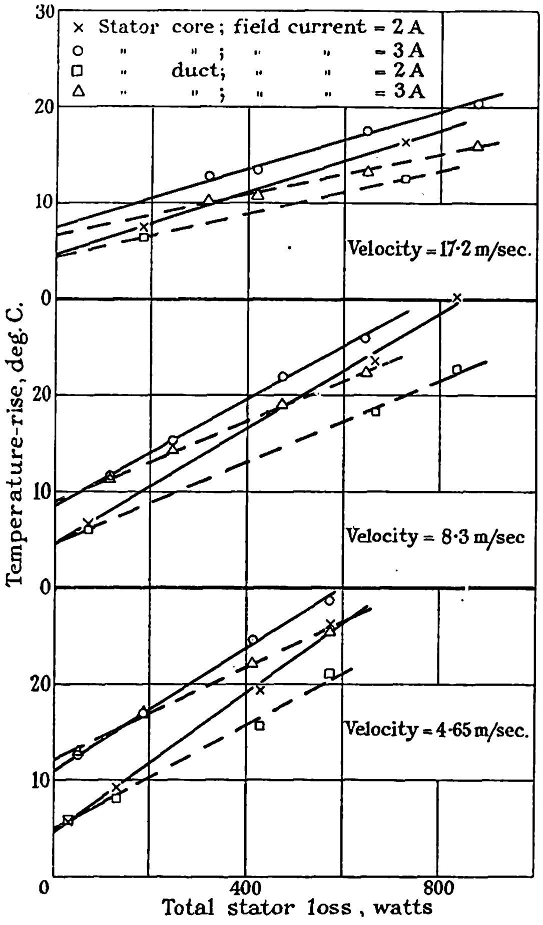

FIG. 19.

Similarly, for the core and the duct junctions, we have

$$\theta_c = a_c\theta_f + b_c W_t$$

and

$$\theta_d = a_d\theta_f + b_d W_t$$

where W_t = total stator loss.

The relationships between the speed and the various coefficients b were determined by plotting $1/b$, i.e. the inverse of the slopes of the different graphs in Figs. 18 and 19 against speed as in Fig. 20. From the latter, it is obvious that the relationship is of the form

$$1/b = c + dv^x$$

The value of c is slightly affected by the excitation, but the values of d and x are practically the same for exciting currents of 2 and 3 amperes. From logarithmic curves, x was found to be 1·79 for curves A, 2·08 for B and 2·10 for C; in other words, the exponent of v for the three curves is approximately 2. By taking the mean of each of the pairs of curves in Fig. 20, it was found that the following expressions represented fairly closely the relationships between the temperature-rises, the power and the speed:—

$$\theta_r = a_r\theta_f + \frac{W_c}{13\cdot5(1 + 0\cdot0027v^2)} \quad . \quad . \quad (12)$$

$$\theta_c = a_c\theta_f + \frac{W_t}{27(1 + 0\cdot0043v^2)}$$

and

$$\theta_d = a_d\theta_f + \frac{W_t}{37(1 + 0\cdot0045v^2)}$$

It is of particular interest to find that these expressions involve the second power of the velocity, whereas for the stationary field-winding of machine A the velocity appeared as a square-root term. Further, most investigators have found that with forced ventilation the exponent of the velocity lies between 0·5 and 1·0; thus J. A. Hughes [*] gives the loss of heat from different cylindrical tubes at 100° C. as proportional to v^n, where n varies from 0·55 for a 0·17-in. diameter tube to 0·98 for a tube 2 inches in diameter. The heat dissipation due to an air-flow between two parallel flat plates with various spacings was found by Luke [†] to be proportional to $v^{0\cdot8}$. With various other arrangements of surfaces he found the heat transfer to be proportional to v^n, where n ranged from 0·7 to 0·93. In Luke's experiments, however, the air-flow was parallel to the dissipating surface. Also, the theoretical investigations of Rice [‡] and Davis [§] suggest that the exponent of the velocity may vary between about 0·5 and 1.

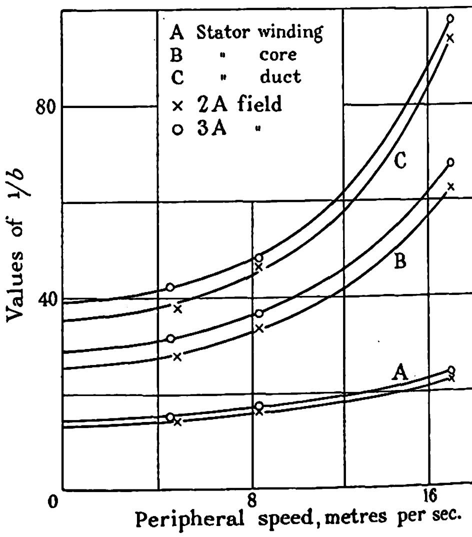

FIG. 20.

In contrast with the above are the results obtained by Symons and Walker [‖] for the temperature-rise of a coil and of a brass cylinder for different air velocities up to 3·5 metres per sec., the air being blown on to the coil from two diametrically opposite sides. For the brass cylinder and the coil of cotton-covered wire the temperature-rises per watt per dm² were $9\cdot 1/(1+0\cdot 78v^2)$ and $9\cdot 1/(1+0\cdot 54v^2)$ respectively. The radial depth of the cylinder and coil was small compared with the diameter. Also, the diameters employed were far greater than those of the wires and tubes used by the other investigators. In view of the results obtained with induced draught in Section 4 of this paper, this matter is discussed more fully at the end of that section.

(3) MACHINE B (ROTATING FIELD) AS A TOTALLY-ENCLOSED TYPE.

The machine was made totally-enclosed by fitting sheet-iron covers over all the openings. The test procedure was precisely the same as before.

Temperature-Rise of Field Winding.—The field temperature-rise per watt was found to be dependent upon the speed, the excitation and the total stator losses in a somewhat similar manner to that found for the same machine arranged as a protected type. From graphs based upon test results, the values of W_f/θ_f for zero stator loss have been derived and plotted in Fig. 21. These curves are represented fairly closely by

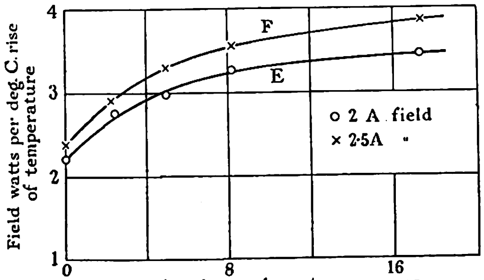

FIG. 21.

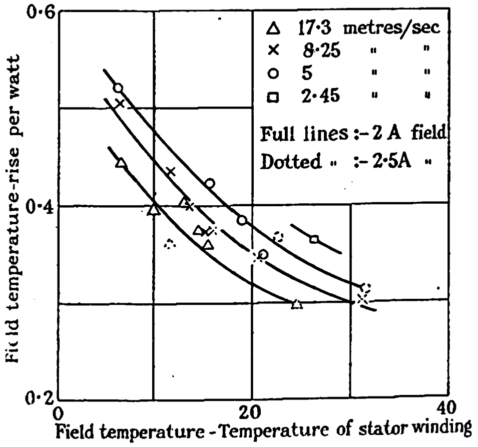

FIG. 22.

$$W_f/\theta_f = 2\cdot 2 + 0\cdot 33\sqrt{v} \text{ for E}$$

and
$$W_f/\theta_f = 2\cdot 4 + 0\cdot 38\sqrt{v} \text{ for F}$$

A comparison of these expressions with those obtained for the machine as a protected type (page 923) shows that the first term is almost identical, probably due to its representing the heat dissipated by radiation. The second term, however, is practically halved, thus showing that the effect of speed on the cooling of the rotating field is far smaller in a totally-enclosed than in a protected-type machine.

Fig. 22 shows the variation of θ_f/W_f with the difference between the temperature-rises of the field and stator windings. It will be seen that the results did not cover a sufficiently wide range to enable the values of θ_f/W_f to be deduced for equal temperature-rises, but they do show that the temperature-rise per watt of the field winding is dependent upon the difference of rotor and stator temperatures and upon the peripheral speed of the rotor but is practically independent of the exciting current. The influence of the relative temperatures of the rotor and stator is, in fact, much greater than for the machine as a protected type (Fig. 17).

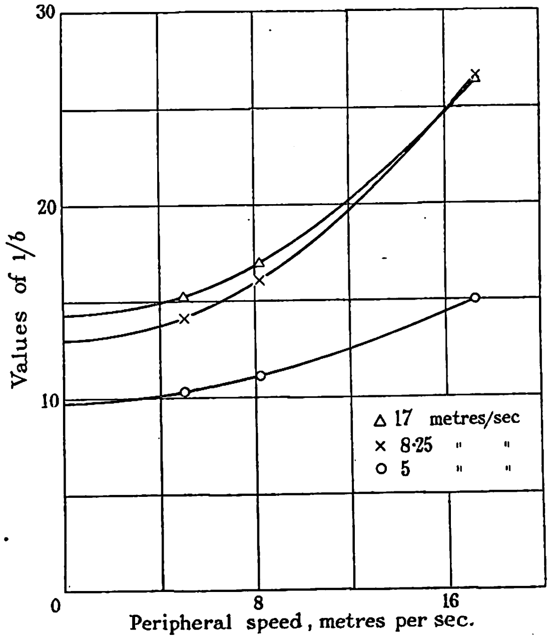

FIG. 23.

Temperature-Rise of the Stator.—The same procedure as that employed in Section (2) was again used for the analysis of these results. Thus, it was found that the temperature-rises of the winding, of the core and of the duct were all functions of the *total* stator loss. From the graphs it was found that the temperature-rise could again be represented by an expression of the form

$$\theta = a\theta_f + bW_t$$

where $a\theta_f$ = temperature-rise due to influence of excitation,

W_t = total stator loss,

and b = a coefficient that is a function of the speed.

The inverse of the slopes of the various graphs, namely $1/b$, has been plotted against the peripheral speed in Fig. 23, from which the relationship again appears to be

$$1/b = c + dv^x$$

The value of x is very nearly 2 in each case; and the temperature-rises are given very closely by

$$\theta_r = a_r\theta_f + \frac{W_t}{9\cdot8(1 + 0\cdot0019v^2)}$$

$$\theta_c = a_c\theta_f + \frac{W_t}{13\cdot1(1 + 0\cdot0034v^2)}$$

and $$\theta_d = a_d\theta_f + \frac{W_t}{14\cdot3(1 + 0\cdot0028v^2)}$$

where θ_r, θ_c and θ_d are the temperature-rises of the stator winding, core and duct respectively.

The question of the velocity entering as a square function has already been referred to in Section (2) and is again discussed on page 929. A comparison of the above expressions with those given for the protected type on page 926 shows that in the totally-enclosed machine the speed is relatively not so important, though the reduction for the stator is less than that already noted for the field winding.

(4) MACHINES A AND B, PIPE-VENTILATED WITH INDUCED DRAUGHT.

Induced ventilation was arranged in each case by fitting a short pipe, 7·5 cm internal diameter, to the sheet-iron cover of one of the bottom openings in the bearing bracket on the slip-ring side, and attaching a metal funnel to the sheet-iron cover on one of the upper openings in the bearing bracket on the coupling side, the outlet being diametrically opposite to the inlet. The air was drawn through the machine by a fan at the outer end of the funnel. The velocity of the air was measured at the inlet by means of a Negretti and Zambra anemometer.

The tests on machine B (revolving field) were performed with the idea of determining the influence of different air velocities with (*a*) different rotor speeds, and (*b*) different distributions of losses in stator and rotor. From the results with 2-ampere excitation, the following quantities have been plotted against air velocity in Fig. 24:—

(*a*) θ_f/W_f, where θ_f and W_f are respectively the temperature-rise and the field loss,

(*b*) θ_r/W_t, where θ_r is the temperature-rise by resistance of the stator winding and W_t is the total stator loss,

(*c*) θ_c/W_t, where θ_c is the temperature-rise of the core, and

(*d*) θ_d/W_t, where θ_d is the temperature-rise of the duct.

An inspection of the curves in Fig. 24 shows shat:—

(1) The shapes of the curves for θ_f, θ_r, θ_c and θ_d are very similar for a given rotor speed; and that all the curves, except those for 17·3 metres per sec., possess a double inflexion, and even these curves seem to indicate that if the draught speed had been increased far enough they also would have had a double inflexion.

(2) The lower the rotor speed, the lower is the air velocity at which the slope of the curves is a maximum.

(3) The effect of the speed of the induced draught upon the temperature-rise bears some resemblance to that of the rotor speed upon the temperature-rise of the stator when the machine is arranged as a protected type and also when it is totally enclosed.

It was at first thought that the difference in the shape of the curves in Fig. 24 might have been due to a variation in the distribution of the losses. This possibility was checked by taking a set of readings at a peripheral speed of 8·4 metres per sec. with a different exciting current, but keeping the total stator loss as nearly as possible the same as with the 2-ampere excitation. The results were similar in every respect to those obtained at the same peripheral speed with the latter excitation; hence the difference between the curves in Fig. 24 was not due to any redistribution of losses. This conclusion was also supported by similar results obtained on machine A.

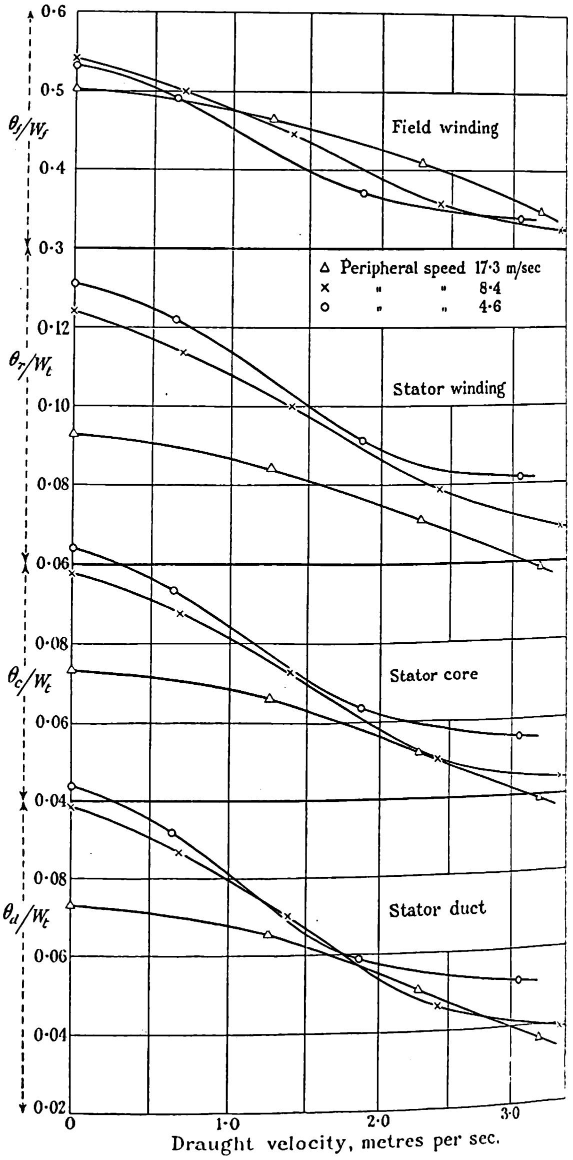

FIG. 24.

It was then thought that the difference was due to the influence of the induced draught upon the direction of the air currents inside the machine. Thus, it can be imagined that with a very low peripheral speed of the rotor the induced draught distributes itself more or less uniformly over the internal section of the machine; and since its direction is mainly axial as it passes the windings it is roughly in space quadrature with that of the air currents set up by the rotor. Consequently, the higher the peripheral speed the greater must be the draught velocity to produce a given change in the magnitude of the resultant air velocity, and thus the higher the draught velocity at which the inflexions noted in Fig. 24 may be expected to occur. Suppose v_r to be the radial air velocity at a certain point due to the speed of the rotor only. Then, if v_a be the axial speed of the air draught at that point due to the external fan, the resultant air velocity is given by $v = \sqrt{(v_r^2 + v_a^2)}$. Let us assume for simplicity that the heat dissipation depends upon the first power of the velocity, as has already been found for the armature of machine A; that is

$$\theta/W = \frac{k}{1 + av}$$
$$= \frac{k}{1 + a\sqrt{(v_r^2 + v_a^2)}} \quad . \quad . \quad . \quad . \quad (13)$$

where k and a are constants for a given machine.

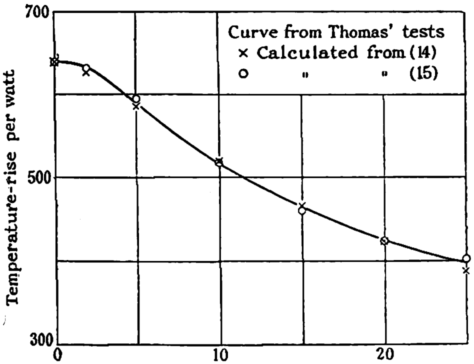

FIG. 25.

The curves in Fig. 24 and similar curves for machine A were investigated from the standpoint of this expression, and it was found that with a fixed value of v_r for a given peripheral speed of a machine the values calculated from (13) agreed very well with the experimental values.

This explanation also provides the reason for the features already noted for the curves of Fig. 24. Thus, the higher the peripheral speed of the rotor the greater is the value of v_r in expression (13), and consequently the greater must be the velocity of the induced draught to cause a given percentage change in the actual air velocity and thereby in the heating of the machine.

A further confirmation of the above explanation is to be found in the experimental work of J. S. G. Thomas.[*] From Fig. 2 of his paper, the temperature-rise per watt of the first of 11 filaments fixed in the same plane inside a tube has been calculated for different air velocities and is represented by the curve in Fig. 25, the only assumption being that the temperature of the incoming air was 15° C. As the temperature of the filament ranged from 560° to 220° C., an error of a few degrees in the air temperature makes very little difference to the calculated values. That this curve is closely represented by expression (13) is obvious from the crosses in Fig. 25, which represent points calculated from

$$\frac{\theta}{W} = \frac{680}{1 + 0 \cdot 03\sqrt{(2^2 + v^2)}} \quad . \quad . \quad . \quad (14)$$

where v = axial speed of air current in cm per sec.

In view of the square-law relationship already derived for the effect of peripheral speed on the cooling of the stator for both the protected and the totally-enclosed types, it is of interest to find that the curve in Fig. 25 is also represented very closely by

$$\frac{\theta}{W} = 350 + \frac{290}{1 + 0 \cdot 0073v^2} \quad . \quad . \quad . \quad (15)$$

Points calculated from this formula are indicated by circles.

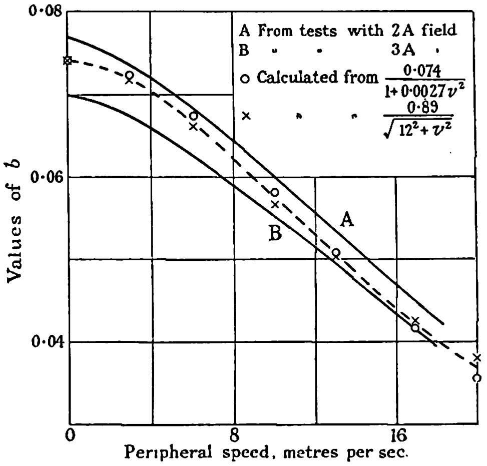

FIG. 26.

The agreement between the results calculated from (14) and (15) suggests that the relationships obtained on pages 926 and 928 should be replaced by expressions of the form represented by (14). In other words, it is suggested that the variation in the slopes of the graphs in Figs. 18 and 19 might be due to the combined effect of the natural draught produced by the hot windings and core and the forced draught caused by the rotation of the field winding. For instance, in Fig. 26 are given curves showing the variation of b (i.e. the slope of the graphs in Fig. 18) for the stator winding of the protected-type machine; and the values calculated from the second part of expression (12) have been indicated by circles. Further, the mean of the curves is represented fairly closely by

$$b = \frac{0 \cdot 89}{\sqrt{(12^2 + v^2)}} \quad . \quad . \quad . \quad . \quad (16)$$

---

[*] "Thermal Effect of a Slow Current of Air Flowing Past Heated Platinum Wires," *Philosophical Magazine*, 1921, vol. 41, p. 240. Somewhat similar experimental results have recently been obtained by R. S. MAXWELL (*ibid.*, 1928, vol. 56, p. 945), by noting the cooling of a filament attached to the prong of a fork.

points calculated from (16) being indicated by crosses. Similar results were obtained with the core and the duct for both the protected and the totally-enclosed types.

It will be seen from (16) that this hypothesis requires the speed of the natural convection currents to be equivalent to those produced by a rotor peripheral speed of about 12 metres per sec. Such an assumption appears almost inconceivable, especially as the two components are only in space quadrature at diametrically opposite points on a horizontal plane through the centre of the machine. At the top of the machine the two components are in the same direction, whereas at the bottom they are in opposition. Also, the objection might be raised that the effect of these natural convection currents was not noticeable with the field winding of either of the machines tested, nor was it noticeable with the winding of the rotating armature. In the latter case, however, it should be pointed out that the results for the core and the thermo-junction (Fig. 10) can be taken as indicating the presence of appreciable natural convection. In the case of the field windings, the air tends to glide over the surface rather than impinge against it. With the stator winding and core, on the other hand, the air is impelled towards them, and this may account for the exponent of the air velocity being higher than for the field winding. This suggestion is supported by the results obtained by J. A. Hughes and quoted on page 926, namely that the exponent increases with increase in the size of the pipe. If Langmuir's film theory be accepted, it follows that the larger the diameter of the pipe the thinner relatively is the air film, and consequently the greater the tendency for the air to impinge normally on to the surface of the pipe.

It appears likely that a good deal of the discrepancies between the experimental results obtained by different investigators is due to the difference in the mode in which the air comes into contact with the dissipating surface and to the disposition of the latter. Thus, the cylinder and coil tested by Symons and Walker and referred to on page 927 appear to be about 8 in. long and 4 in. diameter and were tested with their axes vertical, the air being directed against diametrically opposite portions of their surfaces. Under these circumstances, natural convection would undoubtedly influence the lower portions of the curves in Figs. 11 and 12 of Symons and Walker's paper.

From the above discussion, however, it is obvious that for most practicable purposes it is not possible to take into account all the factors that are introduced even by one variable such as the air velocity; and that in such cases one is forced to use formulæ similar to (12) which may not be fundamentally sound but which are comparatively simple and at the same time give a reasonable degree of accuracy over the ranges for which they have been derived.

CONCLUSIONS.

(*I*) *Protected-Type Machine with Rotating Armature.*

(*a*) *Field Winding.*

(1) The temperature-rise per watt is dependent upon the difference between the temperature-rises of the field and armature windings, the variation of θ_f/W_f per deg. C. difference of temperature being about 1 per cent for temperatures measured by increase of resistance and about 1·4 per cent for those measured by thermometer.

(2) For equal temperature-rises of the field and armature, the temperature-rise per watt is represented by $2 \cdot 7(1 + 0 \cdot 25\sqrt{v})$.

(3) For field temperature-rises deduced on the assumption that the armature has no loss, the variation of W_f/θ_f with speed is very similar to that derived from models by G. E. Luke, but is different from that with the armature loaded.

(4) By means of expression (5), the effects of speed and of armature temperature can be allowed for in calculating the temperature-rise of the field.

(*b*) *Armature Winding.*

(1) The temperature-rise of the winding is practically proportional to the total armature loss and independent of the field temperature.

(2) The temperature-rises of the core and of the thermo-junction placed just outside the armature are practically proportional to the iron and slot I^2R losses and independent of the field temperature.

(3) The watts dissipated per dm^2 per degree rise of temperature is practically a linear function of the speed, being $0 \cdot 13(1 + 0 \cdot 5v)$ for the armature winding and $0 \cdot 18v$ for the armature core.

(4) The effect of velocity is much greater than is represented by the expression $(1 + 0 \cdot 1v)$ commonly used. The latter may considerably underestimate the temperature-rise at low speeds. Hawkins's formula is in fairly good agreement with that obtained for the armature winding but is much more awkward to manipulate. The importance of the velocity term is also confirmed by the experiments of Luke and Hinlein.

(5) The ratio of the temperature-rise by resistance to that by thermometer is a function of the ratio of the total armature loss to the iron and slot I^2R losses, and is also influenced by the peripheral speed.

(6) The ratio of the temperature-rise of the core to that of the thermo-junction remained practically constant at about 1·4. This ratio was only slightly affected by a variation in the distance between the armature and the junction, so long as this distance exceeded the length of the air-gap. It is suggested that by the use of such a thermo-junction the duration of the heating test can be shortened by an initial overloading of the armature and field windings. When the temperatures have attained their anticipated values the currents are adjusted to their normal values. It is shown in a separate paper * that it is impossible to calculate accurately the final temperature-rise from the initial portion of the heating curve.

(*II*) *Protected-Type Machine with Rotating Field.*

(*a*) *Field Winding.*

(1) For equal temperature-rises of the field and stator windings, the power in watts dissipated per degree rise of temperature is represented by $2(1 + 0 \cdot 285\sqrt{v})$.

---

* E. HUGHES: "Determination of the Final Temperature-Rise of Electrical Machines from Heating Tests of Short Duration," *Journal I.E.E.*, 1930, vol. 68, p. 932.

This relationship is very similar to that for the stationary field-winding.

(2) The temperature-rise per watt is dependent upon the difference between the temperatures of the field and stator windings, but the variation is smaller than that for the stationary field-winding.

(*b*) *Stator.*

(1) The temperature-rise of the winding is a linear function of the stator I^2R loss.

(2) The temperature-rises of the core and duct are linear functions of the total stator losses.

(3) The temperature-rises of the winding, core and duct appear to be functions of the square of the speed [see IV (4) below].

(*III*) *Totally-Enclosed Machine with Rotating Field.*

(*a*) *Field Winding.*

(1) The temperature-rise per watt derived for no stator loss is very similar to that for the protected-type machine, except that the effect of the speed is much smaller.

(2) The temperature-rise is more affected by the stator temperature than in the case of the protected-type machine.

(*b*) *Stator.*

(1) The temperature-rises of the winding, core and duct are all linear functions of the total stator loss.

(2) They also appear to be functions of the square of the peripheral speed, though the effect of the speed is not so great as in the protected-type machine [see IV (4) below].

(*IV*) *Both Machines, with Induced Draught.*

(1) The curves of temperature-rise per watt plotted against draught velocity possess a double inflexion, and the lower the rotor speed the lower is the draught velocity at which the slope is a maximum.

(2) The difference between the shapes of the curves for different peripheral speeds is not due to any alteration in the distribution of the losses.

(3) The double inflexion appears to be due to the actual air velocity in the vicinity of the windings being the resultant of two air currents in space quadrature, namely, the induced draught and the radial air currents set up by the rotation of the machine. Consequently, the higher the peripheral speed of the rotor, the greater must be the draught velocity to produce a given percentage change in the resultant air velocity.

(4) The relationship between the temperature-rise and the draught velocity is very similar to that connecting the peripheral speed with the temperature-rises of the stator winding, core and duct of the protected and totally-enclosed machines and attributed to the cooling being a function of the square of the velocity. In consequence, it is suggested that much of the discrepancy concerning the effect of air velocity between the experimental results of different investigators is due to the presence of natural convection currents of air, the magnitude of which depends upon the disposition and the relative proportions of the cooling surfaces.

The author desires to express his gratitude to the Principal and the Governors of the Municipal Technical College, Brighton, for facilities to carry out the experimental work described in this paper.

DETERMINATION OF THE FINAL TEMPERATURE-RISE OF ELECTRICAL MACHINES FROM HEATING TESTS OF SHORT DURATION.[*]

By EDWARD HUGHES, Ph.D., B.Sc., Member.

(*Paper first received 20th August, and in final form 27th November, 1929.*)

SUMMARY.

If the heating curve of a coil or a machine were exponential the final temperature-rise could be calculated from the initial portion of the curve and the heating test thereby shortened. A large number of heating curves have been examined, and it is found that the final temperature, as calculated from the rate of increase of resistance, is always less than—often considerably less than—the actual value. The greater part of the paper is devoted to an analysis of the influence upon the shape of the curve, and thereby upon the ratio of the calculated to the actual rise, of such factors as the variation of (*a*) speed, (*b*) power generated in winding, (*c*) the temperature-rise per watt as affected by radiation and natural convection, (*d*) thermal conductivity, (*e*) specific heat, (*f*) point of maximum temperature and (*g*) heating time-constant.

It has often been suggested that by observing the temperature-rise for the first half-hour or hour of a heating test it is possible to calculate the final temperature-rise from the exponential expression.

$$\theta_t = \theta\left\{1 - \epsilon^{-t/T}\right\} \quad . \quad . \quad . \quad . \quad (1)$$

where θ = final temperature-rise,
θ_t = temperature-rise after time t, and
T = heating time-constant.

The simplest method of applying this relationship for the above purpose is undoubtedly that due to Rowlands,[†] who pointed out that if θ_1 and θ_2 are the temperature-rises after intervals $\frac{1}{2}t$ and t respectively from the commencement of the test, then the final temperature is given by

$$\theta = \frac{\theta_1}{2 - (\theta_2/\theta_1)} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

There are many difficulties in the application of this formula, such as

(1) Uncertainty of the initial temperature of the winding or core under consideration.

(2) Fluctuation of the supply voltage, rendering it very difficult to obtain reliable and consistent results with the voltmeter-ammeter method, though this difficulty can be overcome by a "bridge" method described by the author in a previous paper.[‡]

(3) The greater difficulty of making accurate measurements in the case of windings of low resistance; where there are a large number of joints the method is impracticable.

(4) The continuous application of a thermometer may appreciably modify the temperature-rise of the winding or core.

(5) The complications involved when the temperature-rise of a rotating element is to be measured.

By giving careful attention to every detail, however, it is possible to obtain reasonably good curves of temperature-rise. Having reached this stage we find another difficulty, namely, that the temperature-rise calculated from the initial portion of the heating curve seldom agrees with the actual final temperature-rise.[*]

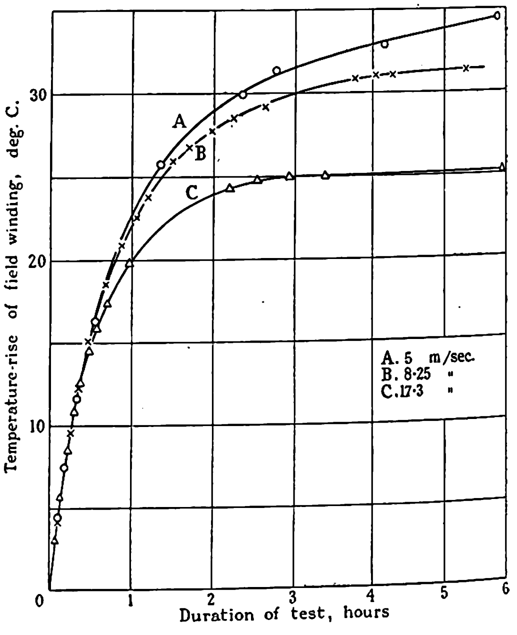

FIG. 1.

A large number of heating curves taken under various conditions have been analysed, and the following selection is typical of the results obtained:—

Case (1).—Machine B, referred to in another paper[†] by the author, when run as a protected type gave heating curves of which those plotted in Fig. 1 are typical. The temperature-rises of the field and stator windings were measured by the resistance method, and those of the stator core and duct by thermo-junctions placed as stated on page 912 of the paper mentioned above. The field current was maintained constant and the stator currents were 19, 19·3 and 18·4 amperes respectively in tests A, B and C; and the corresponding peripheral speeds were 5, 8·25 and 17·3 metres per second. It is obvious that the shape of the curves is different for the different speeds. Also, the heating time-constant (i.e. the time, according to the exponential expression, for the temperature-rise to attain 63·2 per cent of its final value) varied considerably both for speed and for the different parts of the machine.

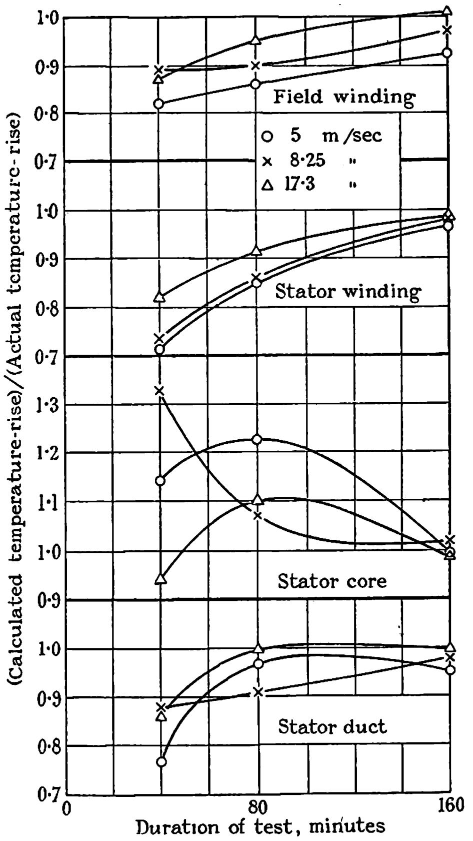

FIG. 2.

By means of formula (2), the final temperature-rises were calculated from each curve for $t = 40$, 80 and 160 minutes, respectively. These calculated values, θ_c, expressed as a fraction of the actual final temperature-rises, θ, have been plotted in Fig. 2. It will be observed that for the field and stator windings the ratio θ_c/θ deduced from a heating test of 40 minutes' duration may be considerably below unity, and that the discrepancy between θ_c and θ is greater (*a*) the smaller the value of t and (*b*) the lower the speed.

The question naturally arises: Should the values of θ_c/θ have been compared on the basis of equal duration of test or should the various "time intervals" * have been taken into account? From the standpoint of actual tests for calculating the final temperatures, the first alternative appears to be the correct one since all parts of the machine must be run for the same period for any particular test. However, in order to examine the discrepancy between the values of θ_c/θ for the different speeds, it is worth while noting the effect of this "time interval." The latter is obtained for each test by noting from the curve the time required for the temperature-rise to reach 63·2 per cent of the final value, and Table 1 shows how it varies for the different parts of the machine and also for the different speeds.

The variation of the heating "time interval" with speed might have been anticipated from a consideration of the usual exponential. Since the heating time-constant may be defined as the time required to attain the final temperature-rise if there were no losses and if the power generated remained constant,

$$T = \frac{\theta W}{P} = W \times \text{temperature-rise per watt}$$

where W = energy in joules to raise temperature 1 deg. C., and
P = power generated in watts.

The author has shown in his other paper † that the temperature-rise per watt for each part of the machine is smaller the higher the speed. Hence it might have been expected that, even for curves that are only approximately exponential, the heating time-constant would be shorter the higher the speed.

TABLE 1.

Test	Peripheral speed	Draught speed	Time interval, T_t			
			Field winding	Stator winding	Stator core	Stator duct
	metres/sec.	metres/sec.	minutes	minutes	minutes	minutes
A	17·3	—	35	13	48	34
B	8·25	—	46	25	61	53
C	5·0	—	58	29	70	64
D	8·25	3·44	51	32	78	69
E	8·25	1·4	80	73	109	100
F	8·25	0	129	134	158	158

---

* The term "time interval" has been introduced to avoid applying the term "time constant" to non-exponential curves, and represents the time required for the temperature-rise to reach 63·2 per cent of the final value.

† See page 930.

From the values of T_i in Table 1 the ratio of θ_c/θ can now be plotted against t/T_i,* as in Fig. 3. It will be seen from the latter that the effect introduced by the speed in Fig. 2 has almost vanished.

Case (2). *Machine B, arranged for Pipe-Ventilation.*—The machine was run on a constant load of 15 amperes, with 2-ampere excitation and a peripheral speed of 8·25 metres per sec., and with induced-draught speeds of 3·44, 1·4 and 0 metres per sec. in tests D, E and F respectively. The difference between the shapes of the curves of temperature-rise for the different speeds was even more marked than that for case (1), a feature that is also evident from a comparison of Fig. 4 with Fig. 2. The values of θ_c/θ for the stator core are erratic and illustrate the impossibility of estimating the final temperature-rise of the core from a short heat-run.

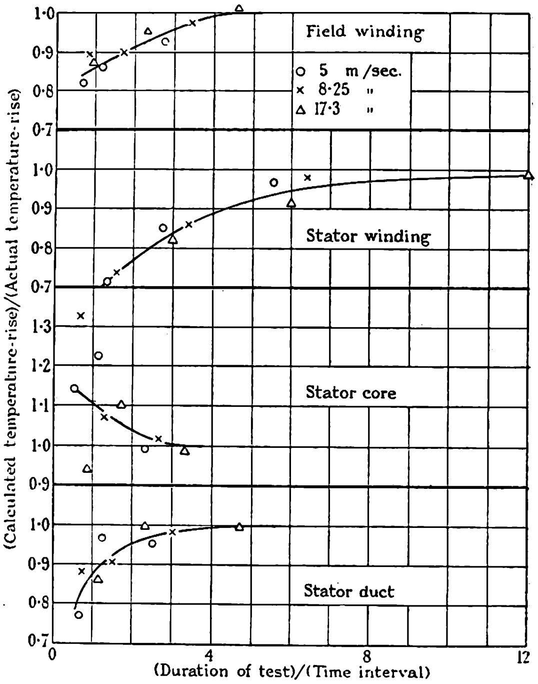

FIG. 3.

The "time intervals" derived from these heating curves have been incorporated in Table 1. The enormous influence of enclosure and of air velocity will be obvious.

TABLE 2.

Test	Field Current	Peripheral speed	Time interval, T_i		
			Field winding	Armature winding	Thermo-junction
	amps.	metres/sec.	minutes	minutes	minutes
A	0·86	16	28	22	32
B	0·86	8	29	42	67
C	0·96	0	40	—	—
D	0·7	0	37	—	—

In Fig. 5 the values of θ_c/θ have been plotted against t/T_i for the field and stator windings. The corresponding points for the stator core are so irregular as not to be worth re-plotting. It will be seen from this figure that for small values of t/T_i the values of θ_c/θ for various air velocities are in good agreement with one another; but with larger values of t/T_i the error in calculating the final temperature is greater the higher the air velocity.

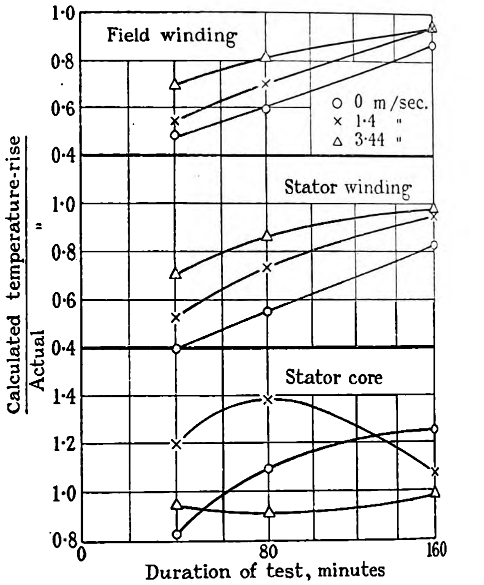

FIG. 4.

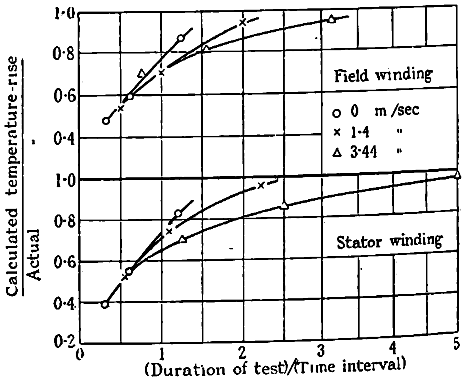

FIG. 5.

Case (3). *Machine A* (*rotating armature*) *as a protected*

---

* Namely, the duration of the heating test up to the second reading used to calculate the final temperatures, divided by the "time interval."

type.—The only data available for plotting heating-curves on this machine had been taken on no load. The field and armature temperatures had been measured by the resistance method, and the temperature at a point midway between the pole-tips and 2·5 mm away from the armature had been noted by a thermo-junction. The values of T_i derived from these heating curves, together with particulars of the tests, are given in Table 2.

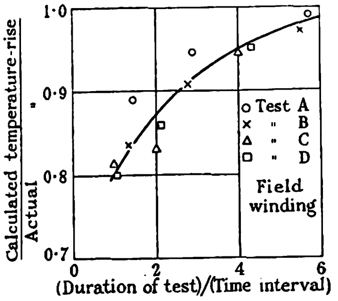

FIG. 6.

The large variation in T_i for the armature winding and thermo-junction seems to be due to these temperatures being greatly influenced by the speed.

The values of θ_c/θ for the field and armature windings and for the thermo-junction have been plotted against the corresponding values of t/T_i in Figs. 6 and 7. Here, again, it is seen that the final temperature-rise calculated from heat runs of short duration may be appreciably smaller than the actual value.

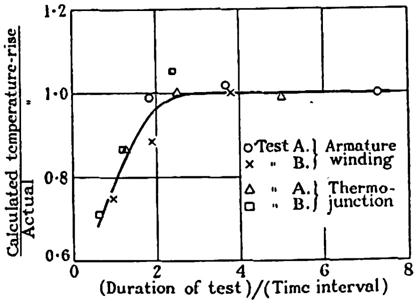

FIG. 7.

DISCUSSION OF THE ABOVE RESULTS.

There are a number of reasons that may be suggested to account for the most common feature noted above, namely that the temperature-rise of a winding calculated from the initial portion of the heating curve is always less than the actual value. Thus we have—

(1) *Variation of Power Generated in Coil.*

The usual exponential equation for the temperature-rise is based on the assumption that the power dissipated in the winding remains constant, whereas in all the above tests the current was kept constant, so that the power increased with increase of temperature-rise. This problem, however, has been fully discussed by the author in another paper,* where it is shown that the effect of the increase of resistance is to increase both the temperature-rise and the heating time-constant by $(1 + a\theta)$, but not to cause the heating curve to deviate from the exponential shape; and the temperature-rise calculated from the initial portion of the curve should agree with the actual value as far as this effect is concerned.

(2) *Variation of the Temperature-Rise per Watt with the Temperature-rise.*

The usual exponential expression assumes that the power dissipated is proportional to the temperature-rise. Actually, however, the power dissipated increases more rapidly than the temperature-rise; and from an analysis of tests on five coils suspended in air the author has found † that the temperature-rise per watt can be expressed very closely by

$$\frac{\theta}{P} = \frac{a}{1 + c\theta}$$

where θ = final temperature-rise, measured by resistance,
a = a constant for a given coil, and
c = a coefficient varying from 0·0036 to 0·005 for the five coils.

From tests on the field coils of six protected-type machines with their armatures stationary, it was found that the temperature-rise per watt was again represented by a similar expression, where a varied between 0·0023 and 0·0085 for the different machines. It is therefore desirable to consider to what extent such a relationship is in accordance with the recognized laws of radiation and of convection, and to see whether this variation in the watts dissipated per degree rise of temperature accounts for the results obtained in the first section of this paper.

(*a*) *Cooling due to Radiation only.*—Stefan-Boltzmann's law states that, for black bodies,

$$\text{Heat radiated per second} \propto \left(T_2^4 - T_1^4\right)$$

where T_2 = absolute temperature of the hot body, and
T_1 = absolute temperature of the surroundings receiving the radiation.

Then temperature-rise per watt

$$= \frac{\theta}{P} = \frac{T_2 - T_1}{P}$$
$$= \frac{k}{(T_2 + T_1)(T_2^2 + T_1^2)} \quad . \quad . \quad . \quad (3)$$

where k is a constant for a given surface.

By assuming the temperature of the surroundings to be 15° C. and k to be such that θ/P is unity when $T_2 = T_1$, the values of θ/P represented by crosses in Fig. 8 have been calculated.

It has previously ‡ been pointed out that for moderate temperature-rises these results are almost identical with those calculated from an expression of the form

$$\frac{\theta}{P} = \frac{1}{1 + 0{\cdot}006\theta} \quad . \quad . \quad . \quad . \quad (4)$$

---

* *Loc. cit.*

† *Loc. cit.*

‡ *Loc. cit.*

where θ is the temperature-rise. The values obtained from (4) are shown by circles in Fig. 8, and it is evident from the latter that for temperature-rises within 100 deg. C. the difference between expressions (3) and (4) is so small that the second expression can be utilized for investigating the effect of Stefan-Boltzmann's law upon the shape of the heating curve.

Let W = energy in joules to raise the temperature of a coil 1 deg. C.,
P = initial power generated in coil,
β = final temperature-rise that would have been reached if the power remained at P, and
T = the corresponding time-constant.

Then $TP = \beta W$, so that $W = TP/\beta$.

If θ_t be the temperature-rise after a time t seconds, the power generated in the coil at that instant is $P(1 + \alpha\theta_t)$, where α is the temperature coefficient of resistance at initial temperature.

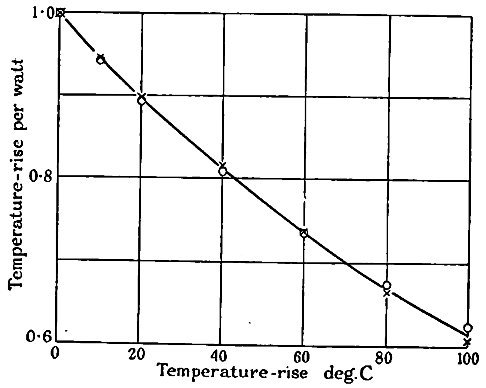

Fig. 8.

From expression (4) it follows that the power dissipated per degree rise of temperature of the coil can be represented by $k(1 + c\theta_t)$, where $c = 0{\cdot}006$ and k is a constant for a given coil. Then

$$P(1 + \alpha\theta_t)dt = Wd\theta + k(1 + c\theta_t)\theta_t dt$$

If θ be the steady temperature-rise of the coil when the *current* is maintained constant, then

$$P(1 + \alpha\theta) = k(1 + c\theta)\theta \quad . \quad . \quad . \quad (5)$$

$$\therefore\ k = \frac{P(1 + \alpha\theta)}{(1 + c\theta)\theta}$$

Substituting for k and W in the above equation, we have

$$P(1 + \alpha\theta_t)dt = \frac{TP}{\beta}d\theta + \frac{P(1 + \alpha\theta)(1 + c\theta_t)\theta_t dt}{(1 + c\theta)\theta}$$

$$\therefore \frac{d\theta}{dt} = \frac{\beta}{T}\left\{(1 + \alpha\theta_t) - \frac{(1 + \alpha\theta)(1 + c\theta_t)\theta_t}{(1 + c\theta)\theta}\right\} \quad . \quad (6)$$

Since

$$P = k(1 + c\beta)\beta \quad . \quad . \quad . \quad . \quad . \quad (7)$$

then, from equations (5) and (7), we have

$$1 + \alpha\theta = \frac{(1 + c\theta)\theta}{(1 + c\beta)\beta} \quad . \quad . \quad . \quad . \quad (8)$$

from which β can be found in terms of α, c and θ.

The simplest method of determining the shape of the heating curve corresponding to expression (6), and thus of comparing it with the exponential curve, is to assume $\theta = 50$ deg. C. (say) and $T = 30$ minutes (say) = 1 800 seconds. We can take α as $0{\cdot}004$ for an initial temperature of about 15° C., and c has already been given as $0{\cdot}006$. By substituting these values in (8) we find that $\beta = 43{\cdot}1$ deg. C.; and by substituting in (6) we have

$$\frac{d\theta}{dt} = 0{\cdot}02395(1 - 0{\cdot}014450_t - 0{\cdot}000111\,\theta_t^2)$$

By assuming various values of θ_t we can calculate the corresponding values of $d\theta/dt$; and since the change in slope of the heating curve is comparatively gradual it is possible by taking a sufficient number of values to derive the heating curve. Thus, for $\theta_t = 0$, $d\theta/dt = 0{\cdot}02395$; and for $\theta_t = 5$ deg. C., $d\theta/dt = 0{\cdot}02215$; so that the mean value of $d\theta/dt$ between 0 and 5° C. is $0{\cdot}02305$. Consequently, the time taken for the temperature to increase from 0° C. to 5° C. is $5/0{\cdot}02305$, namely, 217 seconds. Similarly, for $\theta_t = 10°$ C., $d\theta/dt = 0{\cdot}0202$; so that the mean slope of the heating curve between 5° C. and 10° C. is $0{\cdot}02117$, and the time taken for the temperature to rise this amount is 236 seconds. In this way the values represented by curve A in Fig. 9 were derived.

Let us now see how the final temperature-rises calculated from this curve by means of expression (2) agree with the actual values. The second column of Table 3 gives three values obtained in this way, and the ratio of the calculated to the actual rise has been added in the third column. A comparison of these results with the curves of Fig. 2 shows that the modification in the heating curve caused by Stefan-Boltzmann's law is in the opposite direction to that actually observed.

(*b*) *Cooling due to Natural Convection only.*—It has been demonstrated by numerous investigators * that the power dissipated by natural convection is proportional to (Temperature-rise)$^{1{\cdot}25}$,

$$\text{i.e. Power dissipated} = k\theta_t^{1{\cdot}25}$$

where k = a constant for a given coil, and
θ_t = temperature-rise after t seconds.

We can therefore proceed to determine the corresponding heating curve; thus, using the same symbols as in the preceding section, we have

$$P(1 + \alpha\theta_t)dt = Wd\theta + k\theta_t^{1{\cdot}25}dt$$

But

$$P(1 + \alpha\theta) = k\theta^{1{\cdot}25} \quad . \quad . \quad . \quad . \quad (9)$$

Substituting for W and k, we have

$$P(1 + \alpha\theta_t)dt = \frac{TP}{\beta}d\theta + \frac{P(1 + \alpha\theta)}{\theta^{1{\cdot}25}}\theta_t^{1{\cdot}25}dt$$

$$\therefore \frac{T\theta^{1{\cdot}25}}{\beta}d\theta = \left\{\theta^{1{\cdot}25} - \theta_t^{1{\cdot}25} + \alpha\theta\theta_t(\theta^{0{\cdot}25} - \theta_t^{0{\cdot}25})\right\}dt$$

Also

$$P = k\beta^{1{\cdot}25} \quad . \quad . \quad . \quad . \quad . \quad (10)$$

---

* "Dictionary of Applied Physics," vol. 1, pp. 473–7.

From (9) and (10), we have

$$\beta = \frac{\theta}{(1 + \alpha\theta)^{0\cdot 8}}$$

$$\therefore \frac{d\theta}{dt} = \frac{\left\{\theta^{1\cdot 25} - \theta_t^{1\cdot 25} + \alpha\theta\theta_t(\theta^{0\cdot 25} - \theta_t^{0\cdot 25})\right\}}{T\theta^{0\cdot 25}(1 + \alpha\theta)^{0\cdot 8}}$$

In deriving the heating curve corresponding to this equation, the same procedure was followed as in the last section; i.e. the values of θ and T were assumed to be 50 deg. C. and 1 800 seconds respectively, and the values of $d\theta/dt$ were calculated for various values of θ_t. The corresponding variation of temperature-rise with time is represented by curve B in Fig. 9, and the final temperature-rises calculated from the initial portion of this curve are given in column 4 of Table 3. The values of θ_c/θ have been added in column 5.

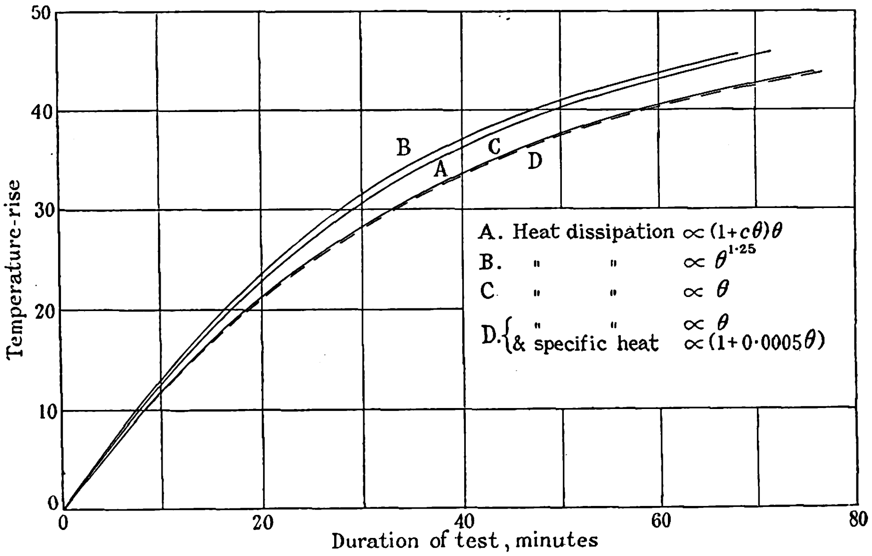

FIG. 9.

TABLE 3.

Time of second reading	Radiation		Natural convection		Variation of specific heat	
	Calculated rise	θ_c/θ	Calculated rise	θ_c/θ	Calculated rise	θ_c/θ
minutes	deg. C.		deg. C.		deg. C.	
13·3	68·1	1·36	72·6	1·45	48·9	0·98
26·6	57·0	1·14	57·2	1·144	49·5	0·99
53·2	52·4	1·048	52·5	1·05	49·6	0·992

Here, again, it is obvious that the effect of natural convection is to give exactly the opposite result to that experimentally observed on windings; i.e. natural convection tends to modify the heating curve so that the value of the final temperature calculated from the initial portion of the curve is greater than the actual value.

(*c*) *Cooling due to forced convection only.*—Both theory and experiment indicate that the loss of heat by forced convection is proportional to the difference of temperature between the hot surface and the ambient fluid.* Newton's law of cooling, upon which the exponential curve of temperature variation is based, was actually given for a body " not in still air but in a uniform current of air." Consequently, the effect of forced convection upon the heating curve is precisely that already assumed in deriving the exponential equation referred to in section (1), page 935, and it cannot therefore be responsible for the problem under investigation. For ease of comparison with the heating curves already derived, the exponential curve C in Fig 9 has been calculated for $\theta = 50$ deg. C. and $T = 1\ 800$ seconds.

(3) *Variation of the Thermal Conductivity of the Winding.* The thermal conductivity of copper † decreases about 1 per cent for an increase of temperature from 18° C. to 100° C. On the other hand, the thermal conductivities of cotton waste ‡ and of air § have been found to increase about 25 per cent and 27·5 per cent respectively between 0° C. and 100° C. Fig. 10 shows the variation in the effective thermal conductivity of the insulation (including the air space) deduced from tests ‖ made by the author on a coil fitted with five thermo-junctions embedded at

---

* " Dictionary of Applied Physics," vol. 1, pp. 471–3.

† *Ibid.*, vol. 1, p. 443.

‡ *Ibid.*, vol. 1, p. 433.

§ *Ibid.*, vol. 1, p. 461.

‖ *Journal I.E.E.*, 1924, vol. 62, p. 632.

different depths. The coil consisted of 3 800 turns of No. 24 S.W.G. copper wire (d.c.c.). From this curve it will be seen that for a temperature-rise of 80 deg. C. the increase of thermal conductivity is only about 9 per cent.

The effect of an increase in the thermal conductivity is to reduce the ratio of the average temperature across the section of the coil to the surface temperature. If we assume, for simplicity, the heat generated in the coil and the emissivity of the latter to remain constant, the greater uniformity of the temperature throughout the coil due to an increase of the thermal conductivity means that the final temperature as measured by increase of resistance is smaller than that calculated from the initial portion of the heating curve. Hence, the phenomenon noted in the first part of this paper cannot be due to any increase of the thermal conductivity.

(4) *Variation of the Specific Heat of Copper.*

The specific heat of copper* increases about 5 per cent for an increase of temperature from 0° C. to 100° C., so that for a temperature-rise of θ_t it can be represented by $s(1 + 0\cdot0005\,\theta_t)$, where s is the specific heat at the initial temperature.

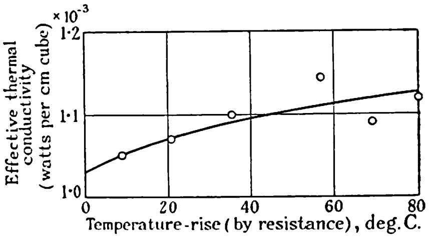

FIG. 10.

Let T be the time required to attain steady temperature-rise β if power and specific heat were to remain constant at their initial values and if no energy were being dissipated. Then

$$TP = bs\beta$$

where $b = 4\cdot2 \times$ mass (grammes) of copper

$$\therefore bs = TP/\beta$$

As we are at present only concerned with finding the influence of the variation of the specific heat upon the exponential curve, it will be assumed that the heat dissipation is proportional to the temperature-rise. Hence, we have

$$P(1 + \alpha\theta_t)dt = bs(1 + 0\cdot0005\theta_t)d\theta + k\theta_t dt \quad (11)$$

If θ be the steady temperature-rise when the *current* is kept constant, then

$$P(1 + \alpha\theta) = k\theta$$

$$\therefore k = \frac{P(1 + \alpha\theta)}{\theta}$$

Substituting for bs and k in (11), we have

$$(1 + \alpha\theta_t)dt = \frac{T}{\beta}(1 + 0\cdot0005\theta_t)d\theta + \frac{1 + \alpha\theta}{\theta}\theta_t dt$$

But $$\theta/\beta = 1 + \alpha\theta$$

Substituting for β and simplifying, we have

$$\frac{dt}{T(1 + \alpha\theta)} = \frac{1 + 0\cdot0005\theta_t}{\theta - \theta_t}d\theta$$

$$\therefore \frac{t}{T(1+ \alpha\theta)} = -\,0\cdot0005\theta_t$$
$$-\,(1 + 0\cdot0005\,\theta)\log_\epsilon(\theta - \theta_t) + A$$

When $t = 0,\quad \theta_t = 0$

$$\therefore A = (1 + 0\cdot0005\,\theta)\log_\epsilon\theta$$

Hence

$$\frac{t}{T(1 + \alpha\theta)} = (1 + 0\cdot0005\theta)\log_\epsilon\frac{\theta}{\theta - \theta_t} - 0\cdot0005\theta_t \quad (12)$$

If the specific heat were constant, we should have

$$\frac{t}{T(1 + \alpha\theta)} = \log_\epsilon\frac{\theta}{\theta - \theta_t}$$

$$\text{i.e. } \theta_t = \theta\left\{1 - \epsilon^{-t/T(1+\alpha\theta)}\right\}$$

which is the same as the expression referred to in section (1), page 935, and represented by curve C in Fig. 9.

A simple method of showing the effect of the variation of specific heat upon the heating curve is to assume $\theta = 50$ deg. C., $T = 30$ minutes and $\alpha = 0\cdot004$, as in the previous sections, and to calculate from equation (12) the values of t for temperature-rises of 5 deg. C., 10 deg. C., etc. The results are represented by curve D in Fig. 9, from which it will be seen that the deviation from the exponential shape is very small. From a carefully-drawn copy of curve D, values of the final temperature-rise were calculated and are given in column 6 of Table 3; and the corresponding values of θ_c/θ are given in column 7 of that table. It will be obvious that, while the increase of specific heat does tend to cause the phenomenon under investigation, the effect is so small as to be almost negligible.

In the above discussion the specific heats of the insulation and of the air enclosed in the interstices have been assumed constant. The specific heat of air has been found * to increase only 0·5 per cent between 20° C. and 100° C. and to be practically unaffected when the pressure is doubled. The author has not been able to find any data in regard to the variation of the specific heat of the insulation.

(5) *Variation of the Point of Maximum Temperature.*

When the temperature distribution across a section of a coil is determined experimentally, it is found that the point of maximum temperature shifts from the centre towards the inner side of the coil. Thus, Fig. 11 is typical of the results obtained by the use of five thermo-junctions on the coil referred to in section (3). In order that the relative shapes of the curves may be as clear as possible, the ratios of the actual temperature-rise to the corresponding temperature-rise at the centre of the coil and not the actual temperature-rises have been plotted. It is evident that the curve shifts inwards quite appreciably. The influence of this redistribution upon the heating curve was first investigated by plotting the heating curves obtained from the thermo-junctions situated in the centre and on the outside and inside respectively of the coil; and from these curves the corresponding final rises were determined by formula (2). The ratios of the calculated to the actual values, plotted in Fig. 12, are typical of those obtained with different currents, and indicate quite definitely that the ratio is less than unity except for the results derived from the earliest portion of the curve for the inner junction. They also show that the shape of the heating curve is not identical for the various depths of the coil.

---

* "Dictionary of Applied Physics," vol 1, p. 41.

* "Dictionary of Applied Physics," vol. 1, p. 44.

Though the curves of temperature distribution are practically parabolic, it was not found possible to derive any mathematical formula whereby the effect of the shift of the point of maximum temperature upon the shape of the heating curve representing the average temperature-rise could be calculated. Consequently another method was tried, namely, to plot curves of temperature distribution—similar to those in Fig. 11—after 10, 20, 40, 80 and 160 minutes, and, finally, after 7 hours of the heating test. By measuring the areas enclosed by these curves, the corresponding average temperature-rises across the section were calculated, and the ratios of these temperatures to the average temperature after 7 hours have been plotted in Fig. 13. These curves indicate that the effect of redistribution of temperature is to modify the heating curve for the average temperature-rise, as determined from thermo-junction readings, in such a way that the ratio of the calculated final rise to the actual rise is less than unity and is therefore in agreement with the results obtained in the first part of this paper, though the magnitude of the effect is not nearly so great.

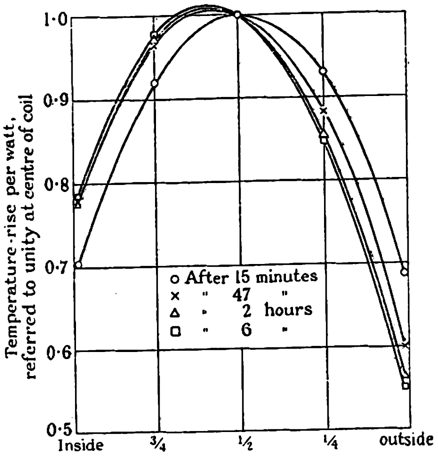

FIG. 11.

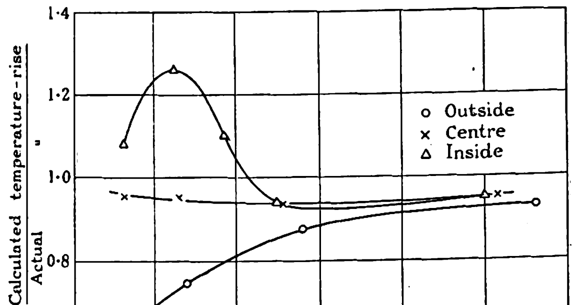

FIG. 12.

The shifting inwards of the point of maximum temperature is mainly due to the presspahn former on which the coil was wound, causing the dissipation of heat per unit area from the inner surface to be smaller than that from the outer surface. (The coil was suspended in air during the above tests.) The distribution of temperature may also have been modified by an alteration in the thermal conductivity of the cotton and of the air in the interstices of the coil, as discussed on page 937.

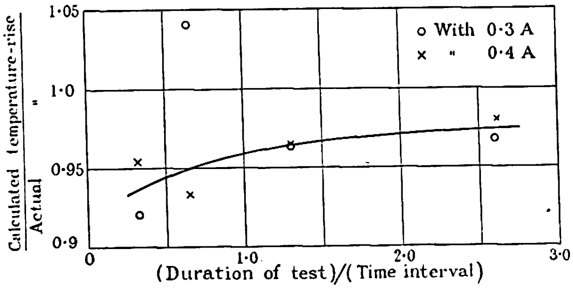

FIG. 13.

(6) *Variation of the Heating Time-Constant for Different Sections of the Winding.*

It has already been explained on page 933 that the better the facilities for heat dissipation, the shorter is the heating time-constant. It is obvious that for no winding is the heat dissipation per unit area uniform over the whole surface. Let us therefore consider an ideal case of a winding consisting of two sections—somewhat on the lines of an armature winding—but quite independent of each other, as far as the dissipation of the generated heat is concerned.

Let P_1 and P_2 be the *steady* powers generated in the two sections,

T_1 and T_2 be the corresponding time-constants,

θ' and θ'' be the corresponding final temperature-rises, and

θ'_t and θ''_t be the corresponding temperature-rises t seconds after commencement of heating test.

Assuming the usual exponential relationship, we have

$$\theta'_t = \theta'(1 - \epsilon^{-t/T_1})$$

and

$$\theta''_t = \theta''(1 - \epsilon^{-t/T_2})$$

Let R' and R'' be the initial resistances of the respective sections,

R'_t and R''_t be the respective resistances after t seconds, and

a be the temperature coefficient of resistance corresponding to the initial temperature.

Then $R'_t = R'(1 + a\theta'_t)$

and $R''_t = R''(1 + a\theta''_t)$

$$\therefore a(R'\theta'_t + R''\theta''_t) = R'_t + R''_t - (R' + R'')$$
$$= \text{increase in resistance of whole coil}$$
$$= r \text{ (say)}$$

If θ_t be the corresponding temperature-rise calculated from the increase of resistance of the *whole* coil,

then $r = a\theta_t(R' + R'')$

$$\therefore \theta_t = \frac{r}{a(R' + R'')} = \frac{R'\theta'_t + R''\,\theta''_t}{R' + R''}$$

If θ be the final temperature-rise calculated from the increase of resistance of the *whole* coil,

then $$\theta = \frac{R'\theta' + R''\theta''}{R' + R''}$$

By assuming different combinations of R' and R'', T_1 and T_2, etc., we can now calculate their influence upon the shape of the heating curve for the whole coil. For instance, assume $\theta' = \theta'' = 40$ deg. C.; $R' = 100$; $R'' = 200$; $T_1 = 20$ minutes; and $T_2 = 40$ minutes. Then for $t = 10$ minutes, $t/T_1 = 0\cdot5$ and $t/T_2 = 0\cdot25$.

$$\therefore \theta'_t = 40(1 - \epsilon^{-0\cdot5}) = 15\cdot74$$

and $$\theta''_t = 40(1 - \epsilon^{-0\cdot25}) = 8\cdot86.$$

Hence,

$$\theta_t = \frac{(100 \times 15\cdot74) + (200 \times 8\cdot86)}{100 + 200} = 11\cdot15$$

Similarly, for $t = 20$ minutes,

$$t/T_1 = 1\cdot0; \quad \theta'_t = 25\cdot3; \quad \text{and} \quad \theta''_t = 15\cdot74$$
$$\therefore \theta_t = 18\cdot91$$

By applying expression (2) we have

$$\left.\begin{array}{r}\text{Calculated final}\\ \text{temperature-rise}\end{array}\right\} = \theta_c = \frac{11\cdot15}{2 - (18\cdot91/11\cdot15)} = 36\cdot55$$

$$\therefore \frac{\text{Calculated final rise}}{\text{Actual final rise}} = 0\cdot914.$$

By repeating this calculation for different combinations of R', R'', etc., the results given in Table 4 have been obtained.

Comparison of the values obtained for θ_c/θ in Table 4 shows that:—

(*a*) Merely a difference of temperature-rise or of power or of both has no influence upon the ratio.

(*b*) Only a difference of time-constant causes θ_c/θ to be less than unity.

(*c*) If the difference in time-constant be accompanied by a difference in power dissipated, then the decrease of θ_c/θ is greater the larger the power dissipated in the section having the longer time-constant.

(*d*) The smaller the value of t/T for a given coil, the smaller is the corresponding value of θ_c/θ. The variation of θ_c/θ with the duration of the heating test for the conditions referred to in the first three rows of Table 4 and plotted in Fig. 14 is so similar to that experienced on actual coils that it would appear that the principal reason for the impossibility of calculating the final rise from the initial portion of the heating curve is the variation in the heat dissipation per unit area from the different portions of the winding.

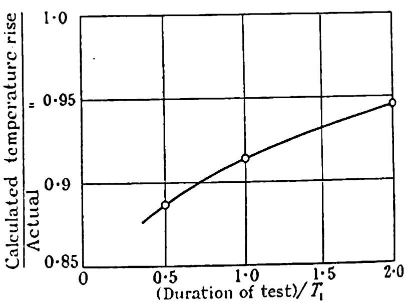

FIG. 14.

In the case of field windings, those portions of the surface that are most exposed dissipate considerably more power per unit area than the shielded portions such as those facing the pole cores; and it will therefore be evident from Table 4 that for such windings the final temperature-rise calculated from the initial portion of the heating curve should be less than the actual rise.

TABLE 4.

t/T_1	R'	R''	T_1	T_2	θ'	θ''	θ	θ_c	θ_c/θ

0·5 and 1	200	100	20	40	40	60	46·7	43·3	0·927

CONCLUSIONS.

(1) The final temperature-rise of windings as calculated by the exponential relationship from the increase of resistance during the initial part of the heating test is less than the actual value.

(2) The discrepancy between the calculated and the actual values is greater (*a*) the shorter the duration of the heating test, and (*b*) the lower the speed.

(3) The effect of speed was found to be due to the heating " time interval " (i.e. the time to attain 63·2 per cent of the steady rise), being shorter the higher the speed.

(4) The increase of power generated in a coil due to variation of resistance increases the temperature-rise and the heating time-constant, but does not cause the heating curve to deviate from the exponential shape.

(5) The decrease of the temperature-rise per watt with increase of temperature causes the heating curve to depart from the exponential form. This variation can be accounted for by the known laws of radiation and of natural convection; but the effect of both radiation and natural convection is to make the calculated final rise greater than the actual value. On the other hand, forced convection, being the basis of the usual exponential expression, cannot be responsible for any discrepancy between the calculated and the actual temperature-rises.

(6) The increase of thermal conductivity of the insulation tends to give a calculated final rise that is greater than the actual value.

(7) The increase of specific heat of copper modifies the heating curve in the required direction, but the magnitude is so small as to be almost negligible.

(8) The shifting of the point of maximum temperature towards the inner side of a coil also accounts for a small part of the discrepancy.

(9) The difference in the heating time-constants of the different portions of a coil seems to be mainly responsible for the difference between the calculated and the actual final rises. The better the heat dissipation, the shorter is the time-constant. The difference in the time-constants may or may not be accompanied by differences of power generated in, and of temperature-rise of, the different portions; but differences of power and of temperature-rise with no difference of time-constant do not account for the discrepancy.

(10) Owing to the impossibility of calculating the final temperature-rise from the initial portion of the heating curve, the only method of minimizing the energy consumed during a heat run and at the same time of ensuring reliable values for the final temperatures, is to maintain an overload on the machine until the temperatures approximate the anticipated values, and then to continue at full load until reasonably steady temperatures are attained. The temperature variation of the armature of a direct-current machine can be followed very closely by the aid of a thermo-junction fixed between the pole-tips, as described in another paper * by the author.

INSTITUTION NOTES.

Library.

The Reference Library of the Institution will be closed from the 14th July until about the 30th September for structural alterations and re-decoration.

By courtesy of the Councils of The Institution of Civil Engineers and The Institution of Mechanical Engineers the Libraries of these Institutions will be available to members for reference purposes during that period.

Members desirous of availing themselves of these facilities should apply to the Secretary of the I.E.E. for a card of introduction.

Premiums.

In addition to the Premiums mentioned on page 795, the Council have awarded the following Premiums for the session 1929–30 for papers read before the Meter and Instrument Section and for Students' papers:—

METER AND INSTRUMENT SECTION PREMIUMS.

Silvanus Thompson Premium (*value* £10).

E. H. RAYNER, Sc.D., W. G. STANDRING, M.A., R. DAVIS, M.Sc., and G. W. BOWDLER, M.Sc.	" Studies in Low-Power-Factor Measurements at High Voltages."

A Premium (*value* £5).

A. E. MOORE, M.Sc.Tech., and W. T. SLATER, M.Sc.Tech.	" An Investigation of the Frequency Variations in Induction Watt-hour Meters."

STUDENTS' PREMIUMS.

Premiums of the Value of £10 *each:*

Author	*Title of Paper*	*Where read*
E. W. CONNON, B.Sc.(Eng.).	" Hydro-Electric Developments in Great Britain."	Liverpool
J. C. EMERSON, B.Sc., and J. W. MOFFATT.	" The Rotary Automatic Telephone System."	London
L. E. C. HUGHES, Ph.D.	" Engineering Acoustics."	London
C. S. T. PAUL.	" The Oil-Immersed Circuit Breaker."	Leeds
W. G. THOMPSON, B.Sc.	" The Electrical Propulsion of Ships."	Newcastle

Premiums of the Value of £5 each:

C. H. BRADBURY.	"Torsional Vibration in the Diesel-Electric Set."	Sheffield
S. M. LEJEUNE.	"Recent Developments in Alternating-Current Protective Gear."	London

The Students' Prize.

The Students' Prize of £10 offered by the Council for the best paper on the subject of "The Relations between Economics and Engineering" submitted by a Student, or a Graduate under the age of 28, during the session 1929–30, has been awarded jointly to Mr. V. A. H. Clements and Mr. A. K. Robinson for the papers submitted by them, the amount of the prize being divided equally between these two authors.

Nominations for Election to the Council.

In addition to those members nominated by the Council (see page 795) the following members have been nominated for ballot as Vice-President and Ordinary Members of Council respectively:—

Vice-President.

E. H. SHAUGHNESSY, O.B.E. (Nominated by W. T. Anderson, A. S. Angwin, D.S.O., M.C., B.Sc. (Eng.), E. S. Byng, A. O. Gibbon, H. H. Harrison, F. Hope-Jones, E. C. McKinnon, W. J. Medlyn, O.B.E., Sir William Noble, and H. C. Turner).

Ordinary Members of Council.

J. FRITH, M.Sc. (Nominated by D. Adamson, D.Sc., R. Brooks, B.Sc., A. G. Ellis, J. F. Fletcher, T. A. Kerr, A. L. Lunn, A. B. Mallinson, J. A. Robertson, L. Romero, and G. F. Sills).

R. B. MATTHEWS (Nominated by W. C. Bexon, J. H. C. Brooking, F. Christy, F. J. Down, B. G. Drummond, W. P. Gauvain, A. W. Isenthal, H. N. Prentice, A. L. Stanton, and F. H. Whysall).

V. WATLINGTON, M.B.E. (Nominated by H. H. Berry, H. W. Clothier, A. P. M. Fleming, C.B.E., M.Sc., S. Mavor, R. K. Morcom, C.B.E., M.A., E. S. New, M. J. Railing, A. E. Tanner, A. Vines, and E. B. Wedmore).

National Certificates and Diplomas in Electrical Engineering (England and Wales).

The undermentioned colleges have been approved under the scheme drawn up by the Board of Education and the Institution:—

Approved for Ordinary Grade Certificates (Senior Part-time Course).

Middlesbrough, Constantine Technical College.
Southall Technical Institute.
Treforest School of Mines.

Approved for Higher Grade Certificates (Advanced Part-time Course).

Derby Technical College.
Hull Municipal Technical College.
Leicester College of Technology.
Middlesbrough, Constantine Technical College.
Wolverton Technical College.

The Benevolent Fund.

On the last page of the cover of this issue of the *Journal* will be found particulars of certain publications, etc., which are on sale on behalf of the Benevolent Fund.

Proceedings of the Meter and Instrument Section.

8TH MEETING OF THE METER AND INSTRUMENT SECTION, 3RD JANUARY, 1930.

Mr. E. W. Hill, Chairman of the Section, took the chair at 7 p.m.

The minutes of the meeting held on the 6th December, 1929, were taken as read, and were confirmed and signed.

A paper by Messrs. J. G. Wellings, Associate Member, and C. G. Mayo, M.A., B.Sc., Graduate, entitled "Instrument Transformers" (see page 704), was read and discussed.

On the motion of the Chairman a vote of thanks to the authors was carried with acclamation, and the meeting terminated at 9.35 p.m.

9TH MEETING OF THE METER AND INSTRUMENT SECTION, 7TH FEBRUARY, 1930.

Mr. E. W. Hill, Chairman of the Section, took the chair at 7 p.m.

The minutes of the meeting held on the 3rd January, 1930, were taken as read, and were confirmed and signed.

A paper by Mr. G. F. Shotter, Associate Member, entitled "A New Null Method of Testing Instrument Transformers, and its Application" (see page 873), a paper by Messrs. R. S. J. Spilsbury, B.Sc., and A. H. M. Arnold, Ph.D., Associate Members, entitled "Some Accessory Apparatus for Precise Measurements of Alternating Current" (see page 889), and a paper by Mr. A. H. M. Arnold, Ph.D., Associate Member, entitled "Precision Testing of Current Transformers" (see page 898), were read and discussed.

On the motion of the Chairman a vote of thanks to the authors was carried with acclamation, and the meeting terminated at 9.35 p.m.

10TH MEETING OF THE METER AND INSTRUMENT SECTION, 7TH MARCH, 1930.

Mr. E. W. Hill, Chairman of the Section, took the chair at 7 p.m.

The Chairman having reported the death of Mr. C. H. W. Gerhardi, a member of the Committee, the members stood in silence as a mark of sympathy and esteem.

The minutes of the meeting held on the 7th February, 1930, were taken as read, and were confirmed and signed.

A paper by Messrs. A. E. Moore, M.Sc.Tech., Member, and W. T. Slater, M.Sc.Tech., Student, entitled "An Investigation of the Frequency Variations in Induction Watt-Hour Meters," was read and discussed.

The meeting terminated at 9.35 p.m. with a vote of thanks to the authors, which was moved by the Chairman and carried with acclamation.

Elections and Transfers of Members.

At the Ordinary Meeting held on the 10th April, 1930, the following elections and transfers were effected:—

ELECTIONS.

Member.

Home, Francis Wyville, Lieut.-Col. R. M.

Associate Members.

Aubrey, Lionel William, B.Sc.
Betts, Douglas.
Carne, William Alfred, B.Sc.(Eng.).
Clotworthy, Stanley Edward, B.Sc.(Eng.).
Edwards, Joseph James, B.Sc.(Eng.).
Hussain, Khateeb Mahmood, M.A.
MacCarthy, Arthur Felix.
MacKay, David Hymers, B.Sc.
Prado, Alberto.
Smith, John Arnold.
Tuck, William Douglas, B.Sc.(Eng.).
Withers, Arthur Sydney.

Associates.

Rolston, Frederick William.
Whelton, George Herbert.

Graduates.

Anderson, Frank Fitzgerald, B.Sc.(Eng.).
Ashbrook, Cecil Scott W.
Bailey, Albert.
Bassett, Joseph Alfred.
Beech, Frank.
Bentley, Desmond Mulock, B.Sc.
Bray, George Rupert R., B.Sc.(Eng.).
Campbell, David Kinghorn, B.Sc.
Carter, John Edwin.
Chauhdri, Mohammad Abdul G.
Dunbar, Charles John, B.Sc.
Greenroyd, Clement Henry.
Hawken, Joseph John.
Helman, Stanley Louis.
Hetherington, Harry Reid.
Hill, Alexander, B.Sc.
Parsonage, Stanley Horace.
Psintros, Costas John.
Rissik, Hendrik, B.Sc.
Thomas, Daniel James, B.Sc.(Eng.).
Venkateswaran, Ailoor Subramanian.
Wai, On.

Students.

Astbury, Herbert Purcell.
Bailey, Herbert Gordon.
Barbara, Anthony.
Bardaloye, Apurba Chandra.
Berry, Jack.
Braidwood, John Alexander.
Brooks, Harold.
Buchan, Hector Kennedy.
Caldwell, John.
Cloude, Albert William.
Desborough, George Vernon.
Eadon, Ronald Oakes.
Easterbrook, Leonard Arthur.
Ewer, Philip Ashley.
Forder, Frederick James.
Gabla, Naval Fakirji.
Goodman, Arthur Frederick.
Grant, Thomas William.
Grundy, John Bennett.
Gupta, Chunni Lal, B.Sc.
Harvey, Arthur Frank.
Horsington, Leslie Richard.
Hotham, John William.
Houchin, John Philip W.
Jones, William Paynter.
Kay-Smith, William Henry S.
Kimberley, Arthur Edward.
Leworthy, Leslie Roland.
Lilley, Francis Hugh.
Makaroff, Igor.
Manville, George Egerton.
Marshall, Allan Dudley.
Mason, Charles Edward.

Students—continued.

Mohile, Bhalchandra Vaman, B.Sc.
Moon, John Leslie.
Morris, Merlin.
Moyes, Noel Robert.
Newman, Frank Samuel.
Ossitt, Bertram Cyril.
Packham, Eric Claude.
Parker, Arthur John.
Parker, John Norman.
Perry, Jack Robert.
Potts, Norman Dean K.
Pullin, Douglas Stanley W.
Richardson, Franklin.
Robertson, Alan Robert S.
Sanders, Kenneth Lesreaulx.
Schofield, William Smith.
Sethi, Om Parkash.
Stott, Ronald Charles.
Sunderland, John.
Todhunter, John Franklin.
Yorath, Edwin McMillin.
Young, Arthur James.
Young, John Alfred.

TRANSFERS.

Associate Member to Member.

Brown, Thomas Alfred.
Doran, John Gillan.
Holroyde, Arthur Gordon C.
Johnston, Archibald.
Leeson, Bruce Hamer.
Pearce, Herbert, B.Sc. (Eng.).
Petford, Cecil Henry.
Smith, Joseph Irvin.
Thrupp, Frederick Edward M.
Wadeson, Maurice.

Associate to Associate Member.

Clements, Henry.
Swarsbrick, Joseph James.

Graduate to Associate Member.

Adams, George Herbert, B.Sc.(Eng.).
Blumlein, Alan Dower, B.Sc.(Eng.).
Crowley, Eric Conger.
Dick, Alastair William, B.Sc.(Eng.).
Godden, William Fenwick.
Halliday, Donald.
Kidd, William.
Lintott, George, B.Sc.(Eng.).
Lund, Granville.
Messent, Sydney William, B.Sc.(Eng.).
Miller, John Leonard, Ph.D., B.Eng.
Munford, Bertram Albert.
Petrides, Sophoclis Achilles, B.Sc.Tech.
Poulson, Arthur Gilbert B.
Powell, Alfred Gerald.
Websdale, Geoffrey John, Major, M.C.
Wilman, William Eric.
Young, James Buchan, B.Sc.

Student to Associate Member.

Hardern, Harold Wilfred.
O'Dowd, Arthur Edward, B.Eng.
Roddam, George.

Addresses Wanted.

The Secretary will be glad to receive the addresses of the following members, which are required for the Institution Register:—

MEMBERS.

THE JET-WAVE RECTIFIER: THE EXPERIMENTAL AND THEORETICAL BASIS OF ITS DESIGN.

By Professor JUL. HARTMANN, Dr.Tech., Member.

(*Paper first received* 26*th October,* 1928, *and in final form* 17*th April,* 1929; *read before* THE INSTITUTION 13*th February, and before the* NORTH MIDLAND CENTRE 11*th February,* 1930.)

SUMMARY.

The subject of this paper is the jet-wave rectifier, a purely mechanical device which, in the course of the last 15 years, has been developed into a means for high-power rectification. Prototypes of the constituent parts of the apparatus have been described elsewhere; in the present paper it is shown how the rectifier can be designed on the basis of these prototypes, and especially on the result of investigations with regard to the theoretical relations between their qualities. These relations are stated and are used in working out examples of typical designs. In addition, a review of the general properties of the jet-wave rectifier, and anticipations with regard to its future development, are given. It is concluded that a new high-capacity rectifier, of a character quite distinct from that of the mercury-arc rectifier, but likely to be used for similar duties, has been brought into existence.

TABLE OF CONTENTS.

(1) Principle of the jet-wave commutator and rectifier.
(2) The jet.
(3) The complete hydrodynamic circuit.
(4) The pump and the pump loss.
(5) The magnet and the magnet loss.
(6) Theory of the amplitude of the jet wave.
(7) Resistance and heating of the jet wave.
(8) The auxiliary-current loss.
(9) The main electrode. The "wearless" and the stabilized commutator.
(10) Design of the main electrode.
(11) Manifold cutting. Parallel and series aggregates. Statistics of the jet-wave commutator.
(12) The auxiliary electrodes. Stray current and stray field.
(13) The complete commutator. Resistance and overload capacity.
(14) The spark loss. Efficiency of the commutator and of the rectifier.
(15) The complete rectifier and the rectifier plant.
(16) Conclusions and anticipations.

(1) PRINCIPLE OF THE JET-WAVE COMMUTATOR AND RECTIFIER.

The following is a review of the experimental and theoretical results upon which the design of the new mechanical rectifier for high powers, namely, the jet-wave rectifier, is based. The principle and the constructional development of this rectifier have already been described in previous papers,* and it is therefore thought to be unnecessary to discuss them in detail in the present paper. It may not, however, prove inappropriate to compare briefly the entirely new principle of the jet-wave commutator—the main constituent of the jet-wave rectifier—with the well-known principles of mechanical synchronous commutation. This is done in Fig. 1, in which (*a*) represents the well-known oscillatory principle and (*b*) the rotary principle. The principle of the new commutator may be termed the translatory principle, its moving member being a wave-shaped conductor J which travels with constant velocity, disappearing into the electrodes E_1 and E_2 and alternately connecting the two sides of the same with a special tapping electrode E. It is explained in the papers referred to how the wave-shaped conductor may be produced from a mercury jet through interaction between a constant field F, Fig. 2, and an auxiliary alternating current supplied by an auxiliary transformer V_A. It is highly essential for the proper understanding of the *modus operandi* of the commutator to note that the jet wave produced moves on as a whole

HARTMANN: "Den konstruktive Udvikling af Straalebolgeensretteren, *Elektroteknikeren*, 1927, vol. 23, p. 541; O. A. GÜNTHERSCHULZE: "Die konstruktive Durchbildung des Quecksilber-Wellenstrahl-Gleichrichters," *Elektrotechnische Zeitschrift*, 1928, vol. 49, p. 1224; J. HARTMANN: "The Jet Wave," *Det kgl. danske Videnskabernes Selskabs Meddelelser*, 1929, vol. 9, p. 2.

with the velocity v of the original jet, each particle of the wave following a straight line through the centre of the field. If the wave is to be used for the rectification of an alternating voltage as indicated in Fig. 2,* it must advance half a wavelength ($\frac{1}{2}\lambda$) during half a period ($\frac{1}{2}$T) of the alternating voltage. This is achieved by utilizing a current synchronous with the voltage to be rectified for producing the wave. Furthermore, the cutting of the wave by the knife P should be effected at a definite point in the voltage wave, generally at the zero-point of the voltage. This may be brought about by adjusting the distance from the field to the electrode E_1E_2. The feature which makes the wave principle superior to the oscillatory and rotary principles [see Fig. 1 (*a*) and (*b*)] is the absolutely stiff coupling between the voltage to be rectified and the motion which effects the rectification, i.e. the motion of the "hitting-point" of the wave in E_1E_2.

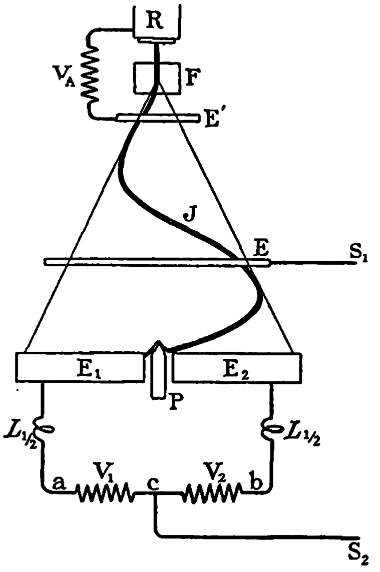

FIG. 2.

Rectification of multi-phase voltages may be effected in several ways by means of jet-wave commutators of the type shown in Fig. 2, or by other similar commutators. The rectifier which has so far been almost exclusively produced and studied is the 6-phase series type, which simply consists of three commutators similar to that in Fig. 2 connected to the 3 secondary phases of a 3-phase transformer, the three 2-phase rectifiers thus formed being connected in series. The resultant rectified voltage exhibits the ordinary 6 ripples per period, and the d.c. component is approximately 0·95 E_0, E_0 being the maximum value of the phase voltage of the transformer secondary.

(2) THE JET.

As the position of the main electrode, E_1E_2 in Fig. 2, depends on the velocity of the jet, this velocity must be kept constant within very fine limits, say within a few tenths of 1 per cent. The jet is therefore produced by means of a reservoir and a jet pipe, the level of the mercury in the former being kept constant by means of an overflow. For the constructional details of the jet-producing system, especially the means for electrically separating the jet from the pump and the commutation chamber (i.e. the so-called "drop separator"), reference should be made to the papers mentioned earlier. Here, only the essential properties of the jet will be considered.

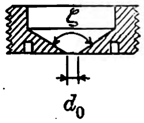

FIG. 3.

These properties are, first, the mass m per cm of the jet, and secondly, its velocity v. The former is determined by the equation

$$m = \rho(\tfrac{1}{4}\pi d^2) \quad . \quad . \quad . \quad . \quad . \quad (1)$$

ρ being the density of the mercury and d the diameter of the jet. With the obtuse conical bore shown in Fig. 3, which is the standard form of the nozzle, the diameter of the jet, d, is determined by

$$d = c_c d_0 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where d_0 is the diameter of the bore and c_c the coefficient of contraction. The variation of the latter with the apex angle of the bore, ζ, may be derived from Fig. 4, which shows the percentage contraction. With the standard apex angle of 120° the contraction is 15 per cent. The velocity v of the jet may in all practical cases be calculated from the simple Torricelli expression

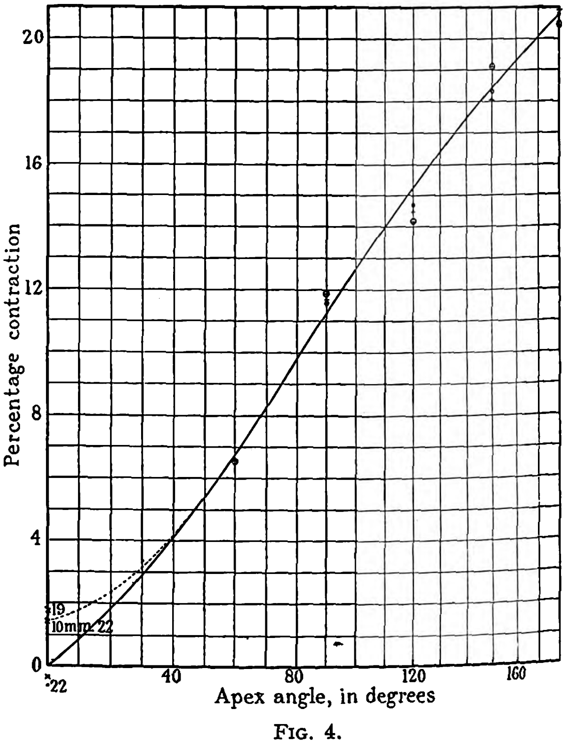

FIG. 4.

$$v = \sqrt{(2gh)} \quad . \quad . \quad . \quad . \quad . \quad (3)$$

---

* The function of the coils marked $L_{\frac{1}{2}}$ is explained in Section (9).

with an accuracy within, say, 1 to 2 per cent. The figures given in Table 1 for the percentage difference between the theoretical velocity v_t derived from expression (3) and the actual velocity v_a, which was about 6 metres per sec., were obtained with the same bores as the curve in Fig. 4.

TABLE 1.

ζ	60°	90°	120°	150°	180°
$\frac{v_t - v_a}{v_t} \times 100$	+ 0·9	− 0·05	− 0·6	− 0·3	+ 0·2

The constancy of the characteristics m and v of a jet produced by a standard nozzle is seen from Table 2, which contains repeated observations of the quantity emitted per sec. and the corresponding momentum.

TABLE 2.

Fluctuation of a Mercury Jet.

$d_0 = 3{\cdot}555$ mm, $\phi = 120°$, $v = 605$ cm per sec.

Quantity emitted mv	Deviation from mean quantity	Momentum of jet $\frac{mv^2}{g}$	Deviation from mean momentum
g/sec.	g/sec.		
594·96	+ 0·62	374·64	+ 1·41
596·35	+ 2·01	375·28	+ 2·05
597·74	+ 3·40	375·44	+ 2·21
591·83	− 2·51	375·29	+ 2·06
592·98	− 1·36	371·76	− 1·47
592·16	− 2·18	373·15	− 0·08
		375·57	+ 2·34
594·34		373·13	− 0·10
Maximum deviation from mean: 0·57 per cent.		373·13	− 0·10
		372·69	− 0·54
		371·61	− 1·62
		369·55	− 3·68
		370·70	− 2·53
		373·23	
		Maximum deviation from mean: 0·99 per cent.	

It follows from the figures in the table that the fluctuation in velocity cannot be greater than 0·6 per cent and is probably somewhat smaller. It may be noted that at the present time 6 metres per sec. represents the maximum velocity employed in jet-wave commutators, and that the percentage fluctuation generally diminishes somewhat with decreasing velocity. Nozzles with cylindrical bores or with conical bores of small apex angle cannot be used because the velocity exhibits sudden changes due to corresponding changes in the adhesion between the mercury and the walls of the bore.

(3) THE COMPLETE HYDRODYNAMIC CIRCUIT.

The maintenance of the jet requires a hydrodynamic circuit with a pump: a diagram of this circuit is given in Fig. 5. After being used in the jet wave, the mercury flows to the centrifugal pump P through the pit R_2 and the pipe T_4. The pump raises the mercury through the pressure pipe T_2 to the main reservoir R_1 with the drop separator D_1. The overflow T_3 opens into a container R_3, the bottom reservoir, which communicates with T_4 and serves to store the mercury from the upper part of the circuit when the rectifier is not working.

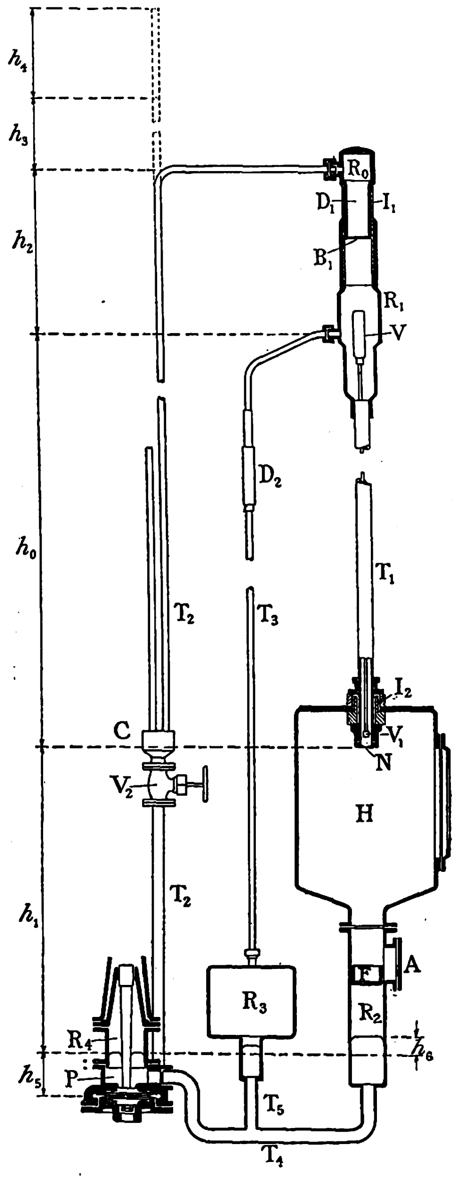

FIG. 5.

In the design of the hydrodynamic circuit two problems arise; first, the limiting velocities in the various parts of the circuit, and secondly, the permissible pressure-drop in the pipes.

With regard to the former, it should be noted that special care must be taken in the dimensioning of the members R_1, R_2, and R_4. If the velocity in the main reservoir be too great, air may be drawn down into the commutation chamber. This would be detrimental for two reasons. In the first instance an air bubble in the jet may cause the latter to break down, which again may cause the auxiliary electrodes E and E′ (Fig. 2) to be impaired. In the second instance the air will mix with the hydrogen (see Section 15) in the commutation chamber and, if the pump is running for any length of time with the rectifier disconnected from the transformer, may give rise to an explosion when commutation is again started. During commutation the oxygen of the air will combine with hydrogen to form water vapour, which will cause corrosion of the steel walls, etc., of the chamber. Again, if the velocity in the pit exceeds a certain limit hydrogen may be drawn out of the chamber and the consumption of this gas be thus increased. Finally, if the downward velocity in the space above the rotor of the centrifugal pump is too great air may be drawn into the rotor, causing irregular pumping. It has been found that the velocities in R_1, R_2, and R_4 should be kept below 10 cm per sec., and that the height of mercury above the bottom of the reservoirs should generally not be less than from 6 to 10 cm. In T_1 velocities up to 50 cm per sec. may be allowed. In T_4 a velocity of from 50 to 75 cm per sec. or even more is considered safe, and in T_2 the velocity is generally chosen at 150 cm per sec. It is essential to ensure a regular distribution of the flow to the surfaces in R_1 and R_2. With R_1 the drop separator solves the problem, while with R_2 a filter F serves as distributor.

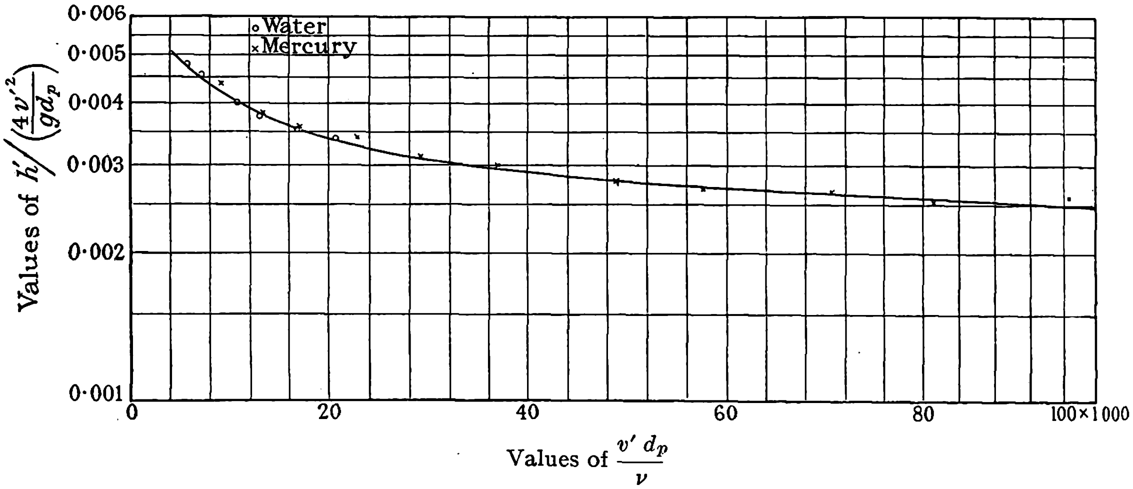

FIG. 6.

TABLE 3.

Temperature	Values of ν
C.	C.G.S. units
0°	0·00125
20°	0·00116
40°	0·00108
60°	0·00102
80°	0·00096
100°	0·00091
120°	0·00087

In order to elucidate the question of the pressure loss in the pipes, an investigation of the flow of mercury through steel pipes was undertaken,* and it was proved that the pressure-drop can be calculated by means of the expression

$$h' = \frac{4v'^2}{d_p g} f\left(\frac{v'd_p}{\nu}\right) \quad . \quad . \quad . \quad . \quad . \quad (4)$$

where h' = pressure-drop per cm of the pipe, in cm of mercury,
v' = mean velocity over the cross-section of the pipe, in cm per sec.,
d_p = diameter of the pipe, in cm,
g = acceleration due to gravity, in cm per sec².,
ν = dynamic viscosity of mercury, in C.G.S. units,

and $f(v'd_p/\nu)$ = Osborne Reynolds's function.

The function $f(v'd_p/\nu)$ found from the investigation is shown graphically in Fig. 6. It is the same for water and for mercury, as might be expected from the law of similarity set forth by Osborne Reynolds. Values of ν corresponding to a series of temperatures are given in Table 3.

(4) The Pump and the Pump Loss.

The pump is a centrifugal pump and is ordinarily operated by an induction motor. The axis of the rotor passes freely down into the pump chamber R_4 (Fig. 5), and thus no stuffing box is provided. The efficiency of the pump aggregate is of great importance in the question of economy of the rectifier. From tests on various plants it has been proved that the highest efficiency is obtained with comparatively low-speed pumps. Hence in 6-phase rectifier plants of 50 periods a 1 400-r.p.m. induction motor is to be preferred to one of twice that speed. In Fig. 7, characteristic curves for a standard

---

* "A Comparison between the Flow of Water and Mercury, etc.," *Mémoires de l'Académie Royal des Sciences et Lettres de Danemark, Copenhagen. Section des Sciences*, 1926, 8th series, vol. 10, No. 5.

1 400-r.p.m. pump are reproduced. The pump was designed for raising 1 200 cm^3 per sec. through a distance of 3·5 metres. The upper curve represents the available pressure h measured in cm of mercury. It is seen that at 1 200 cm^3 a head of 6 metres is available to cover the 3·5-metres pressure-drop in the pressure pipe and a necessary additional excess pressure. Furthermore, it is seen that the efficiency η_p of the pump proper amounts to about 36 per cent, while the efficiency η_a of the complete pump aggregate is nearly 30 per cent at full load. In larger pumps it is likely that efficiencies well above 30 per cent may be obtained, but the latter figure is now generally used in estimates of the efficiencies of rectifiers under design.

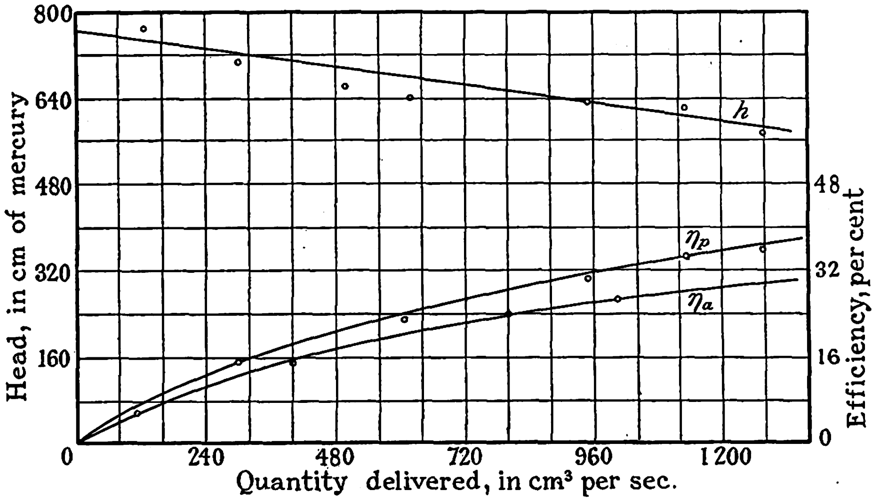

FIG. 7.

On the basis of the experimental facts now stated the power necessary for the maintenance of the jet can be calculated. The head for which the pump must be designed is indicated in Fig. 5, and comprises the heads, h_0, h_1, h_2, h_3 and h_4. Of these, h_3 denotes the excess pressure which is thought necessary to produce a well-defined flow through a nozzle inserted in T$_2$ at the entrance to the top reservoir R$_0$; while h_4 stands for the pressure-drop in the tube T$_2$ which is calculated on the basis of Fig. 6. In Table 4 two commutators with jets of 5 and 6 metres per sec. velocity respectively, and with a diameter $d = 4$ mm, are considered. V indicates the volume per sec. carried by a jet. To this volume 10 per cent is added in order to take into account the flow through the overflow T$_3$, Fig. 5. Q is the quantity in kg per sec. A density of 13·4 is assumed for the mercury, corresponding to a stationary temperature of about 80° C. The height h_0 is calculated from Torricelli's law,

$$v = \sqrt{(2gh_0)} \quad . \quad . \quad . \quad . \quad . \quad (5)$$

The sum $(h_1 + h_2)$ is taken from actual constructions. Under A_{net} the work per sec. found from

$$A_{net} = Qh_r . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

is stated, while A_a is the actual work per sec. based on the assumption of an efficiency of 30 per cent for the pump aggregate.

TABLE 4.

Pump Loss. $d = 4$ *mm,* $\eta_a = 30$ *per cent.*

Velocity v	Volume pumped $V + 0{\cdot}1V$	Quantity pumped Q	Pressure head					Work done		
			h_0	$h_1 + h_2$	h_4	h_3	$\Sigma h = h_r$	Actual $A_{net} = Qh_r$	Calculated $A_a = A_{net}/0{\cdot}3$	
m/sec.	cm³/sec.	kg/sec.	m	m	m	m	m	kg-m/sec.	kg-m/sec.	watts
5	69·3	0·927	1·27	1·23	0·5	0·75	3·75	3·48	11·6	114
6	83·2	1·115	1·84	1·56	0·5	0·75	4·65	5·18	17·3	170

The two jets referred to are at the present time considered suitable in the following commutators:

Commutator I: 20 kW, 75 volts, $d = 4{\cdot}0$ mm, $v = 5$ m per sec.

Commutator II: 33·3 kW, 180 volts, $d = 4{\cdot}0$ mm, $v = 6$ m per sec.

It is seen from Table 4 that the percentage pump loss with the 20-kW, 75-volt commutator is 0·57 per cent, and with the 33·3-kW, 180-volt commutator 0·51 per cent of the normal load. The two commutators specified will serve as examples throughout the paper.

In a 200-kW, 550-volt rectifier with 6 jets of 3·8 mm diameter and velocity 6 metres per sec. the total amount of mercury raised per sec. was 450 cm^3, or per jet per sec. 75 cm^3, representing 1 kg. The pump aggregate corresponding to Fig. 7 was employed. Its efficiency is only 17 per cent at 450 cm^3 per sec. Its pressure head is about 7·0 metres, of which the excess was absorbed in a valve. The power absorbed by the pump motor should accordingly be (1 × 7·0 × 100/17) kg-m = 41·0 kg-m, or 402 watts; or, again, (402/33 000) × 100 = 1·2 per cent with the jet used in a 33·3-kW, 180-volt commutator. Actually it was found that the pump consumed 2·86 kW, or 476 watts per jet, equivalent to a loss of 1·4 per cent. The slight difference between the actual value and that derived from the characteristics of the pump is probably due to the amount of mercury passing the overflow being somewhat larger than that assumed. Otherwise the example shows that the pump loss may be calculated with fair accuracy on the basis of the pump characteristics. The value of 0·51 per cent found above may therefore be relied on as the actual loss with a suitably chosen pump. The pump employed in the rectifier of the example was, as a matter of fact, originally designed for a rectifier with jets of velocity 7 metres per sec. and a total capacity of 1 200 cm^3 per sec. Hence the abnormally low efficiency of the pump.

(5) THE MAGNET AND THE MAGNET LOSS.

The jet wave is now almost always produced by means of a constant field in interaction with a synchronous alternating current passed through the jet as indicated in Fig. 2. For the production of this field an electromagnet is generally employed, the coils of which are kept outside the chamber in which commutation takes place, the limbs being carried through the top of the chamber and insulated from the top plate. The current for excitating the magnet is generally taken from a d.c. source, if available; otherwise the magnet is fed from a small d.c. generator which may be coupled to the axis of the a.c. motor operating the pump. With the coils taken outside the commutation chamber the latter need no longer contain any material which may be attacked by mercury (e.g. copper) or damaged by heat (e.g. cotton). Hence a considerable temperature can be tolerated in the chamber, say 100° C. or more, and artificial cooling of the chamber may in many cases be avoided. With a chamber of ordinary cast iron the intensity of the magnet field is reduced considerably by the magnetic flux straying to the top plate. The latter, or alternatively the whole chamber, should therefore be constructed of non-magnetic cast iron. It may be noted that magnets with coils enclosed in air-tight boxes of non-magnetic cast iron may be mounted wholly inside the chamber. The construction is, however, objectionable on account of the poor cooling of the coils. A good many types of magnets other than that indicated above have been tested. The pattern here described is, however, found to be the best suited to the purpose, especially as it leaves the space beneath the pole-pieces free for the mounting of the various electrodes of the commutator and for the easy inspection of the wave.

The characteristics of the magnetic field are its intensity *H*, its width *b* and its length *l*, i.e. its extension in the direction of the jet. The greater *H* the less is the auxiliary current necessary for the production of a given amplitude. For this reason it is desirable that the magnet should be built with as high an intensity as is consistent with a reasonable size of magnet. In Fig. 8, characteristic curves of a magnet of normal design are reproduced. With single-jet commutators field intensities of from 5 000 to 7 500 gauss are generally found convenient.

The width of the field-gap is, of course, determined by the diameter *d* of the jet, and with large commutators (d = 3 to 4 mm) is about 2 mm greater than *d*.

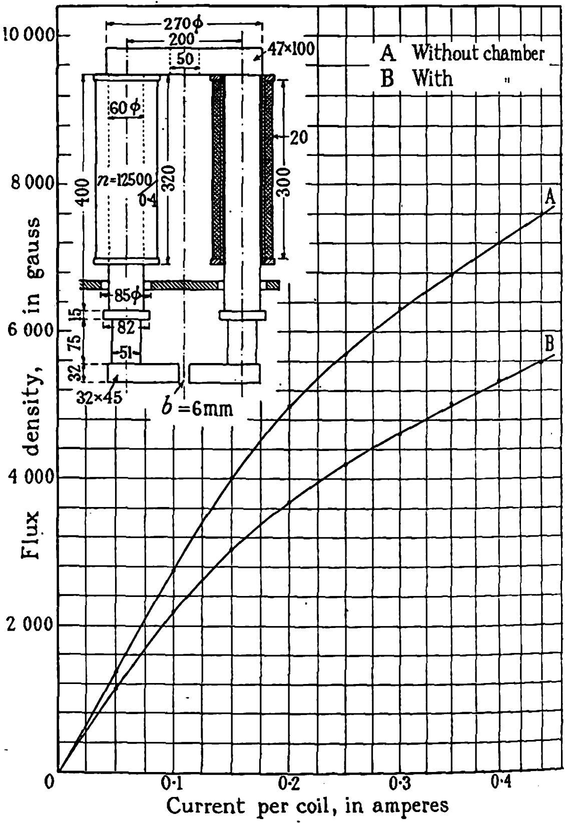

FIG. 8.

It is shown in the theory of the jet wave (see below) that the amplitude is proportional to sin $(\pi l/\lambda)$ provided the field is homogeneous. Thus a field of length $\frac{1}{2}\lambda$ would give maximum amplitude. Actually it does not pay to employ a field of this length; first, because of the very nature of the sine relationship, and secondly, on account of the field not being homogeneous. The actual shape of the field is generally as shown in Fig. 9, extending beyond the boundaries of the pole-piece. Such a field, as shown in the theory of the jet wave, is equivalent to a homogeneous field with the maximum intensity of the actual field and of a length somewhat greater than the height of the pole-piece. The "effective length of the field" may therefore be written

$$l_e = l + l'$$

where l' is roughly equal to the width b of the field. Under these circumstances l is generally $0 \cdot 3\lambda$ or somewhat less. Magnets of the type shown in Fig. 8 have been carefully studied in order to produce a safe basis for their design. From characteristics of the type shown in Fig. 8 it is known how many ampere-turns are necessary for the production of a field of given dimensions and intensity. From investigations on the variation of the flux round the magnetic circuit of the magnet the dimensions of the various members of the circuit are derived. In the design of the coils the number of ampere-turns and the interior diameter of the coils can therefore be considered as given. The voltage to be applied to each coil is, as a rule, predetermined. The problem is to design the coil in such a way that its stationary temperature does not exceed a certain limit.

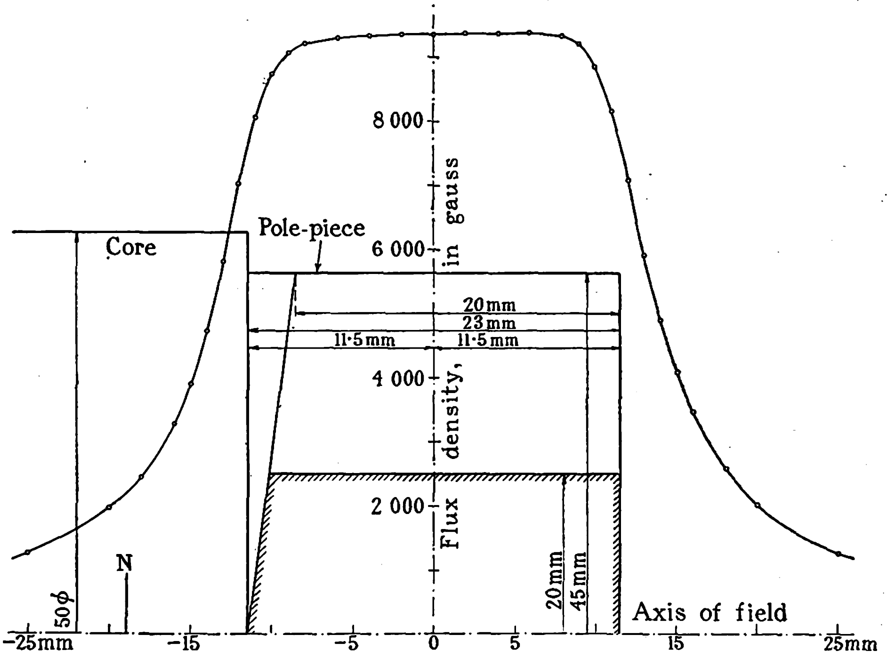

FIG. 9.

It would take too long to give the complete theory for the design of the magnet coils, and hence only a brief account of the investigations on which the determination of the heating of a coil is based will be given. In the stationary state it is assumed that the heat q resulting from the flow of a current i_s is carried away solely through the external cylindrical surface a_c of the coil. Now

$$q = \frac{ei_s}{4 \cdot 19} \text{ g-cal. per sec.} \quad . \quad . \quad . \quad . \quad (7)$$

where e is the voltage across the coil. The heat transmitted through a_c may be written

$$q = ca_c(T_s - T_u) \text{ g-cal. per sec.} \quad . \quad . \quad (8)$$

where T_s is the stationary temperature of the coil, while T_u is the temperature of the surroundings and c is a constant. The quantity $(T_s - T_u)$ may be determined for a given coil by measuring its resistances r_s and r_u corresponding to the temperatures T_s and T_u respectively, for

$$r_s = r_u\left\{1 + a_u(T_s - T_u)\right\} \quad . \quad . \quad . \quad (9)$$

where the temperature coefficient a_u may be expressed by

$$\frac{1}{a_u} = 235 + T_u \quad . \quad . \quad . \quad . \quad (10)$$

From equations (7) to (10) the formula

$$c = \frac{ei_s}{4 \cdot 19 a_c} \times \frac{235 + T_u}{(i_u/i_s) - 1} \quad . \quad . \quad . \quad (11)$$

is derived, where i_s and i_u are the currents which the constant voltage e will send through the coil when the latter has the resistances r_s and r_u respectively. The currents are introduced instead of r_s and r_u, the relation $(i_u/i_s) = (r_s/r_u)$ connecting the two sets of quantities.

An experimental investigation was carried out with the object of determining c for a series of coils with the same interior diameter and the same amount of wire but with different lengths l_s of the coil and with a correspondingly different number of layers. The results are given in Fig. 10. The abscissa is the power in watts, P', dissipated per cm^2 of the exterior cylindrical surface. It will be seen that c [calculated from equation (11)] is independent of the depth b_s of the winding space and is a linear function of P'. The symbols used in the figure have the following meanings: d_w = diameter of copper core of the wire, 2δ = thickness of the insulation (double cotton-covered), d_c = internal diameter of coil. The investigation was supplemented by measurement of c for a coil wound with $0 \cdot 40$-mm wire ($0 \cdot 60$ mm over covering) on a tube with a diameter $d_e = 6 \cdot 8$ cm. The value for c agrees almost exactly with that predicted from the main investigation. From the curves in Fig. 10 the following formulæ are derived:

$$c = (2\cdot 2 + 8\cdot 0P')10^{-4} \text{ (g-cal., sec., °C., cm}^2\text{, watts)} \quad (12)$$

$$T_s - T_u = \frac{P'}{4\cdot 19(2\cdot 2 + 8\cdot 0P') \,.\, 10^{-4}} \quad . \quad (13)$$

In order to convey an idea of the power necessary for the maintenance of the field, we shall consider a magnet of the type indicated in Fig. 8. The magnet, with the pole-pieces indicated in Fig. 8, is of the size employed in a 33·3-kW, 180-volt commutator with a jet of 3·8 to 4·0 mm diameter and a velocity of 6 m per sec. From curve A in Fig. 8 it is seen that the production of a field of 7 500 gauss requires about 11 200 ampere-turns. Coils for such a magnet with a 60-mm diameter iron core and an internal diameter of windings $d_c = 68$ mm were calculated. It was assumed that $T_u = 30°$ C. and that a temperature T_s of 90° C. could be allowed. Two cases were considered, namely, $e = 36\frac{2}{3}$ volts and $e = 110$ volts.

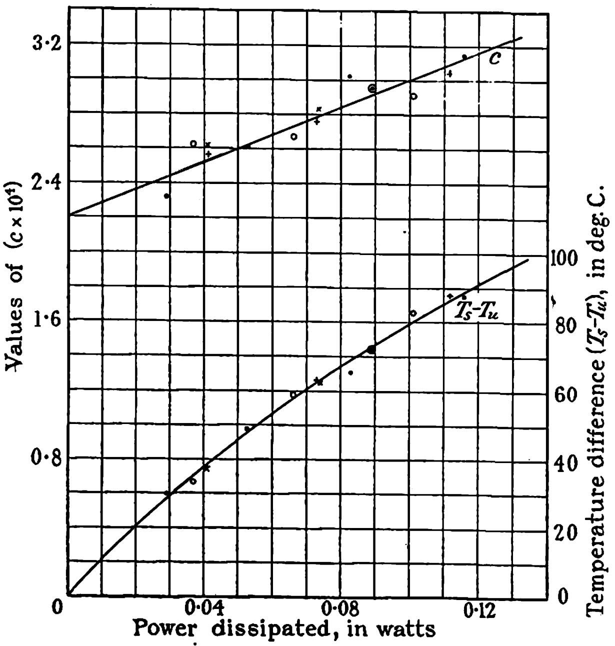

Fig. 10.

Key.

	Number of layers	b_s	l_s	d_w	2δ	d_c
		cm	cm	cm	cm	cm
●	9	1·23	42·4	0·12	0·02	9·15
+	13	1·65	27·9			
o	17	2·17	24·0			
×	21	2·73	19·0			
⊙	26	1·6	30·0	0·04	0·02	6·8

With $e = 36\frac{2}{3}$ volts the diameter d_w of the core of the wire was 1·10 mm. With double cotton covering the overall diameter d' of the wire is then 1·30 mm. The following quantities can now be calculated:

Depth of winding space, $b_s = 1\cdot 90$ cm $(d_c + 2b_s = 10\cdot 60$ cm).
Length of winding space, $l_s = 28\cdot 5$ cm.
Power consumed per coil, $P_s = 65\cdot 5$ watts, or per magnet, 131 watts.
Number of turns per coil, $N = 3\,135$.
Total length of wire per coil, $l_w \doteq 858$ m.
Total weight of copper per coil, $w = 7\cdot 26$ kg.

With $e = 110$ volts, d_w was taken as 0·65 mm, and the following figures were obtained:

$b_s = 2\cdot 32$ cm $(d_c + 2b_s = 11\cdot 44$ cm).
$l_s = 28\cdot 1$ cm.
$P_s = 69\cdot 5$ watts per coil, or 139 watts per magnet.
$N = 8\,860$.
$l_w = 2\,540$ m.
$w = 7\cdot 50$ kg.

Used with commutator No. II [Section (4)] the percentage loss with the 110-volt magnet is thus

$$\frac{139 \times 100}{33\cdot 3 \times 1\,000} = 0\cdot 42 \text{ per cent.}$$

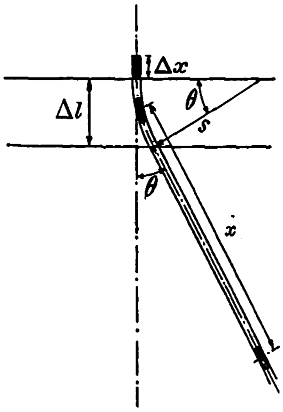

Fig. 11.

With commutator No. I [Section (4)] the loss is 0·70 per cent.

(6) Theory of the Amplitude of the Jet Wave.

We shall now show how, in a very simple way, an expression may be derived from which the excitation current necessary for the production of a jet wave of given characteristics may be obtained.

In the development of this expression we shall assume the wave to be produced by means of a current

$$i = I \sin \omega t = I \sin (2\pi t/\mathrm{T}) \quad . \quad . \quad . \quad (14)$$

We shall assume the separate particles (Fig. 11) of the jet and the wave to move quite independently of each other. We shall also suppose the field to be homogeneous. Finally, we shall in the first instance imagine the field as laminar, i.e. of an extension Δl in the direction of the jet so short compared with the wavelength that practically no change takes place in the value of the current i during the passage of a particle Δx of the jet.

The particle which passes the field at the moment t_0 experiences a mechanical force which is perpendicular to the direction of its motion and to the lines of force of the field. The force is expressed by

$$F = \tfrac{1}{10}\,\Delta x\,.\,HI \sin \omega t_0 \text{ (dynes, cm, gauss, amperes)} \tag{15}$$

H being the intensity of the magnetic field.

Under the influence of this force the particle will move along a circle the radius s of which is given by

$$(m\,.\,\Delta x\,.\,v^2/s) = F \quad . \quad . \quad . \quad . \tag{16}$$

m being the mass per cm of the jet, and v the velocity of the particle, which is that of the jet. After having passed the field with unaltered velocity v, the force being all the time perpendicular to the path, the particle will follow the tangent to the last point of the circular path, i.e. a straight line. As seen from Fig. 11, the direction of the straight path is given by

$$\sin\theta = \Delta l/s \quad . \quad . \quad . \quad . \quad . \tag{17}$$

Introducing $(1/s)$ as determined by equations (15) and (16):

$$\sin\theta = \tfrac{1}{10}(HI/mv^2)\Delta l\,.\,\sin\omega t_0 \quad . \quad . \tag{18}$$

This is the expression for the path of the particular particle. At the time $t > t_0$ we shall find the particle at a distance x from the field, say the centre of the latter, given by

$$x = v(t - t_0) \quad . \quad . \quad . \quad . \quad . \quad . \tag{19}$$

From equations (18) and (19) we finally obtain the expression for the jet wave proper by eliminating t_0. We find

$$\sin\theta = \tfrac{1}{10}(HI/mv^2)\Delta l\,.\,\sin\left[\omega\left\{t - (x/v)\right\}\right] \quad . \tag{20}$$

from which it is seen that the wave as a whole travels on with the velocity v of the jet and that its amplitude increases in proportion to the distance from the field.

Now, as a matter of fact, the fields employed in the actual jet-wave commutators are not short compared with the wavelength. As seen above they may amount to $0{\cdot}3\lambda$. It can be proved that with such fields the shape of the wave, and especially its amplitude, may be fairly accurately determined in the following way. In the first instance it is assumed that the wave will be nearly the same as would be produced if the exciting current were constant during the passage of each particle and equal to the mean value of the actual current during the passage. Furthermore, in calculating the mean value the time taken for the passage is assumed to be l/v, that is, equal to the time required for a particle of the original jet to pass the field. This mean value for the particle which at the moment t_0 passes the middle of the field is determined by

$$I_m = \frac{1}{\gamma T/2}\cdot\int_{t_0-\gamma T/4}^{t_0+\gamma T/4} I\sin\omega t\,.\,dt = \frac{\sin(\gamma\pi/2)}{\gamma\pi/2} I\sin\omega t_0 \tag{21}$$

where γ is the length of the field measured with half a wavelength $(\frac{1}{2}\lambda)$ as unit; thus $\gamma = l/(\frac{1}{2}\lambda)$. From what has been said above it is now at once seen that the deflection of the particle in question is given by

$$\sin\theta = \tfrac{1}{10}(HI/mv^2)l\,\frac{\sin(\gamma\pi/2)}{\gamma\pi/2}\sin\omega t_0 \quad . \tag{22}$$

and that the equation of the jet wave at the moment t is

$$\sin\theta = \tfrac{1}{10}(HI/mv^2)l\,\frac{\sin(\gamma\pi/2)}{\gamma\pi/2}\sin\left[\omega\left\{t - (x/v)\right\}\right] \tag{23}$$

x indicating the distance from the centre of the field to the point considered. Denoting the angular amplitude of the wave by θ_m

$$\sin\theta_m = \tfrac{1}{10}(HI/mv^2)l\,\frac{\sin(\gamma\pi/2)}{\gamma\pi/2} \quad . \quad . \tag{24}$$

It was assumed that the field was homogeneous. As shown in Fig. 9, the actual field is not homogeneous. We shall take this fact into account by substituting for the actual length of the field the effective length of field l_e as defined earlier in the paper. This may easily be calculated from the curve representing the shape of the field. We thus obtain the expression

$$\sin\theta_m = \tfrac{1}{10}\,(HI/mv^2)l_e\,\frac{\sin(\gamma_e\pi/2)}{\gamma_e\pi/2} \quad . \quad . \tag{25}$$

where $\gamma_e = l_e/(\frac{1}{2}\lambda)$.

It was furthermore assumed that the various particles constituting the jet wave moved independently of each other. One might expect that this assumption would not be correct, owing to cohesion and viscosity in the jet. The effect of these qualities of the liquid would be a "damping" of the wave which could be taken into account by applying an inverse factor of damping f' to the right-hand side of equation (25), by writing

$$\sin\theta_m = \tfrac{1}{10}f'(HI/mv^2)l_e\,\frac{\sin(\gamma_e\pi/2)}{\gamma_e\pi/2} \quad . \tag{26}$$

It can be proved, however, that with the velocities generally used in jet-wave commutators the damping is practically zero, whence $f' = 1$.

In order to illustrate this, the results of an experimental test are reproduced in Table 5.

The figures in the table refer to 6 commutators in a 6-phase series twin rectifier. The head of the jets was 177 cm, from which, by Torricelli's formula, their velocity is found to be 590 cm per sec. The frequency of the exciting current was 50; thus the wavelength was $11{\cdot}8$ cm. The mass m per cm of the jet was calculated from the diameter d of the jet and from the density ρ of the mercury. The former was determined from the diameter d_0 of the bores and from the coefficients of contraction c_c found by special measurements. The density was assumed to be $13{\cdot}4$, corresponding to a stationary temperature of about 80° C. of the mercury during the test. The effective lengths of the fields were determined from the field curves of the magnets; in all cases l' was found to be very nearly $4{\cdot}9$ mm. Finally, it should be noted that a correction of $2{\cdot}7$ per cent is applied to the values in column 5, i.e. the values calculated from equation (25). This correction takes into account the fact that the particle in the outermost path, i.e. the path which determines the amplitude, inside the imaginary homogeneous field follows an approximately circular path and thus remains there for a time which is slightly longer (in the case considered $2{\cdot}7$ per cent longer) than if it had passed the field along the path of the original jet, as assumed in equation (25).

It is seen that the actual amplitude is not smaller but, on the contrary, about 2 per cent greater than the theoretical amplitude calculated from equation (25). This, in all probability, is due to the circumstance that v is assumed about 2 per cent too large when derived from Torricelli's law. This again means that m is assumed 2 per cent too small, mv^2 is 2 per cent too high, and finally $\sin \theta_m$ is 2 per cent too small. It will be appreciated that equation (25) gives the amplitude, or alternatively the current I necessary for the production of a given amplitude, with an error not exceeding about 1 or 2 per cent.

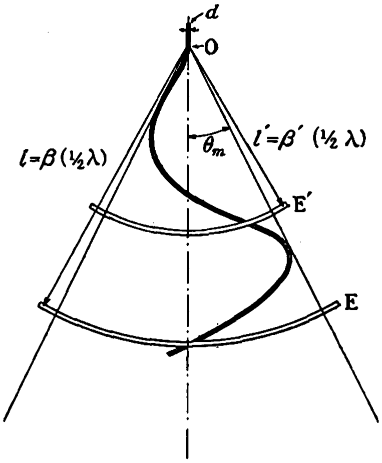
(7) RESISTANCE AND HEATING OF THE JET WAVE.



d
O
$l=\beta(\frac{1}{2}\lambda)$
θ_m
$l'=\beta'(\frac{1}{2}\lambda)$
E′
E

FIG. 12.

In the design of the commutator the resistance of the jet wave plays a great part. The resistance between the starting point, i.e. the centre O of the field (Fig. 12), and a circular electrode like E′, or the resistance between two such electrodes as E′ and E, varies periodically, though not quite harmonically, with twice the frequency of the alternating current by which the jet wave is produced. Now it has fortunately proved possible to obtain an explicit expression for the mean value, over a given period of time, of the resistance of the wave down to a circular electrode at the distance of $\beta(\frac{1}{2}\lambda)$ from the starting point. This expression is

$$k-1=\frac{\pi^2\beta^2(\sin\theta_m)^2}{6}\times\left(1+\frac{(\sin\theta_m)^2}{4}+\frac{(\sin\theta_m)^4}{8}+\frac{5}{64}(\sin\theta_m)^6+\ldots\right) \quad (27)$$

where k indicates the ratio of the mean resistance to the resistance of the corresponding length $\beta(\frac{1}{2}\lambda)$ of the original non-undulating jet. The resistance per cm of the jet in the case of mercury may be calculated as $\frac{0\cdot01}{(\pi/4)d^2}$ ohm at 80° C., d being the diameter of the jet in mm.

The resistance between two circular electrodes such as E′ and E is found by subtracting the resistance down to E′ from the resistance down to E.

In a jet carrying an electric current the temperature will rise from the point at which the current is introduced, say the nozzle, in the direction of the flow. An element of the jet will commence to heat up at the moment it enters the current-carrying portion of the jet, and it will go on heating up as long as it is traversing this portion. Its temperature must therefore increase steadily, which means that the temperature of the jet must rise in the direction of motion. The amount of heat dq stored up in the element Δx during the time dt is

$$dq = 0\cdot239\, I^2r'(\Delta x/a)dt \quad . \quad . \quad . \quad (28)$$

I being the current in amperes, r' the specific resistance of the liquid in ohms per cm³, and a the area of cross-section of the jet in cm². The corresponding rise of temperature $d\vartheta$ is given by

$$j\rho a\,.\,\Delta x\,.\,d\vartheta = 0\cdot239\, I^2r'(\Delta x/a)dt\,. \quad . \quad (29)$$

j being the specific heat and ρ the density of the liquid. During the interval dt the particle proceeds through the distance dx, where

$$dx = v \, . \, dt \quad . \quad . \quad . \quad . \quad . \quad (30)$$

v being the velocity of the jet in cm per sec. Hence the rise of temperature along a portion dx of the jet is

$$d\vartheta = 0 \cdot 239 \frac{r'}{j\rho} \cdot \frac{I^2}{va^2} dx \quad . \quad . \quad . \quad . \quad (31)$$

from which it follows that the temperature gradient (rise per cm) is

$$\dot{\vartheta} = 0 \cdot 239 \, . \, \frac{r'}{j\rho} \cdot \frac{I^2}{va^2} \quad . \quad . \quad . \quad . \quad (32)$$

With a mercury jet, $r' = (0 \cdot 958 \times 10^{-4})$, $j = 0 \cdot 033$, and $\rho = 13 \cdot 6$; hence

$$\dot{\vartheta} = (5 \cdot 10 \times 10^{-5}) I^2 / va^2$$
(deg. C. per cm, amperes, cm per sec., cm^2) (33)

Expression (31) takes no account of conductivity and the radiation of heat. Estimates of the effect of these factors show that in most cases they are practically insignificant. The formula has been tested experimentally and found to be correct within a few per cent. In order to form an idea of the heating we may consider a jet as used in a fairly large commutator, say a 30- to 40-kW commutator. With such a jet v may be 600 cm per sec., and d = diameter of jet = 0·4 cm. With these figures, $\dot{\vartheta} = (0 \cdot 540 \times 10^{-5}) I^2$. Hence with $I = 500$ amperes, $\dot{\vartheta} = 1 \cdot 35$ deg. C. per cm. If a length of 10 cm of the jet is carrying this current, the rise of temperature through the jet would thus be only 13·5 deg. C. With 1 000 amperes it would be $(4 \times 13 \cdot 5) = 54$ deg. C. A mercury jet is a conductor which will stand extremely high current densities. Thus with 1 000 amperes the density is (1 000/12·6) = 79 amperes per mm^2, and the portion of jet in question will obviously carry more than double that density before evaporation takes place.

It should be noted that the different particles of the wave suffer different heating when carrying a current. The particle following the axis of the wave undergoes the greatest rise of temperature. If with a non-undulating jet of length l_0 the latter rise is ϑ_0, the corresponding rise for the central particle of a wave produced from the jet-piece is $\vartheta_0 + \Delta\vartheta$, where

$$(\Delta\vartheta / \vartheta_0) = \tfrac{1}{3}\pi^2\beta^2\alpha'^2 \quad . \quad . \quad . \quad . \quad (34)$$

where $\beta = l_0 / \frac{1}{2}\lambda$ and $\alpha' = \sin\theta_m$. If a jet wave of wavelength 12 cm is produced from a jet-piece of length 10 cm, then $\beta = 1 \cdot 66$. With $\tan\theta_m = 0 \cdot 5$, $\sin\theta_m = 0 \cdot 447$ and $(\Delta\vartheta / \vartheta_0)$ becomes 1·83; hence the total heating is 2·83 times the heating of the non-undulating jet. With a current of 1 000 amperes the rise of temperature in the axial particles thus becomes $(2 \cdot 83 \times 54) = 153$ deg. C.

(8) THE AUXILIARY-CURRENT LOSS.

On the basis of the theory given above we are now able to calculate the current which, with a given jet, is necessary to produce a wave of given amplitude. Fig. 13 is a diagram of the upper part of the jet-wave commutator with the nozzle N, the field F and the auxiliary-current electrode E′. The latter is of the "curry-comb" type, a description of which is given in Section (12). It touches the wave along a circle the centre of which lies at the mid-point O of the field, i.e. in the starting point of the wave. In the following we shall consider the two commutators I and II specified on page 949.

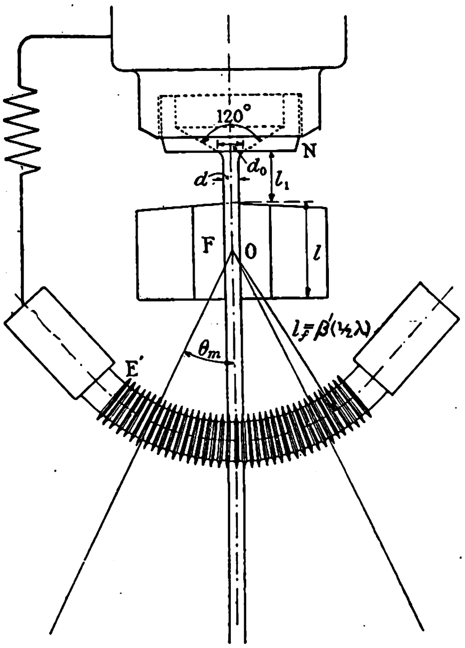


FIG. 13.

Commutator I: v = 5 metres per sec.:—

$d = 4$ mm, $\alpha' = \sin\theta_m = 0 \cdot 371$, $\frac{1}{2}\lambda = 5 \cdot 00$ cm,
$l_1 = 1 \cdot 0$ cm, $\gamma_e = 0 \cdot 5 (l_e = 2 \cdot 5$ cm),
$\beta' = l_f / (\frac{1}{2}\lambda) = 0 \cdot 8 (l_f = 4 \cdot 0$ cm), $H = 7\,500$ gauss.

Commutator II: v = 6 metres per sec.:—

$d = 4$ mm, $\alpha' = \sin\theta_m = 0 \cdot 447$, $\frac{1}{2}\lambda = 6 \cdot 00$ cm,
$l_1 = 1 \cdot 2$ cm, $\gamma_e = 0 \cdot 5$ ($l_e = 3 \cdot 0$ cm),
$\beta' = 0 \cdot 8$ ($l_f = 4 \cdot 8$ cm), $H = 7\,500$ gauss.

In both cases the mass m per cm of the jet is 1·69 g, and the resistance r per cm of the undeflected jet is $0 \cdot 810 \times 10^{-3}$ ohm, it being assumed that the density of mercury is 13·4 g per cm^3 and the specific resistance 1·017 ohm (m/mm^2), corresponding to a stationary temperature of the mercury of about 80° C. From equation (26), with $f' = 1$, the values $I = 92 \cdot 8$ amperes and 134·4 amperes are found for commutators I and II respectively. I indicates the maximum value of the auxiliary current. The effective value is obtained by dividing by $\sqrt{2}$. The effective auxiliary currents are therefore:

Commutator I: $I_{eff} = 65 \cdot 6$ amperes.
Commutator II: $I_{eff} = 95 \cdot 0$ amperes.

We now find the resistances of that part of the commutator carrying the auxiliary current. From equation (27) we find that $k - 1 = 0{\cdot}151$ and $k - 1 = 0{\cdot}223$ for the two commutators respectively.

The resistance from O to E′ is therefore:

Commutator I:
$(1{\cdot}151 \times 0{\cdot}810 \times 10^{-3} \times 4{\cdot}0) = 3{\cdot}73 \times 10^{-3}$ ohm.

Commutator II:
$(1{\cdot}223 \times 0{\cdot}810 \times 10^{-3} \times 4{\cdot}8) = 4{\cdot}75 \times 10^{-3}$ ohm.

The resistance from the nozzle to O is nearly:

Commutator I:
$(0{\cdot}810 \times 10^{-3} \times 2{\cdot}25) = 1{\cdot}82 \times 10^{-3}$ ohm.

Commutator II:
$(0{\cdot}810 \times 10^{-3} \times 2{\cdot}70) = 2{\cdot}19 \times 10^{-3}$ ohm,

the height l at the pole-piece being here identified with l_e.

Finally it is found that the contact resistance between the wave and the electrode E′ is about (4×10^{-3}) ohm, while the contact resistance between the mercury and the jet pipe through which the current is transmitted into the jet may amount to something like 10^{-3} ohm. The total resistance in the two cases is therefore about $10{\cdot}6 \times 10^{-3}$ and $12{\cdot}0 \times 10^{-3}$ ohm respectively. The power absorbed in the resistances becomes:

Commutator I: $(65{\cdot}6^2 \times 10{\cdot}6 \times 10^{-3}) = 45{\cdot}5$ watts.
Commutator II: $(95^2 \times 12{\cdot}0 \times 10^{-3}) = 108$ watts.

The first commutator serves as a 20-kW, 75-volt commutator in a 6-phase, 225-volt series rectifier, while the other is used as a 33·3-kW, 180-volt commutator in a 6-phase, 540-volt series rectifier. The percentage loss is thus:

Commutator I: $(100 \times 45{\cdot}5)/20\,000 = 0{\cdot}23$ per cent.
Commutator II: $(100 \times 108)/33\,300 = 0{\cdot}32$ per cent.

Finally, in order to take the loss in the auxiliary-current transformer and in the exterior connections into account we may increase these figures by, say, 20 per cent, thus giving the total auxiliary-current losses as

Commutator I: 0·3 per cent.
Commutator II: 0·4 per cent.

In a commutator very nearly similar to No. II, but with a jet of diameter 3·8 mm, it was found by direct measurement that the resistance in the auxiliary-current circuit was 13×10^{-3} ohm, in almost exact agreement with the above calculation.

(9) THE MAIN ELECTRODE. THE "WEARLESS" AND THE STABILIZED COMMUTATOR.

With the jet-wave commutator, commutation is accompanied by a transient arc. The latter originates from the stray fields of the transformer, the effect of these fields being in the main the same as that of two self-inductances $L_\frac{1}{2}$, inserted as indicated in Fig. 2. When the supply of the rectified current I_d is changed from, say, the left-hand to the right-hand side of the transformer, the energy stored in the left-hand inductance must be made to disappear, while an equivalent amount of energy must be produced in the right-hand inductance. The commutation spark is the direct consequence of this process, and has an important effect on the economical working of the jet-wave rectifier inasmuch as the electric energy which is transformed into heat in the spark generally represents the largest loss in the rectifier plant. On the other hand the spark has given rise to one of the main problems in the constructional development of the main electrode in that the latter, and especially the cutting device, must be capable of withstanding the corroding effect of the commutation spark. It had hitherto been considered almost impossible to solve this problem; nevertheless a complete and simple solution has been found.*

The solution consists in replacing the insulating wall P, indicated in Figs. 2 and 14 (*a*), by a knife W of conducting material, and preferably of high melting-point [Fig. 14 (*b*)]. A tungsten knife is generally employed. While with a cutting device like that of Fig. 14 (*a*) the spark occurs at the edge of the insulating wall, and so impairs the latter more or less, the spark with the tungsten knife almost always remains between the cut ends of the jet wave. It therefore only evaporates mercury which is presently again condensed in other parts of the system. With an ordinary high-power commutator for, say, 30 kW the height of the knife may be 5 mm and the width of its base about 3 mm. Such a knife will withstand the normal spark power, which may amount to 1 or 1·5 kW, for practically any length of time, and so a "wearless" commutator for mechanical rectification has been brought into existence.

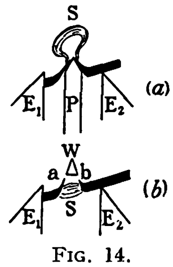

FIG. 14.

Immediately the cutting of the jet wave is completed two sparks are undoubtedly formed at "a" and "b." These sparks, however, unite almost instantly into one single spark as indicated in Fig. 14 (*b*). It has been found that if the normal spark of a large-power commutator is in some way or other forced to bridge over to the tungsten knife, then the latter is almost immediately destroyed by melting. On the other hand, it has been proved that with regular operation of the knife the latter will handle overloads of 50 or 100 per cent for considerable periods, and that it is not impaired by direct short-circuiting of the commutator.

With normal commutation the knife must be adjusted to such a position relatively to the two sides of the main electrode that these sides are short-circuited for a short time—the "interval of metallic short-circuiting" or the "overlapping interval"—during each commutation. Otherwise the circuit of the rectified current is obviously broken and a greatly increased spark loss ensues, especially if the circuit contains self-inductance. During the overlapping interval a short-circuit current i_c will generally grow up in the transformer, and this current will add to the normal rectified current I_d, thereby increasing the energy stored in the stray field and, hence, in the commutation spark. It will thus be gathered that for economical reasons it is essential to reduce i_c to as small a value as possible. Generally this is achieved by reducing the interval of overlapping but, on the other hand, this interval must not be made too small, for then the inevitable uncertainty of the process of cutting may too frequently change the overlapping into an interruption, with the effect of a heavy increase in the spark loss, especially at greater loads. Generally, however, the overlapping interval may be taken as low as 2 to 3 per cent of the half-period of the alternating voltage to be rectified. But even with such small values of the interval it has proved necessary, or advantageous, with large-capacity commutators to provide special means for reducing the short-circuit current i_c.

---

* The information given in the remainder of this section has already appeared in the papers referred to in Section (1). As, however, recent experiences have thrown new light on the extremely important process of commutation, and as these experiences cannot be made intelligible without a fairly thorough representation of the facts in question, it would seem justifiable partially to re-state the latter.

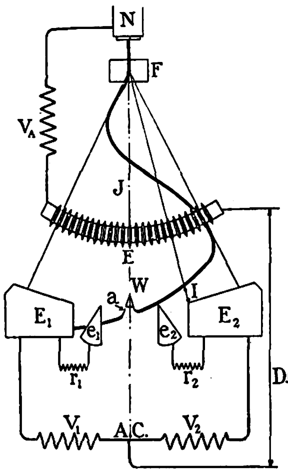

FIG. 15.

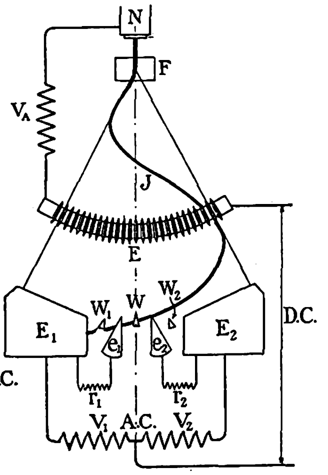

FIG. 16.

In this way the so-called "complex electrode" was introduced.

Fig. 15 represents such an electrode. Each of the two electrode sides now consists of two pieces, the main pieces E_1, E_2 and the secondary electrodes e_1, e_2. Between the two members of each side the electrode resistances r_1, r_2 are inserted. At the instant depicted in the figure the left-hand resistance r_1 is short-circuited by part of the jet wave connecting E_1 and e_1, while the right-hand resistance r_2 is inserted in the short-circuiting circuit of the transformer, reducing the current i_c. It will be noted that no new idea is involved in the device here considered, which obviously is based on a well-known principle from cell-switching practice.

In addition to the means here considered for controlling the short-circuit current, it has been found useful with large-capacity plants to add to the effective self-inductance of the transformer. This is done by inserting suitable coils in one (or in both) of the connections between the transformer and the main electrode, as indicated by $L_{\frac{1}{2}}$, $L_{\frac{1}{2}}$ in Fig. 2.

If commutation with a mechanical rectifier has not been completed—that is to say, if the spark has not vanished—before a certain moment, the normal commutation spark is changed into a permanent arc which during the next half-period, or even longer, completely short-circuits the transformer, generally throwing the rectifier out of action. The explanation of this instability is as follows: The spark lasts for a certain interval which generally extends beyond the zero-point of the voltage to be commutated. This does not matter, provided the voltage of the transformer has not, at the end of the interval, risen beyond a certain limit. If, however, this limit is passed, the voltage may be sufficient to produce a new discharge in the opposite direction in continuation of the original spark. This new discharge will be acted upon by an increasing voltage and will therefore develop into a permanent arc. This phenomenon of instability greatly endangered the development of large-capacity rectifiers until perfect stability was ensured by the simple stabilizing device indicated in Fig. 16. The commutator here shown is much the same as that in Fig. 15, the only difference being that two tungsten knives, W_1, W_2 have been inserted between the secondary electrodes e_1, e_2 and the main parts E_1, E_2. During the commutation indicated in the figure the knife W_1 will cut the wave nearly at the same moment as the main knife W, thereby inserting the resistance r_1 in series with the spark created at W. If this spark should tend to change into an arc the tendency is checked by the resistance r_1 [see Section (11)]. In order to illustrate the significance of the stabilizing device, Fig. 17, showing the constants of commutation, is reproduced. E indicates the voltage to be commutated, say the voltage across the half-phase V_1 in Figs. 15 and 16. The metallic short-circuiting commences at a time t_1 before the zero-point of the voltage. The overlapping interval is shown as τ_1 and the spark interval as τ_2. Now it was found that with a commutator with no stabilizing device, t_1—with a 200-kW, 550-volt rectifier—must be made as great as 10 or 12 per cent of the half-period in order to ensure safe commutation; while with a stabilizing device t_1 might be reduced to 3 per cent. Alternatively, commutation might be effected practically at the moment of zero voltage, which of course meant a considerably improved commutator efficiency. At the same time it was found that the commutator was made practically independent of the ordinary fluctuations in frequency.

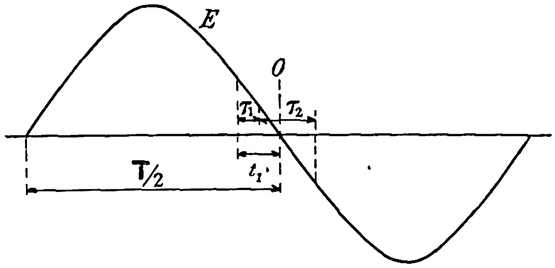

FIG. 17.

(10) DESIGN OF THE MAIN ELECTRODE.

Fig. 18 shows the component members of a high-capacity main electrode. This electrode was used in a

33·3-kW commutator in a 200-kW, 550-volt series rectifier. The jet wave was produced from a jet 3·8 mm in diameter with a velocity of 595 cm per sec. The distance from the centre of the field to the level of the secondary electrodes was $1 \cdot 95 \times \frac{1}{2}\lambda$, $\frac{1}{2}\lambda$ being 5·95 cm as the frequency was 50. The angular amplitude $a = \tan\theta_m$ (Fig. 13) was 0·50. It will be seen that the secondary electrodes consist of two steel wedges and that the inner members of the two main sides E_1 and E_2 are likewise given the shape of wedges. The wings of E_1 and E_2 consist of so-called " curry-combs," a description of which is given in Section (12).

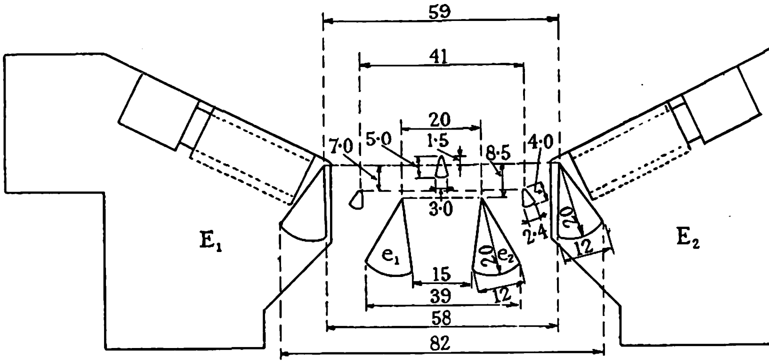

FIG. 18.

All dimensions in mm.

The following indicates how a main electrode for operation with a given jet wave is designed. In order to simplify the problem we will confine ourselves to the case of an electrode without secondary electrodes.

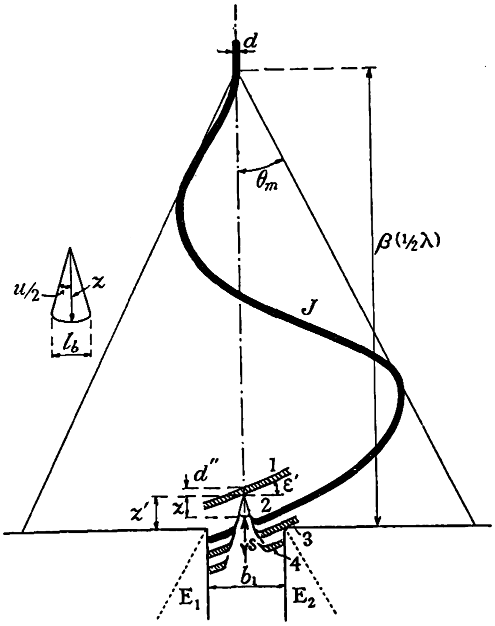

FIG. 19.

In Fig. 19 part of the jet wave is shown in a series of positions (1, 2, 3 and 4) during commutation. In position 3 the metallic short-circuiting is just commencing. In position 4 it is assumed that the strings between the wave and the knife break after having reached a length s'. The overlapping interval τ_1 is thus the time required for the wave to travel from position 3 to position 4. With the notation of the figure it is seen that

$$\tau_1 = \frac{z + s'}{v} - \frac{z'}{v} - \frac{b_1}{2v}\tan\varepsilon' + \frac{d''}{v} \quad . \quad . \quad (35)$$

Now in the theory of the jet wave it is found that

$$d'' = d\frac{\sqrt[4]{(1 + \pi^2\beta^2a'^2)}}{\pi\beta a'} \quad . \quad . \quad . \quad (36)$$

where $a' = \sin\theta_m$, and β is the distance from the centre of the field to the main electrode measured in half wavelengths. Furthermore,

$$\tan\varepsilon' = \frac{1}{\pi\beta a'} \cdot \quad . \quad . \quad . \quad . \quad . \quad (37)$$

Introducing the values of d'' and $\tan\varepsilon'$ (see Fig. 19) in equation (35), we obtain

$$\frac{\tau_1}{\mathrm{T}/2} = \frac{z + s'}{\lambda/2} - \frac{z'}{\lambda/2} - \left(\frac{b_1}{\lambda/2} \cdot \frac{1}{2\pi\beta a'}\right) + \left(\frac{d}{\lambda/2} \cdot \frac{\sqrt[4]{(1 + \pi^2\beta^2a'^2)}}{\pi\beta a'}\right) \quad . \quad (38)$$

This formula generally serves for the determination of the level z' of the knife-edge which is required for obtaining a given value of τ_1 with a given electrode and a given jet wave. It can, however, only be used for this purpose provided s' is known. Hence it was necessary to carry out elaborate investigations regarding the dependency on the various factors of the breaking-length of the string. The result of these investigations is given in the formula

$$s' = (0 \cdot 244 \times 10^{-3})v^2dz\frac{\sqrt[4]{(1 + \pi^2\beta^2a'^2)}}{\pi\beta a'}\tan^2\frac{u}{2} \quad (39)$$

where all dimensions are in cm. With three very nearly equal commutators C_4, C_5 and C_6, for which $b_1 = 2 \cdot 0$ cm, $z = 0 \cdot 5$ cm, $l_b = 0 \cdot 3$ cm, $a' = 0 \cdot 447$, $\beta = 1 \cdot 95$, $v = 595$ cm per sec., $\frac{1}{2}\lambda = 5 \cdot 95$ cm, and $d = 0 \cdot 380$ cm, the values of $(\tau_1/\frac{1}{2}\mathrm{T})100$ stated in Table 6 were found by direct measurement, while equations (38) and (39) give a value of 5·0.

The agreement is very satisfactory. It should, however, be noted that the length of the string s', and hence τ_1, are not constant, but depend very markedly on the temperature of the knife. Generally, when cold, the knife exhibits extremely high values for s' and τ_1. The values in Table 6 are "cold" values, and equation (39) corresponds to a cold knife. When heated after normal operation for some time the values of $(\tau_1/\tfrac{1}{2}T)100$ were found to be 2·6, 2·0, and 3·7 for the three commutators respectively. Generally, changes of up to 2 or 3 per cent of the half-period must be expected in the value of τ_1, which means that the "cold" value of τ_1 should not be taken as less than 2 or 3 per cent, in order to avoid too frequent interruptions.

(11) MANIFOLD CUTTING. PARALLEL AND SERIES AGGREGATES. STATISTICS OF THE JET-WAVE COMMUTATOR.

During recent investigations the explanation of the *modus operandi* of the stabilized electrode in Fig. 16 was doubted. If the jet wave is cut by, say, the knife W_1 before the spark below W is extinguished—and such are generally the conditions—a spark appears below W_1, short-circuiting the resistance r_1. Possibly, therefore, the resistance is not alone responsible for the increase of stability, or is not even of any great importance. This doubt gave rise to an experiment which led to a new and simpler main electrode, which is shown in Fig. 20. Here the secondary electrodes and the resistances are dispensed with, and are replaced by a series of tungsten knives, introducing manifold cutting. With 3 symmetrically arranged knives simultaneous cutting by 2 knives may be obtained, and it at once proved that stability equal to that of the electrode in Fig. 16 is achieved. With a 5-knife electrode (Fig. 20) the wave is cut simultaneously by 3 knives; and with an electrode of this description in a 33·3-kW, 180-volt commutator the stability was increased to such an extent that t_1 (Fig. 17) might be reduced to zero or even made negative. Obviously, the arrangement of spark-gaps in series affords a simple and most effective means of stabilizing the commutation process. Recognition of this fact is likely to lead to results of great consequence. In the first instance it is evident that the higher stability opens up the possibility of producing commutators for higher voltages, e.g. for 500 or even 1 000 volts. For the present, 3- and 5-knife electrodes are used co-ordinately with the older electrode of Fig. 16 in high-capacity commutators for voltages up to 180.

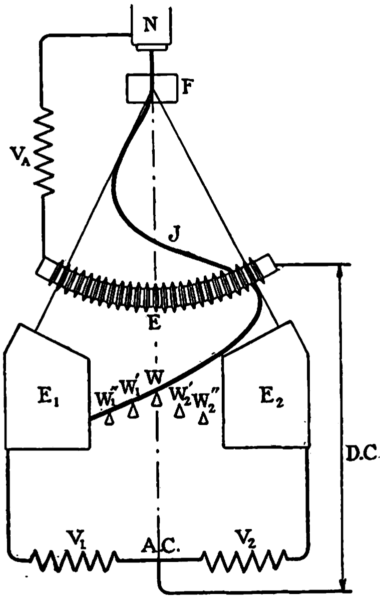

FIG. 20.

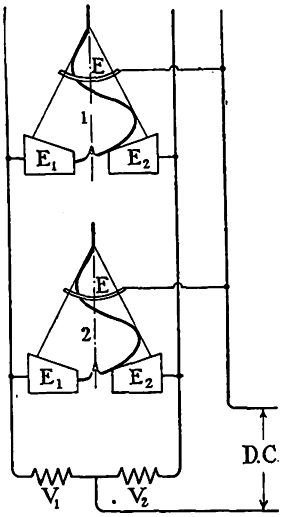

FIG. 21.

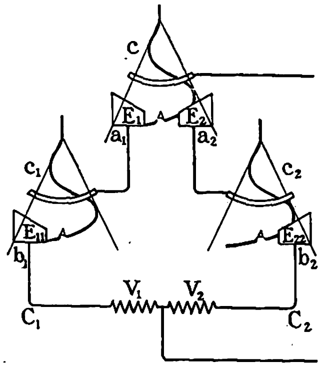

FIG. 22.

In order to commutate larger currents or powers than can be handled by a single commutator, two or more commutators may be operated in parallel in the simple way indicated in Fig. 21. It should be understood that the jets of such aggregates may be fed from a joint reservoir, but each jet must as a rule have its own jet-pipe. Furthermore, the fields may be produced by means of a single magnet. With suitable design of the joint members the aggregate assumes the character of a unit commutator, the capacity of which may be raised to several hundred kilowatts. It has proved feasible to produce simple commutators which have two jet waves instead of one playing on a single main electrode of ordinary design.

Again, several commutators may be connected in series for the commutation of extra-high voltages. The principle is illustrated in Fig. 22. It will be noted that during every alternate half-period the rectified current is carried by c_1 and c through E_{11} and E_1, while during the remaining half-period the same current passes through c_2 and c via E_{22} and E_2. Obviously, any number of commutators like c_1 may be inserted in series in the branch b_1a_1, and it is seen that all the spark-gaps of the series-connected commutators are in series during the commutation. Moreover, as the principle of manifold cutting may be used in each of the several commutators, the possibility of commutating extremely high voltages by means of aggregates like that of Fig. 22 is evident.

In connection with the problems of manifold cutting and of aggregates of parallel or series-connected commutators, the statistics of the jet-wave commutators have been studied. The subject of this investigation is the overlapping interval τ_1. While the foremost boundary (the left-hand in Fig. 17) is well defined owing to it being determined by the moment of arrival of the jet wave at the edge of the electrode-side [or the secondary electrode (compare Fig. 15 or 16)], the rear boundary of τ_1 is characterized by a marked uncertainty μ_1 owing to the fact that the boundary is determined by the breaking of the strings between the knife and the wave. Now it is of interest to learn how, first, the width of the resultant overlapping interval τ_1 and, secondly, the value of μ_1, are affected by the number of commutators connected in parallel, or commutators or knives operated in series.

TABLE 7.

Number of commutators n	Ratio $\frac{\Delta\tau_{1n}}{\mu_1}$	Ratio $\frac{\mu_{1n}}{\mu_1}$
2	0·516	0·808
3	0·778	0·727
4	0·926	0·689
5	1·061	0·654
6	1·160	0·629
7	1·240	0·609
8	1·309	0·593
9	1·365	0·577
10	1·420	0·572

In the first instance it will be noted that if two or more commutators are operated in parallel (Fig. 21), the overlapping (short-circuiting of the transformer) lasts as long as any of the commutators exhibit overlapping, while with series-connected commutators the overlapping only exists until one or more of the commutators commence cutting. Hence it will be understood that with parallel connections the average value of τ_1 will be increased, while with series connections it will be reduced. The increase and decrease $\Delta\tau_1$ is, *ceteris paribus*, numerically the same with the same number of commutators. On the other hand, the value of μ_1 is reduced in both cases and the reduction is the same with the same number of commutators. A few numerical values originating from the investigation referred to are given in Table 7. $\Delta\tau_{1n}$ represents the increase (or decrease) of τ_1 with n commutators in parallel (or series), while μ_{1n} stands for the corresponding decrease of μ_1. In the table both quantities are expressed in relation to the mean value of μ_1 with one commutator.

(12) THE AUXILIARY ELECTRODES. STRAY CURRENT AND STRAY FIELD.

The electrodes E′ and E (Fig. 2), used for the introduction of the auxiliary current and for the tapping of the rectified current, are called the auxiliary electrodes. Of the several types which have so far been developed a few have been described in the papers referred to in Section (1), especially the so-called "curry-comb electrode" and the wedge electrode. The former, which is now generally used in large-capacity commutators, is the one indicated in Figs. 13, 15 and 16. The curry-comb is produced in the following manner. On the surface of a cylindrical piece of steel a series of equidistant ribs with sharp edges are turned, or a sharp angular thread is cut. The cylinder is then bent into an arc of a circle with a radius equal to the distance from the field to the electrode in its proper position. The two curry-combs of which the electrode generally consists are separated by a gap through which the jet wave passes. The width of the gap is so adjusted that the ribs will cut, say, a few tenths of a millimetre into the wave. Under these circumstances there will, with the proper jet wave, be safe contact between an unimpaired wave and the electrode, and comparatively heavy currents of several hundred amperes may be passed from the latter into the wave. The deformation to which the electrode gives rise is, at the same time, relatively small. The dimensions in mm of a normal curry-comb for tapping 200 or 300 amperes may be taken from Fig. 23. With a jet wave produced from a jet of diameter 3·8 mm and with an angular amplitude $\alpha = \tan\theta_m = 0{\cdot}5$, the width of the slit between the component combs was from 1·8 to 2·0 mm.

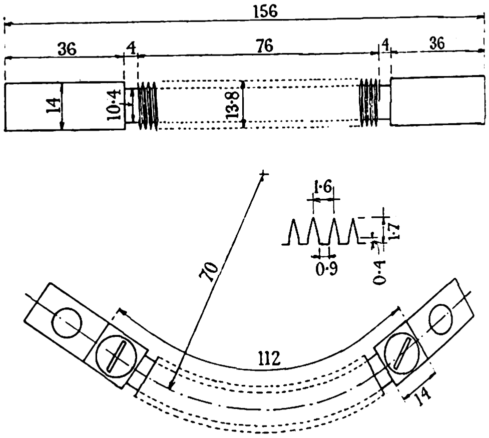

FIG. 23.

All dimensions in mm.

In the problem of the tapping of the rectified current a peculiar difficulty had to be faced. In Figs. 15 and 16 the auxiliary current is transmitted into the jet wave by means of the curry-comb through which the rectified current is tapped from the jet wave. This arrangement, with a single joint electrode instead of two, as in Fig. 2, has proved adequate as long as the rectified current is small compared with the auxiliary current. Generally, however, this is not the case, and a complication arises which may be explained thus.

Between the jet wave and the tapping electrode, say a curry-comb electrode, there will always be a contact resistance. In Fig. 24A, E indicates an auxiliary electrode used both for the transmission of the exciting current, supplied by the transformer V_A, and for the rectified current I_d. The contact resistance referred to is indicated as R. Owing to the latter resistance the fraction $\frac{R}{R+R_0}$ of the rectified current, the so-called "stray current," will pass through the part "c d b" of the auxiliary-current circuit, R_0 being the resistance of this part. This is detrimental if the stray current is not small compared with the auxiliary current, for the stray current is a direct current and, by interaction with the constant field generally used in the production of the wave, it will therefore give rise to a deflection of the whole jet wave proportional to the rectified current. The consequence is illustrated in Fig. 24B, which shows that alternate commutations will be advanced and retarded, respectively. Retardation of the commutation, however, means a danger of instability, while too early commutation involves an increase of the spark loss. The stray field of the magnet has just the same effect as the stray current had. The latter is perceptible at a rather considerable distance from the field and, if the tapping electrode is arranged close to the latter, the part of the wave which carries direct current will pass the constant stray field. Thus a deflection is caused, and unfortunately this will, as indicated, be in the same direction as that caused by the stray current.

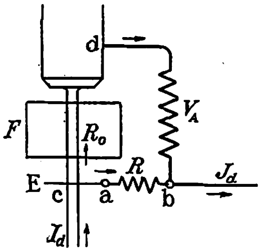

FIG. 24A.

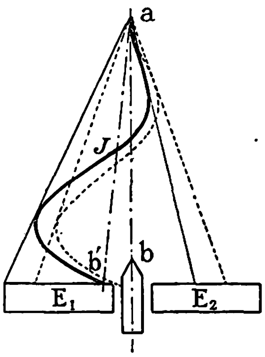

FIG. 24B.

Obviously, the effectively way to avoid the stray-current and stray-field complications is to employ separate electrodes for the auxiliary and the rectified current, and to mount the electrode for the latter close to the main electrode and well outside the stray field. With curry-comb electrodes, however, this scheme introduces a new difficulty, since the deformation of the wave—especially of the top of the wave—caused by the upper comb is apt to make the contact between the wave and the tapping electrode less definite. This is very unfortunate, for if contact was broken with the rectifier on load an arc appeared and at once destroyed the curry-comb. For a long while, therefore, the tapping electrode was a joint electrode and the stray-current phenomenon was counteracted in various ways. Thus the stray current was reduced by the introduction of resistance in the auxiliary-current circuit. The auxiliary-current loss was, of course, increased thereby, but as this loss is comparatively small, as seen above, a certain increase might be tolerated. The auxiliary current was led in through one end of the joint electrode, while the rectified current was tapped out of the other. The two components of the electrode were sometimes insulated from each other and each component used for its current. Generally, however, connection was maintained between the two components through a suitable resistance in order to ensure safer contact relations. Finally, the main electrode was often turned through a small angle about the centre of the field in the direction of the deflection of the wave in order partially to compensate for this deflection. By such means the six 20-kW, 75-volt commutators in a 120-kW, 220-volt rectifier for practically constant load were made to operate satisfactorily. As, however, the problem of producing 33·3-kW, 180-volt commutators for a 200-kW, 550-volt rectifier destined for tramway-traction service had to be faced, and as it was realized that such commutators would have to withstand overloads of up to 100 per cent or more, the measures indicated above were obviously insufficient. Hence separate electrodes had to be introduced. Generally the commutators referred to above were operated in pairs of two connected in parallel, and with this arrangement the deformation was less dangerous, for, if the contact failed on one of the two parallel commutators, the tapping electrode of the other would take over the whole current and no arc would appear. As a matter of fact the 200-kW, 550-volt rectifier indicated was operated on the tramway feeders for about 2 months without any trouble. Nevertheless, it was unsatisfactory that the commutator with two combs could not be used alone, and the problem of overcoming the trouble due to the deformation was therefore again taken up, and was solved in two entirely different ways.

In one solution the teeth of the outer ends of the combs of the tapping electrodes were made higher than the rest, so that the slit between the component combs became narrower at the ends, where the deformation was most liable to take place, than at the middle, where no deformation occurred. This construction is known as the "stepped curry-comb." In an electrode which was otherwise identical with that shown in Fig. 23, the two values of the width, with the jet wave indicated above, were 2·0 and 1·2 mm respectively, and the extension of the middle was about half the length of the comb. With this electrode the deformation caused by the auxiliary-current electrode proved harmless.

In the other solution referred to, the single tapping electrode was replaced by an aggregate of two twin combs arranged at a distance from each other of about a quarter of a wavelength. With this distance the teeth on the ends of the combs may be removed, for if the wave were to make contact with these teeth in one of the twin combs it would at the same time make safe contact with the centre teeth of the other, and so the end teeth, with the indifferent contact, are not essential. The arrangement was tested in the 200-kW, 550-volt rectifier mentioned above, and was found to be reliable.

(13) THE COMPLETE COMMUTATOR. RESISTANCE AND OVERLOAD CAPACITY.

For the reasons stated above, the jet-wave commutator of to-day is generally a curry-comb commutator with separate curry-comb electrodes for the exciting and rectified currents. The following is a review of the main properties of this type of commutator.

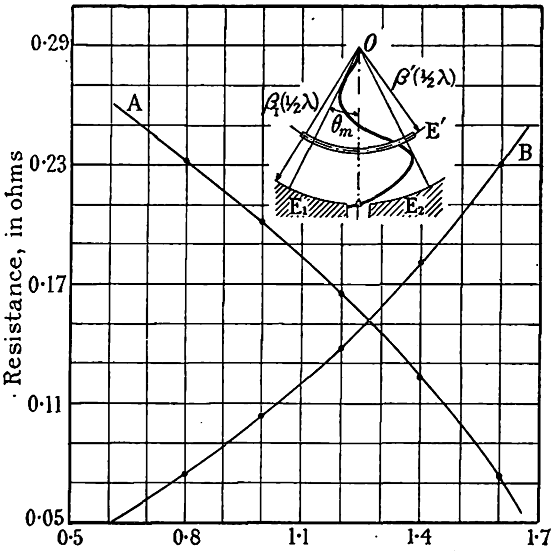

FIG. 25.

We shall first consider the resistance of the commutator, i.e. the resistance between the circular tapping electrode and the main electrode. The surface of the latter also is nearly circular, and the resistance of the commutator is therefore roughly equal to the resistance of the jet wave between two circular electrodes, which resistance may easily be calculated by means of equation (27). (Compare the calculation of the resistance of the auxiliary-current circuit.) In Fig. 25, curve A shows how the resistance varies with the position of the tapping electrode in the case of a wave for which $d = 1 \cdot 0$ mm, $\alpha' = \sin\theta_m = 0 \cdot 447$, and $\frac{1}{2}\lambda = 6$ cm. The main electrode is kept at a distance $\beta_1(\frac{1}{2}\lambda) = (1 \cdot 83 \times 6) = 11$ cm from the centre of the field. The resistance per cm of the jet is taken to be $12 \cdot 75 \times 10^{-3}$ ohm, corresponding to a stationary temperature of the mercury of 80° C.

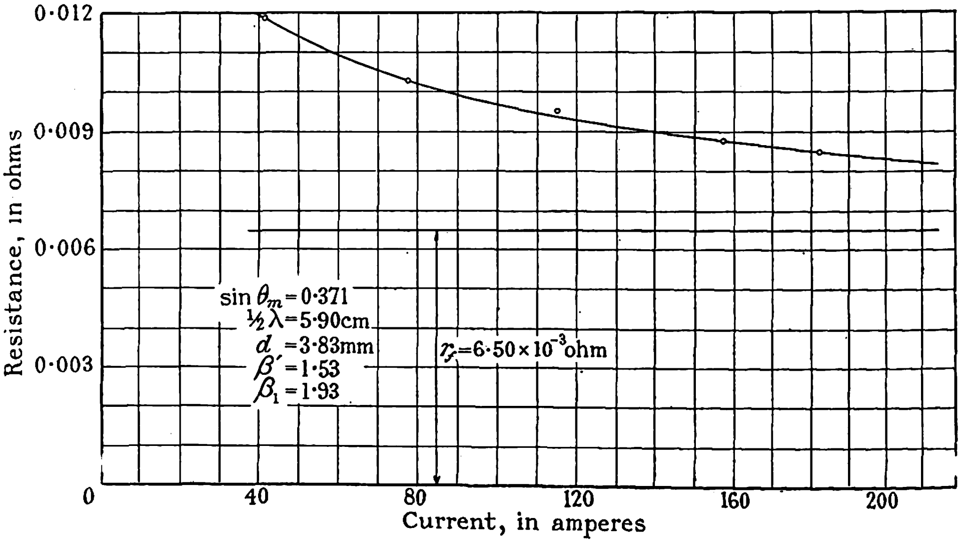

FIG. 26.

Now the resistance calculated from the theory of Section (7) does not represent the whole resistance of the commutator. There are still the contact resistances between the wave and the two electrodes the main electrode E_1 E_2 and the tapping electrode E′ furthermore, the resistance in the connections and the connecting bolts to be taken into account. In Fig. 26 the variation with the load of the total resistance of the commutator proper (not including the connections) is shown for a commutator with the constants indicated in the figure (compare Fig. 25). The resistance alters rather considerably with the load, owing in the main to the contact resistance between the wave and the tapping electrode. The commutator has a capacity of 33·3 kW at 180 volts and the normal load current is thus about 185 amperes. From theory the wave resistance was found to be $6 \cdot 50 \times 10^{-3}$ ohm. Thus at full load the contact resistance is 2×10^{-3} ohm. The resistance of the connections can, in a commutator of the type indicated, be reduced to 1 or $1 \cdot 5 \times 10^{-3}$ ohm, so that the amount to be added to the resistance of the wave is, say, $3 \cdot 5 \times 10^{-3}$ ohm.

From the curves in Figs. 25 and 26 we may now find the total resistances of the two representative commutators considered. We shall suppose the first commutator to be furnished with a wave for which $d = 4 \cdot 0$ mm, $v = 5$ m per sec., $\frac{1}{2}\lambda = 5$ cm, $\alpha' = \sin\theta_m = 0 \cdot 371$; and we shall assume $\beta' = 1 \cdot 42$ and $\beta_1 = 1 \cdot 83$. From Fig. 25 it is seen that the wave resistance for $d = 1$ mm and $\alpha' = 0 \cdot 447$ is 120×10^{-3} ohm with $\beta' = 1 \cdot 42$. This resistance is reduced in the ratio 1 : 16 owing to the larger diameter, in the ratio 5 : 6 owing to the smaller velocity, which implies a smaller wavelength, and in the ratio $\{0\cdot371/0\cdot447)^2 \times (1\cdot037/1\cdot055)\} : 1 = 0\cdot675 : 1$ due to the smaller amplitude. The wave resistance thus becomes

$$(120 \times 10^{-3} \times \tfrac{1}{16} \times \tfrac{5}{6} \times 0\cdot675) = 4\cdot2 \times 10^{-3}\,\text{ohm}$$

The total resistance of the commutator is therefore $(4\cdot2 + 3\cdot5) \times 10^{-3} = 7\cdot7 \times 10^{-3}$ ohm. As the current at full load is $(20 \times 10^3)/75 = 267$ amperes, the main-current loss becomes $\{(7\cdot7 \times 10^{-3}) \times 267^2\} = 547$ watts, and the percentage loss very nearly 2·7.

In the case of the second commutator we shall assume a wave having $d = 4\cdot0$ mm, $v = 6$ m per sec, $\alpha' = \sin\theta_m = 0\cdot447$; also $\beta' = 1\cdot17$ and $\beta_1 = 1\cdot83$. From Fig. 25 we find the wave resistance to be $(170 \times 10^{-3})/16 = 10\cdot6 \times 10^{-3}$ ohm. The total resistance of the commutator is thus $14\cdot1 \times 10^{-3}$ ohm. The rectified current at full load is 185 amperes, and thus the main-current loss $\{(14\cdot1 \times 10^{-3}) \times 185^2\} = 482$ watts, i.e 1·45 per cent, or about 1·5 per cent of the d.c. load.

The two commutators are both very nearly identical with normal constructions tested in practical rectifiers. Hence we are justified in stating for the main-current loss:

20-kW, 75-volt commutator: 2·7 per cent.
33·3-kW, 180-volt commutator: 1·5 per cent.

Jet-wave commutators and rectifiers will withstand a considerable overload. Thus with a 16·6-kW, 75-volt commutator in a 100-kW, 225-volt series rectifier plant it was found that the load could be raised for a considerable time to 50 per cent above the normal value (220 amperes per commutator) and the commutator would withstand complete short-circuiting. More systematic investigations were carried out with the 33·3-kW, 180-volt commutators of a 200-kW, 540-volt series rectifier plant. The normal current load per commutator was here about 185 amperes. The load could, however, be kept at 300 amperes per commutator for 20 or 30 minutes at a time with practically no irregularity of operation. If the current was increased to 400 amperes arcing of the commutators set in, but the arcs were checked by the stabilizing device and no damage was done to the commutators.

It is easy enough to see why instability must occur when the load per commutator is raised above a certain limit. The spark interval τ_2 becomes too long, i.e. the voltage across the transformer assumes such large values before the spark is extinguished that a discharge in the opposite direction sets in.

It is interesting to note that the growth of the spark-interval τ_2 can be predicted with fair accuracy on the basis of an investigation on the commutation spark. It has been found that the way in which the current through the spark diminishes may be represented by the expression

$$i = i_0\epsilon^{-yt^3} \quad . \quad . \quad . \quad . \quad . \quad (40)$$

where

$$y = \frac{c'}{P_{g.100}} \quad . \quad . \quad . \quad . \quad . \quad (41)$$

Here $P_{g.100}$ means the spark power with 100 sparks per sec., while c' is a numerical constant. In plants similar to those indicated above, c' may have a value of about $4\,000 \times 10^9$, P_g being measured in watts. We are now able roughly to calculate the time $t_{\frac{1}{2}}$ during which the current falls to half its original value. It is determined by the equation

$$t_{\frac{1}{2}} = \sqrt[3]{\left(\frac{\log_\epsilon 2}{y}\right)} = \sqrt[3]{\left(\frac{\log 2}{4\,000 \times 10^9}\right)} \times \sqrt[3]{(P_{g.100})}$$

In Table 8, P_d indicates the d.c. outputs in kW corresponding to the currents 92, 185, 277 and 370 amperes per commutator in the overload experiment with the 200-kW, 540-volt, 6-commutator rectifier indicated above. It will be seen that the spark interval rises from about 10 to about 17 per cent of the half-period ($\frac{1}{2}$T) when the load is increased from 100 to 400 kW, it being assumed that τ_2 is nearly equal to $2t_{\frac{1}{2}}$. The spark starts nearly at the moment of zero voltage; hence with 400 kW, or nearly 400 amperes, per commutator the spark is not extinguished until the voltage across the transformer has reached a value $E_0 \sin\{(17/100)\,180\} = E_0 \sin 30\cdot6°$, or about $\frac{1}{2}E_0$, where E_0 is the maximum value of the transformer secondary voltage. In the case considered the latter was about $(420 \times \sqrt{2})$ volts, or nearly 600 volts. Hence at the end of the spark interval the spark-gap is subject to a potential difference of at least 300 volts. The increase by 7 per cent of the half-period of τ_2 in Table 8 is equivalent to a lowering of the main electrode by 7 per cent of a half-wave. Such a lowering would inevitably give rise to instability with the commutator in question. It should be noted that the figures of the example only represent rough estimates, and furthermore that the case considered is actually that of a simple single-knife electrode.

TABLE 8.

D.C. output P_d	Spark power $P_{g.100}$	Ratio $\left(\frac{t_{\frac{1}{2}}}{\frac{1}{2}T}\right)$	Ratio $\left(\frac{\tau_2}{\frac{1}{2}T}\right)$

(14) THE SPARK LOSS. THE EFFICIENCY OF THE COMMUTATOR AND OF THE RECTIFIER.

As indicated in Section (9), the commutation spark originates from the stray fields of the transformer. The latter fields, as stated, may to some degree be considered as equivalent to inductance coils $L_{\frac{1}{2}}$, $L_{\frac{1}{2}}$ (Fig. 27) inserted in the connections from the transformer V_1V_0 to the main electrode E_1E_2.

The spark power, which determines the spark loss, does not depend solely on the inductance $L_{\frac{1}{2}}$ and on the magnitude of the rectified current. During the interval of metallic short-circuiting τ_1 (Fig. 17) a short-circuit current i_c will rise in the transformer [compare Section (9)] and add to the intensity of the spark. On the other hand part of the energy may be absorbed in the electrode resistances, which may thus act as spark-damping devices. Finally, the voltage across the terminals of the transformer may in some cases, with large values of t_1 (Fig. 17), give rise to an increase of the spark power, while in other cases the voltage may have a highly damping effect, e.g. if the spark interval stretches essentially beyond the zero-point of the voltage. All these relations are considered in the theory of commutation which is, however, outside the scope of the present paper. Here it need only be mentioned that if we neglect the effects of the electrode resistances r_1, r_2 (Fig. 27) and of the transformer voltage, the spark power, with completely smoothed-out rectified current, should be

$$P_g = 2p \times L_{\frac{1}{2}} \times (I_d + i_c)^2 \quad . \quad . \quad . \quad (42)$$

where $2p$ is the number of commutations per sec. From this equation it is seen that the spark power does not become zero for zero rectified current owing to the current i_c. Generally, however, the latter is made comparatively small, so that it tends to be negligible at large loads. Therefore one may find, especially if commutation takes place close to the point of zero voltage, that the spark power with increasing load tends to a value given by

$$P_g = 2pL_{\frac{1}{2}} \times I_d^2 \quad . \quad . \quad . \quad . \quad (43)$$

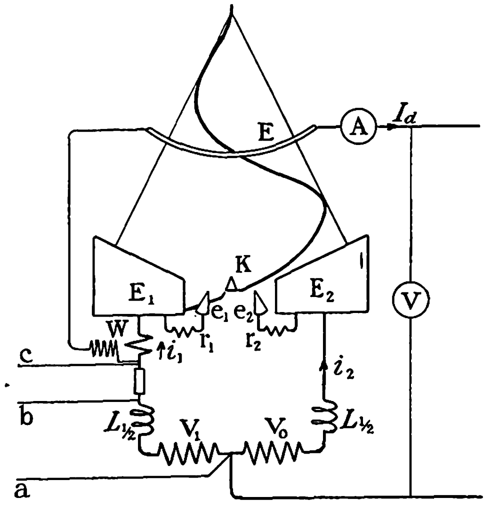

FIG. 27.

This statement, however, is only to be taken as roughly representing the actual conditions, which are generally rather intricate.

We shall therefore base our statements with regard to the spark loss on direct observations obtained from a series of plants of various descriptions. With such plants elaborate investigations of the spark loss in its dependency on the load have been carried out by means of the instruments indicated in Fig. 27, where W indicates a wattmeter. A similar instrument may be imagined in the right-hand connection between the transformer and the main electrode. The sum of the readings of the two instruments gives the total loss originating from (1) the spark (P_1); (2) the resistance of the jet wave (P_2); and (3) the electrode resistances (r_1, r_2), (P_3). From knowledge of the wave resistance, which may either be calculated or measured directly, the main-current loss P_2 may be determined. From measurement of the effective currents flowing in r_1 and r_2 the loss in these resistances is found. Thus the spark loss may be found by subtracting P_2 and P_3 from the total loss. Two instances are now given.

The first deals with a 100-kW, 230-volt series rectifier furnished with 6 commutators (3 pairs in series). The rectifier was fed from a 150-kVA, 6 100/182-volt, 50-cycle transformer. The jet waves had the constants $d = 3 \cdot 8$ mm, $v = 6$ m per sec., $\frac{1}{2}\lambda = 6$ cm, and $\alpha' = 0 \cdot 371$. A joint curry-comb electrode placed at a distance $1 \cdot 42(\frac{1}{2}\lambda)$ from the field was used for the transmission of the auxiliary current and the main current. The main electrode was at a distance of nearly $1 \cdot 83(\frac{1}{2}\lambda)$ from the centre of the field. In Fig. 28, curves representing as percentages the losses P_1, P_2 and P_3 (and in addition the voltage-drop Δe_r), are given. Of special interest here are the percentage spark loss P_1 and the loss P_3 in the electrode resistances, these losses being in the main independent of the commutator and the wave. It will be seen that less than 1 per cent energy loss is involved in stabilizing the commutator by means of the resistances. The percentage spark loss is by no means negligible at low loads. This, of course, is due to the short-circuit current. At full load (240 amperes) it amounts to nearly 5 per cent.

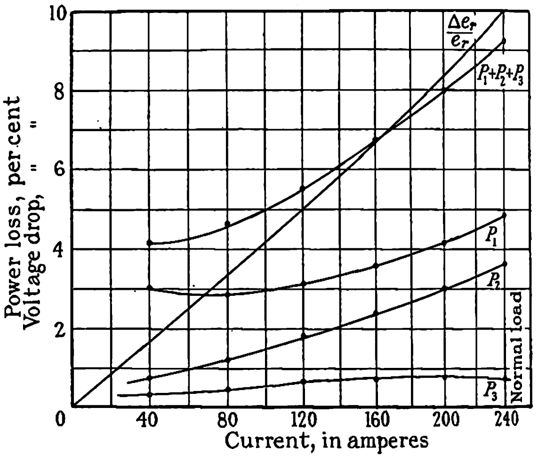

FIG. 28.

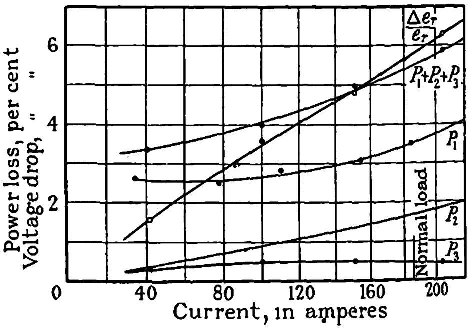

FIG. 29.

The second example originates from a 200-kW, 550-volt series rectifier—the same as was used in the 100-kW, 230-volt plant. It was run on a 400-kVA, 10 250/450-volt transformer. In Fig. 29, curves for P_1, P_2 and P_3 for the commutators of this plant are given. The curves are obviously of the same types as in the former case but the percentage losses are somewhat smaller. While with the 230-volt rectifier no damping coils were inserted in the places indicated by $L_{\frac{1}{2}}$, $L_{\frac{1}{2}}$ in Fig. 27, the 550-volt rectifier was furnished with two coils of $0 \cdot 1 \times 10^{-3}$ henry in each of the 3 pairs of commutators.

We have now considered all the losses of a jet-wave commutator and so are able to draw the efficiency curves of various commutators and rectifiers—for the efficiency of the complete rectifier is of course identical with that of the component commutators. We shall confine ourselves to the two commutators I and II considered in Sections (4), (5), (8) and (13). At normal (maximum) load the losses are then

Commutator I (20-*kW*, 75-*volt*):

$d = 4 \cdot 0$ mm, $v = 5$ m per sec., $\frac{1}{2}\lambda = 5$ cm, $a' = 0 \cdot 371$

	Per cent
Pump loss	0·57
Auxiliary-current loss	0·30
Magnet loss	0·70
Total constant losses	1·57
Main-current loss	2·7
Spark loss Electrode-resistance loss	to be deduced from Fig. 28.

Commutator II (33·3-*kW*, 180-*volt*):

$d = 4 \cdot 0$ mm, $v = 6$ m per sec., $\frac{1}{2}\lambda = 6$ cm, $a' = 0 \cdot 447$

	Per cent
Pump loss	0·51
Auxiliary-current loss	0·40
Magnet loss	0·42
Total constant losses	1·33
Main-current loss	1·5
Spark loss .. Electrode-resistance loss	to be deduced from Fig. 29.

Figs. 30A and B show the efficiency curves for the two cases. As indicated, the spark loss and the electrode-resistance loss have been deduced from the curves in Figs. 28 and 29, and are thus based on direct observations. The latter is true with regard to all the other losses, as these have been calculated on the basis of formulæ amply controlled by observations. The efficiency curves in Figs. 30A and B may therefore be taken to represent that which can at the present time at least be achieved.*

The efficiency curves for the rectifier plants from which Figs. 28 and 29 originate are not reproduced because they would be rather misleading, owing to the constant losses being to some extent abnormally large with these plants. Thus in the 200-kW, 550-volt plant (Fig. 29) they are

	Per cent
Pump loss	1·40
Auxiliary-current loss	0·56
Magnet loss	0·49
Total constant losses	2·45

The explanation is that the pump [compare Section (4)] was designed for more than twice the quantity required by the actual rectifier and, in addition, for a greater head. Furthermore the magnetic field was only about 5 000 gauss instead of 7 500 gauss, owing to the commutation chamber consisting of ordinary cast iron instead of being a non-magnetic casting. The auxiliary current must therefore be taken as about 50 per cent larger, with the effect of a 100 per cent larger loss.

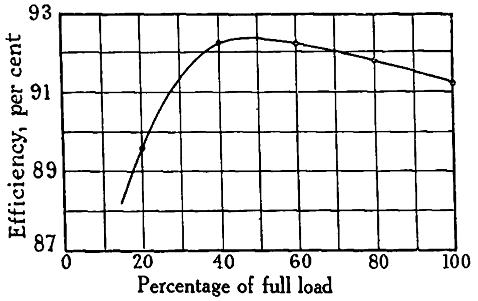

FIG. 30A.—Efficiency curve for 20-kW, 75-volt commutator.

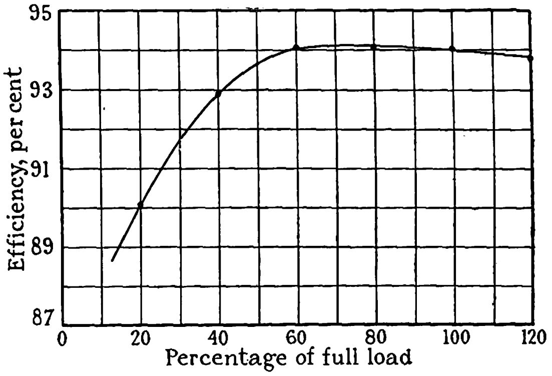

Fig. 30B.—Efficiency curve for 33·3-kW, 180-volt commutator.

(15) THE COMPLETE RECTIFIER AND THE RECTIFIER PLANT.

The so-called 6-phase series rectifier, which is considered here exclusively, consists as indicated of 3 commutators (or aggregates of commutators) connected in series. The component commutators are generally mounted in a joint chamber [compare the papers referred to in Section (1)]. The chamber is kept filled with hydrogen because this gas alone of all gases (barring, perhaps, helium) is able to absorb the energy of the spark within the time available for absorption to take place. The ratio of the duration of a spark in hydrogen

and atmospheric air or nitrogen is something like 1:10. A few words may be said here concerning the maintenance of the constant excess pressure of about 5 cm of water which is thought appropriate for the hydrogen in the commutation chamber. The arrangement is shown in Fig. 31, where C is the chamber and B is the bottle (0·040 m^3) from which the hydrogen is supplied. It is furnished with a reduction valve R, which is opened if the container of the gasometer G sinks below a certain level. The gasometer is especially suited for smoothing out the changes in pressure which, without G, would arise from changes in the load on the rectifier. By adjustment of the weight W the regulator may easily be set to a given excess pressure read on the water manometer M. If the supply from B is too small, W will rise, and its motion may, as indicated, be used for opening the reduction valve, thus preventing a deficiency of supply. If the cylinder B becomes empty, W will continue rising and may, when G has sunk below a certain level, close an alarm-bell circuit. It may be noted that the loss of hydrogen to which inevitable leakages give rise may easily be made quite negligible.

FIG. 33.

The jet-wave rectifier was developed in the municipal power station of Copenhagen, the H. C. Oersted Works. The rectifier here used had a capacity of 200 kW at 550 volts, and the transformer was a 400-kVA, 6 300-volt Siemens-Schuckert transformer. After the completion of the work of development, two complete plants were tested under ordinary working conditions. The first, a 100-kW, 230-volt plant, was erected at the Northern Cable and Wire Works, Copenhagen. The plant was here used for running d.c. motors either alone or in parallel with the various d.c. sources of the works (a 200-kW rotary convertor, a 500-kW motor generator, and a 500-kW turbo-generator). It was kept under observation for 9 months and during this time behaved to the satisfaction of all concerned. From this plant, a diagram of which is shown in Fig. 32, the characteristics represented in Fig. 28 originate. A series of oscillograms are reproduced in Fig. 33. Fig. 33 (*a*) shows the rectified voltage (upper curve) and current with non-inductive load, while Fig. 33 (*b*) indicates the current in one of the secondary half-phases of the transformer, together with the voltage across the same. The latter figure shows that commutation takes place exactly at the zero point of the voltage. Fig. 33 (*c*) refers to the same circuit as Fig. 33 (*a*), the only difference being that a small choking coil was inserted in the d.c. circuit inside the terminals of the rectifier. Fig. 33 (*d*) and (*e*) show the current and voltage with motor load without and with the choking coil. Finally, Fig. 33 (*f*) indicates the current and voltage of the rectifier plant operated in parallel with a 500-kW turbo-generator. The latter maintains a perfectly smooth voltage, and so the ripples on the voltage of the rectifier must give rise to considerable fluctuations in the rectified current.

The other of the two plants indicated above is a 200-kW, 550-volt plant which is still in operation. The rectifier proper is the same as was used in the former test. The plant is erected in the Nordsjællands Elektricitets-og Sporvejs-Aktieselskabs power station at Skovshoved, just outside Copenhagen, and is used to drive the electric street cars on the lines of that company. From this plant the curves of Fig. 29 originate, and with it the overload and short-circuiting experiments indicated in Section (13) were carried out. The plant has been kept under observation for several months and operates with complete satisfaction, handling without difficulty the disturbances which must be reckoned with in a substation for traction purposes.

Some interesting experiences with this plant may here be stated. The substation in which the rectifier was erected was supplied with power from a 50-kV main covering a good deal of the southern part of Sweden and the eastern part of Denmark. At a certain juncture very interesting large-scale experiments were carried out on this main, the latter being several times short-circuited through arcs for from 1 to 3 secs. The result was to throw practically all rotary convertors out of operation, but the jet-wave rectifier continued to operate during the short-circuits, though with greatly reduced voltage, and continued working after the short-circuits had ceased and the normal voltage returned. The street cars were thus practically uninfluenced by the severe disturbances on the main, and it was probably not even noticed that experiments were being carried out.

Later, the effect on the rectifier of direct short-circuiting of the street-car feeder proper, and thus of the d.c. circuit of the rectifier, was investigated. Three feeders, each with its overload circuit-breaker, were operated in parallel by the rectifier, and one of the feeders was short-circuited. The effect on the rectifier was hardly perceptible, and the operation of the two parallel feeders was by no means affected. The short-circuit current per commutator was estimated to be 1 000 amperes, i.e. more than 5 times the normal load current.

From these tests it may be concluded that the jet-wave rectifier has been developed into a perfectly reliable d.c. source, allowing, of course, for such transient irregularities as are likely to occur in the course of the development of any new apparatus.

A few words about the current and voltage relations of the rectifier plant may not be out of place. These relations are represented in Fig. 34, where I_s indicates the current in a secondary half-phase of the transformer, while I_p is the current in the primary phase-winding and I_l the current in the a.c. line. The current diagrams are drawn on the assumption of a completely smoothed-out rectified current and the stray-field reactance of the transformer is neglected. Furthermore, the magnetizing current of the transformer is considered to be negligible. In the figure, different transformers and connections have been considered. In (A) an ordinary 3-phase transformer is assumed. With the primary phases star-connected, the full line represents the primary current. This connection cannot, however, be used with the series rectifier owing to the fact that the primary and secondary ampere-turns of each leg of the transformer do not compensate each other. The result is that a periodic flux with 3 times the frequency of the alternating current is set up in the iron, causing greatly increased spark losses in the rectifier. The normal connection of the primary windings is the mesh connection, with which perfect compensation takes place and the primary current assumes the shape indicated by the dotted curve. In (B) the relations with 3 single-phase transformers are shown, while (C) corresponds to a 3-phase transformer with the primary windings in mesh and with zig-zag secondary half-phases.

Fig. 34 originates from a complete discussion of the current and voltage relations with the many different rectifiers which can be built up from jet-wave commutators. From the discussion the following figures are taken. With the normal transformer-connection [(A), primary phases mesh-connected] the transformer should be chosen for a load 1·34 times the normal d.c. load of the rectifier. The heating of the transformer will then be nearly that for which it is designed as an a.c. source in a circuit without inductance. The power factor of the line will be reduced in the ratio 0·955 : 1.

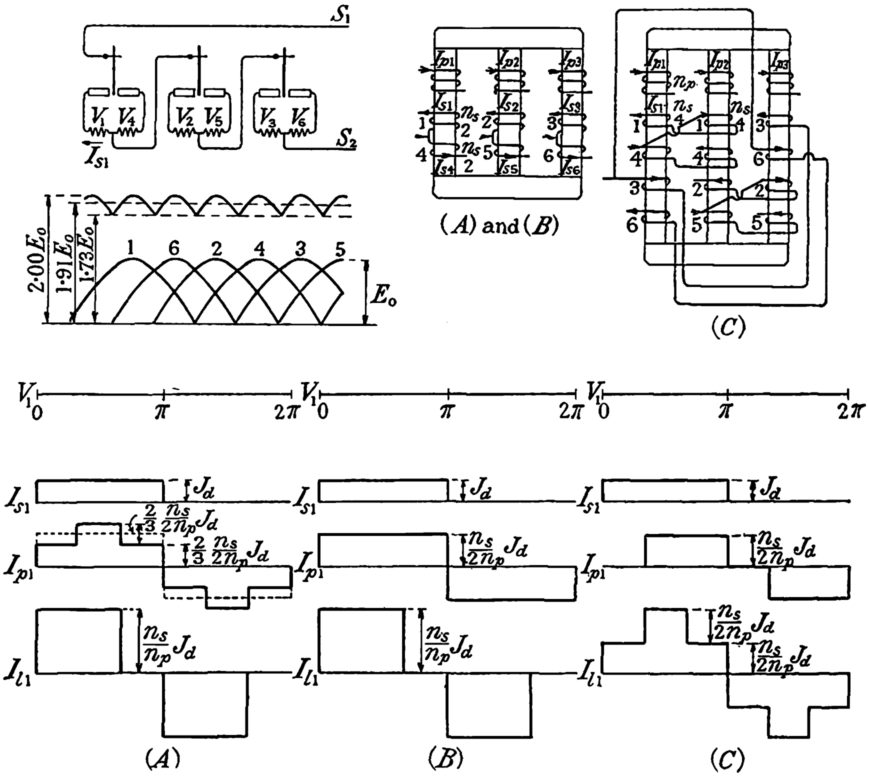

FIG. 34.

(16) CONCLUSIONS AND ANTICIPATIONS.

The new rectifier has hitherto been produced for outputs up to 200 or 300 kW (with 6 commutators) and for voltages from 220 to 550 volts. It is hoped that the present paper will leave no question as to the practicability of rectifiers for larger capacities. Obviously, jet-wave rectifiers of any size may be produced on the basis of the theoretical and experimental knowledge at hand in connection with the constructional members available. With regard to such very large systems it may be anticipated that the efficiency will be slightly raised and that the amount of mercury required per kW will diminish. An interesting question is whether the interval for the d.c. voltage can be extended; and there is no doubt that it can. It will be noted that the efficiency of a 230-volt rectifier can be made nearly as high as that of a 550-volt plant with practically the same commutator. With a special main electrode the resistance of the commutator can be very considerably reduced, and as it is the resistance which is the predominant factor with low-voltage rectifiers it may be concluded that economical rectifiers for 110-volt, or probably even 55-volt, direct current may be constructed. On the other hand, the only reason why 550 has hitherto been the limiting voltage in the development is the accidental circumstance that rectifiers of this voltage could easily be tested on traction service. Obviously, if an economical 200-kW, 500-volt rectifier is developed, a 600-kW, 1 500-volt rectifier of at least the same efficiency is equally practicable, in that 3 commutators per phase can be used in series. But as a matter of fact there is nothing to indicate that it will prove necessary to build a 1 500-volt rectifier from commutators of (1 500/9), i.e. 167 volts. Commutators for much higher voltages can undoubtedly be produced, so that most likely a 1 500-volt rectifier can be made from 3 commutators for 500 volts each and possibly a 3 000-volt rectifier from 3 commutators for 1 000 volts each. With such a rectifier the main-current loss will, with commutator of the same capacity, be reduced to one-third of that in a 500-volt rectifier, i.e. the efficiency will be raised by more than 1 per cent.

Rectifiers of 1 500 or 3 000 volts are, however, not our final goal. The author is convinced that the jet-wave commutator affords a practical means for the production of very high d.c. voltages, say, 100 kV or more, and, on the basis of certain observations, would venture to predict that a 100-kV rectifier can be made from 100 very simple jet-wave commutators connected in series.

In connection with the question of high-voltage production it is interesting to note that the jet-wave rectifier is capable of transforming d.c. into a.c. energy under certain conditions. This, as will be seen, opens up the possibility of producing a d.c. transformer by means of which the high d.c. voltage suitable for energy transmission may be stepped down to a value suitable for motor operation and electric illumination.

Finally, a few words may be said with regard to the important question of the cost of production of the rectifier. The majority of the readers of this paper will probably admit that the jet-wave rectifier in its present shape is, comparatively speaking, a very simple system consisting of a few inexpensive parts adaptable to mass production. The most expensive material employed is, of course, the mercury. The amount necessary approximates at the present moment to 0·5 kg per kW for the larger rectifiers. A further and very essential reduction may, however, be anticipated. It should be noted that absolutely no loss of mercury takes place and that ordinary commercial mercury is perfectly suitable for the purpose. The substitution for mercury of some other metal or alloy of low melting point has been carefully considered, and this could probably be done. While it is impossible to give exact figures for the cost of production at the present stage, it seems safe to say that in this respect the new rectifier will easily compete with other available means of a.c. rectification.

DISCUSSION BEFORE THE INSTITUTION, 13TH FEBRUARY, 1930.

Mr. W. W. E. French: I wish to speak on the commutation in the jet-wave rectifier and to explain it in a way which, although quantitatively incorrect, does provide a qualitative analysis of the process. When approaching the problem, I recalled the earlier conceptions in which the ideal is straight-line commutation, the current in the short-circuited armature coil having a zero value at $\tau/2$, the mid-period of commutation. Although an appreciable amount of inductance in the coil is permissible, provided that a complete reversal of current can be produced within the period of commutation, the condition in which the current has not commutated after the time τ, must be avoided, because it gives rise to a spark. τ, the time of commutation, must be larger than the time-constant of the coil. In the jet-wave commutator, the author has completely broken with this tradition. He deliberately invites the spark and provides for its control, and he does not find it necessary that the current should commutate within the overlapping or short-circuit period. The apparatus used for controlling the spark is constructed of materials such as tungsten-steel and mercury which are immune from the harmful effects of the short-circuit current, and a cooling and spark-quenching atmosphere of hydrogen is provided. Provided that the spark is accurately controlled no danger from reactance voltage need be feared. There is first the overlapping period when the short-circuit current arises, then the instant at which the mercury jet is cut by the knife—when the spark is rapidly formed and extinguished. After the short-circuiting or overlapping period (see Fig. 17 of the paper) the events of commutation become, in effect, a switching process and can be explained by means of the well-known arc characteristics. The equivalent circuit of the author's stabilized commutator (see Fig. 15 of the paper) is shown in Fig. A, and the total circuit characteristic is obtained by superposing the typical curves of the mercury arc on the characteristics of the main circuit (1).* The effect of the shunt circuit characteristic (2) is to bend the curve, as indicated in the figure by the dotted part of the curve. As the current (I_a) dies down in the process of commutation, it attains a certain value below which it cannot fall unless the arc extinguishes, which must take place at point P, as shown in the figure. When this has occurred the current I_a is reduced exponentially to zero, according to the time-constant of the circuit involved. It is necessary to investigate whether extinction takes place within the period allotted for the whole of the commutation. Within this period the main voltage $E \sin \omega t$ should not have risen to such a value as to restart or maintain the arc. The various time intervals (t), at which the instan-

FIG. B.

taneous values of the current I_a and the instantaneous voltage values of the total circuit characteristic occur, can be obtained by successive integrations of the area 10–M–P–E_{τ_1}–10, in Fig. A. The results are plotted in Fig. B, where the integral for t' is given. E is part of the wave $E \sin \omega t$ which is to be rectified and I have taken $\tau_1 = 0 \cdot 1 \times T/2$. "O" indicates the zero passage of the voltage wave (see Fig. 17 of the paper). At the commencement of τ_1, the overlapping period (metallic short-circuit), the short-circuit current rises exponentially according to τ_c, the time-constant of the circuit, to the value I_c at B. Now the arc sets in, and the arc current I_a dies down, the intervals t' being determined as explained. The total circuit characteristic of Fig. A is plotted correspondingly for the same time intervals as the currents I_a. The arc breaks at P, after which the current dies down exponentially and the voltage changes to $(-E)$, as shown in Fig. A. At no instant during the period τ_2 or $(\tau_2 - \tau')$ is the impressed voltage $E \sin \omega t$ in excess of the total circuit characteristic, and large enough to restart or maintain the arc. It will be observed that the commutation period could have been started later by the time interval τ'. Excessive increase of frequency would shift "O" to the left with a given setting of the commutator, and with excessive fall of the frequency "O" would move to the right, which could, in either case, bring the values of the impressed voltage above those of the total circuit characteristics and endanger safe and stable commutation. But it is quite clear that, within the normal working frequency-changes, there is a safe margin of operation for the jet-wave rectifier. I have also attempted to explain stable commutation by multiple cutting, that is commutation without the stabilizing resistance r (see Fig. 20 of the paper). It has been assumed, in order to establish some kind of working basis, that two arcs exist simultaneously and so two arc characteristics in additive superposition have been shown in Fig. C and E_{τ_2}M becomes the total circuit characteristic, which now belongs to a simple series circuit as shown in Fig. C. Otherwise the procedure of Fig. D is much the same as explained in Fig. A. But it will be observed that since in the calculation of the time-intervals the time t' is inversely proportional to e', the period after the overlapping interval must be considerably shortened. This is the case, and the time-interval τ' (Fig. D) is now almost twice as great as previously and commutation could have been started considerably later with complete safety. In addition, it will be seen that the total circuit characteristic E_{τ_1}P lies very much higher than in Fig. B; for this reason alone, commutation could be easily started very near to zero passage of the voltage $E \sin \omega t$, which is in full agreement with the author's statement. I understand that the jet-wave rectifier can also be used as an inverted rectifier, and I would ask the author if he could give some idea of the efficiency of commutation under these conditions.

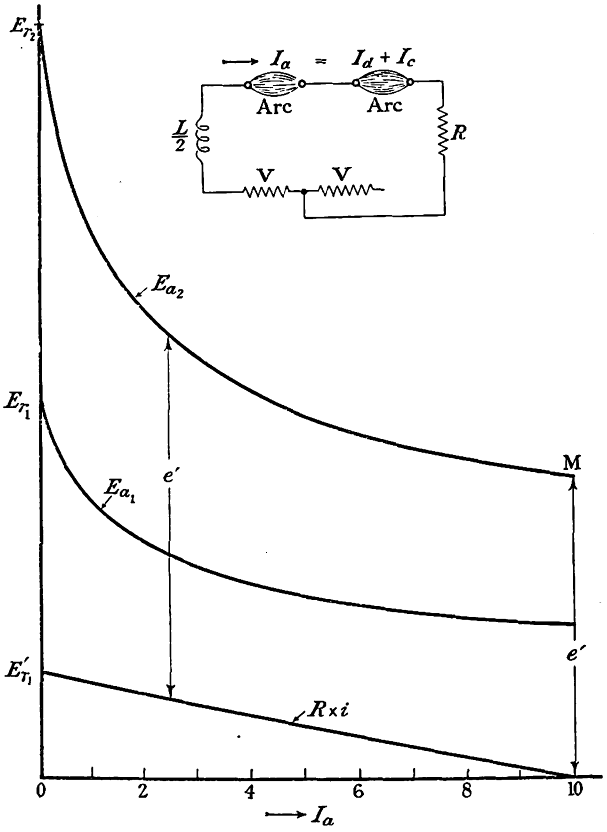

FIG. C.

Prof. W. M. Thornton: Although other accounts of this interesting development have been given none of them, I think, has dealt so fully with its design and the problems met with and overcome during the 15 years throughout which the author has been at work upon it. I only wish to encourage the author when I say that the rotary convertor, utilizing as it does the alternating voltages generated in every electromagnetic machine, is at first sight a more direct attack upon the problem of rectification; but even now—40 years or more since it was introduced—papers and books are still published to explain its action. It is perhaps unfortunate that Fig. 1 (*c*) shows the jet flowing upwards, though there is no reason why this should not happen. I take it that in Fig. 2 the lead S_1 is always negative and S_2 is positive. Accordingly, the auxiliary alternating current which deflects the jet by its reaction upon the fixed magnetic field must have a definite phasing-out relation to the current in V_1 or V_2; this relation depends on the magnetic polarity of the field F. It would perhaps be better to refer to the rectifier as a double-phase rather than as a 2-phase instrument (as in the first paragraph), for there is no 90-degree phase relationship between V_1 and V_2. I should like to ask the author whether any distortion has been perceived in the jet, say from circular to elliptical section, while passing through the field, for it is clear that the mercury, itself a conductor, will be polarized as it cuts the field—one side of the jet becoming positively, the other negatively, charged—and a current may flow across the jet. The voltage across the latter is, in any case, about 10 millivolts for a diameter of 4 mm. If a current could flow along a diameter and then divide and return by each side (as an eddy current), its density should be about 350 amperes per cm². This current is independent of the diameter, for as the latter becomes greater the voltage and the resistance increase in the same ratio. I may point out that the surface tension of mercury is extremely sensitive to external conditions and if at any point, either from the above action or in a parallel orifice, surface conditions suddenly change there is a tendency to change the curvature of the surface. At the top of page 948 there is a reference to the possibility of the occurrence of an explosion of hydrogen through air being drawn in. Hydrogen-air mixtures are not explosive so long as the proportion of hydrogen is above 75 per cent, and a relatively large volume of air would have to be drawn in for this to be possible. The resistance of the jet is as low as or lower than that of a rotary machine of corresponding power, and the efficiency, as shown in Fig. 30, is of much the same order, or rather higher. In order to understand Figs. 14, 15 and 16 the wave should be regarded as falling bodily. The device of the cutting points is very ingenious and satisfactory. The ripples in the current wave (Fig. 33) are not unduly great in view of the fact that when machines of such low resistance are used in parallel a small difference in voltage produces large pulsations of current. It is the old problem of a single-phase rotary convertor used for charging batteries, in which case the d.c. pulsation may be nearly 100 per cent of the mean current. I estimate that a difference of 2 to 4 volts in 500 may produce the pulsation shown. This is a practical consideration which may have to be given attention, for it does not affect ordinary mercury-vapour rectifiers where the resistance of the arc circuit stabilizes the current-flow. The regulation is very good, the mechanical stability of the apparatus on short-circuit has been proved, there are no inertia effects and the only questions which appear to be in doubt are those of cost. The quantity of mercury does not seem to be unduly great in comparison with the size of the plant. 7·5 litres or 2 cwt. are required for a 250-kW machine and a quantity of this size is often locked up as a catalyst in operations of, say, chemical manufacture. Every new idea is a direct asset to the industry, and I hope that the author will find engineers willing to give this one an extended trial on a commercial basis. I hope that its suitability for extra-high-tension systems will be considered. A system of rectifiers in series would, no doubt, be necessary for the purpose and there is a definite need for such equipment in cases where short-circuits would probably destroy other forms of apparatus.

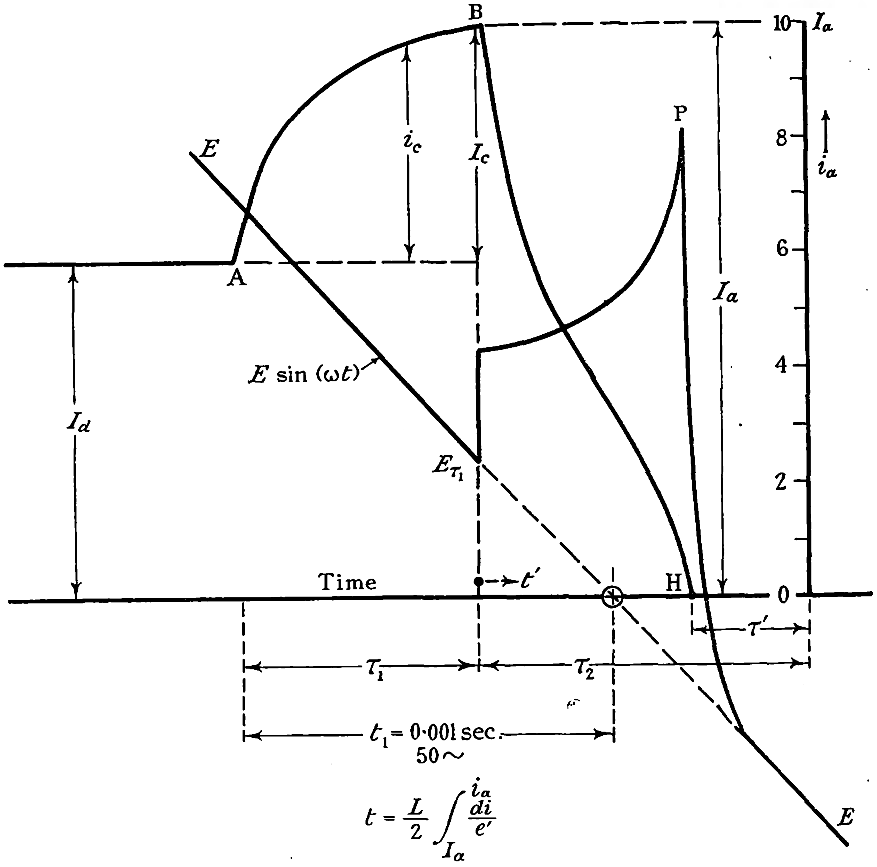

FIG. D.

Mr. A. T. Bartlett: The subject of power rectifiers is one which, in spite of its neglect by English engineers, is, I think, destined to play an important part in the developments of the near future. Several years ago a full description of the author's jet-wave rectifier was brought to my notice, and I formed an unfavourable opinion of it. My judgment was then, and to a large extent still is, that mercury or other types of rectifiers could not compete with rotary machines unless the voltage and power were high. The author was at that time using only about 150 volts per jet, whilst I believed a voltage of 600 to 1 000 to be the least which would justify the use of a rectifier. I fully appreciated that when a rectifier was required for low voltage the author's device was more suitable than the mercury-arc rectifier, as it had under these conditions a much higher efficiency, there being a constant potential-drop of about 20 volts in the latter. In the theory of his device the author has had to deal with the dynamics of common matter, and the task is very much easier than is the case with the mercury-arc rectifier. With regard to overload, the author states, on page 963, that a jet which will normally carry 185 amperes can stand a maximum of 300 amperes for 20 to 30 minutes, but that arcing sets in at 400 amperes. Such an overload current is very low in comparison with those which mercury-arc rectifiers are now being called upon to stand. Equipment of this type is now being supplied under contract to give 50 per cent overload for 2 hours, 120 per cent for 30 minutes and a maximum of 200 per cent; an arc rectifier the normal current of which is 200 amperes will therefore stand a peak load of 600 amperes—an overload which far exceeds that of any other rectifying plant. The arc rectifier can stand a prolonged overload, assuming that the heat produced is the only limiting factor, because the losses in it depend only upon the first power of the current, while in the jet-wave rectifier and rotary machines the loss is proportional to the square of the current. The author mentions a 300-kW rectifier as an example of the capacity of the plants which have hitherto been produced. Although this output is large in comparison with those of his earlier machines, it is not comparable with the sizes in general use to-day. Does the jet-wave apparatus require a large floor space? I have seen a 4 270-kW rectifier working at 1 500 volts on a floor space 9 ft. square. No statement of the initial cost of the equipment is given, and I should be pleased to have some information on this point. The author appears to be somewhat optimistic when he states that, although the highest pressure yet dealt with has been 550 volts, he hopes to be able to work with 100 jet-wave commutators giving a total of 100 kV. I find it difficult to visualize such a large number of jets at work with adequate insulation. Perhaps one of the most important statements in the paper is that referring to the possibility of the rectifier operating in the reverse direction, that is, transforming d.c. energy into a.c. energy. I should like to know whether this has ever been carried out in practice and, if so, what kind of wave-form is obtained. If the author can rectify to anything approaching 100 kV and can then convert the direct current to alternating current satisfactorily he has accomplished something for which we have all been hoping for many years, and such an achievement would revolutionize the methods of distribution of power. I should like to know whether the effects of a short-circuit are comparable with those of the back-firing of a mercury-vapour rectifier. Is there, in such a case, much destruction of the light mechanical parts, such as the knives, etc., which are used in the jet-wave machine?

Mr. S. A. Stevens: Will the author explain how it was that he first thought of using this principle? Had the cathode-ray oscillograph anything to do with it? With regard to high-tension apparatus, could not a small current at a high voltage such as is required by X-ray tubes be obtained on this principle, using water instead of mercury, or is the surface tension of water too low? We have been shown three separate rectifiers for a 3-phase supply. Could not one rectifier be used with a rotating field to cause the jet to oscillate in three dimensions instead of in one plane? Again, could an electrostatic field replace the magnetic field? In the description of the apparatus it has been assumed that the d.c. load is a pure resistance. Most loads have considerable reactance; what will be the effect of this? Can hydrocarbons be used instead of hydrogen in the commutation chamber, as was done in Poulsen arc wireless transmitters? The problem seems to be similar. What effect has the pressure of the gas? It is possible that a high pressure would be an advantage. At the moment of commutation the apparatus resembles the arc wireless transmitter. Can it give rise to similar high-frequency oscillations? Its use might seriously interfere with telephone and wireless circuits. I notice that the efficiency, as shown by the curve, falls off at low loads in the characteristic manner of d.c. motor-generators, although I believe the curves of mercury-vapour rectifiers maintain a higher general level.

Prof. E. W. Marchant: A mercury column which is conveying a current tends to break up when that current exceeds a certain value. This was shown in one of the photographs, and if it were to occur inside the rectifier this effect might cause excessive arcing. In the event of a short-circuit I imagine that the jet itself would break, so that there should not be much trouble involved in breaking a circuit which is connected to it externally. I am indebted to Mr. R. O. Street of the University of Liverpool for a calculation which he has made of the effect of the inward pressure on a jet of mercury carrying current, due to the interaction between the magnetic field produced by the current itself and the electric current in the jet. The effect is like the pressure on the surface of a tube due to some external source and increases as the jet becomes thinner. The "pinch" effect produced by it is often observed if a thin layer of mercury at the bottom of a narrow trough is used as a regulating resistance; if the layer becomes very thin it will break at that point owing to the "pinch" effect, and the process of making and breaking will continue indefinitely. Mr. Street finds that if there were no surface tension in the jet such a jet would be unstable when carrying current, that is, the jet would always tend to break into drops as soon as there was the slightest irregularity in it. Taking the ordinary figures for the surface tension of mercury the jet is stable, but the greater the current passing through it the less stable it becomes. If the current through the jet is 100 amperes and its diameter is 0·4 cm the force at the surface is about two-thirds of that due to surface tension, and the jet is just stable. If the current exceeds this value, however, the jet will immediately break up. This is probably the explanation of the fact that when the jet-wave rectifier takes an excessive current, owing to a short-circuit or some other cause, the circuit breakers controlling it do not come out. The jet itself acts as a circuit breaker and disconnects the load from the supply.

Mr. R. O. Street (*communicated*): It has been shown by Rayleigh * that a circular jet is not unstable for oscillations which alter its cross-section, and is unstable for longitudinal disturbances the wavelengths of which exceed the circumference of the jet. If the jet is of conducting matter, such as mercury, and is carrying an electric current, it is now shown that the electromagnetic forces decrease the stability of the jet. Only the simplest case is considered, in which the axis of the jet remains approximately straight, and in which the cross-section differs but little from a circle. Consider a section of the jet of radius R. At a point within it at a distance r from the axis, the magnetic force is $2(Qr^2/R^2)/r$ or $2Qr/R^2$, where Q is the total current, which is assumed to be uniformly distributed across the section. The force per unit length on a filament of cross-section δS parallel to the axis is thus

$$\left(\frac{Q\delta S}{\pi R^2}\right)\frac{2Qr}{R^2} \quad \text{or} \quad \frac{2Q^2 r\delta S}{\pi R^4}$$

inwards. The electromagnetic force is thus $2Q^2r/(\pi R^4)$ per unit volume, and this can be regarded as derived from a potential $Q^2r^2/(\pi R^4)$ per unit volume. If the equation of the surface of the jet is $r = a + \xi$, where ξ/a is small, the value of this potential per unit volume at the surface is $Q^2/[(a + \xi)^2\pi]$, or approximately

$$\frac{Q^2}{\pi a^2}\left(1 - \frac{2\xi}{a}\right)$$

If the mean speed of the jet remains uniform throughout its length, the oscillations will be independent of this speed, and so it may be taken to be zero. Assume, then, for the velocity potential in the fluid

$$\phi = CI_s(kr)\cos s\theta \cos(kz - \sigma t)$$

where the axis OZ is the axis of the jet in its undisturbed position, and (r, θ) are polar co-ordinates in a plane perpendicular to OZ. The constant C is small, $I_s(kr) \equiv (-i)^s J_s(ikr)$, where $i^2 = -1$, and J_s is the Bessel Function. The radial velocity at the surface is $\partial\xi/\partial t$; and as it must equal the radial velocity of the fluid there, $-\partial\phi/\partial r$, it follows that

$$\xi = [Ck/\sigma]I_s'(ka)\cos s\theta \sin(kz - \sigma t)$$

The effect of the surface tension T is to produce an inward force

$$T\left(\frac{1}{r} - \frac{1}{r^2}\frac{\partial^2\xi}{\partial\theta^2} - \frac{\partial^2\xi}{\partial z^2}\right)$$

or approximately

$$T\left(\frac{1}{a} + \frac{s^2 + k^2a^2 - 1}{a^2}\xi\right)$$

per unit area at the surface. Hence the pressure equation at the surface gives

$$\frac{Q^2}{\pi a^2}\left(1 - \frac{2\xi}{a}\right) + T\left(\frac{1}{a} + \frac{s^2 + k^2a^2 - 1}{a^2}\xi\right) = \rho\frac{\partial\phi}{\partial t} + \text{constant},$$

neglecting the square of the velocity. Substituting for ϕ and ξ, and equating the variable parts, we find

$$T(s^2 + k^2a^2 - 1) - \frac{2Q^2}{\pi a} = \frac{\rho\sigma^2a^2}{k}\frac{I_s(ka)}{I_s'(ka)}$$

If the oscillations are to be stable, all the constants must be real. The right-hand side of this equation is then always positive. Hence the condition for stability is

$$s^2 + k^2a^2 - 1 > 2Q^2/(\pi aT)$$

Case (I).—Oscillations in planes perpendicular to the axis.—Here $k = 0$, so that the condition for stability is

$$s^2 > 1 + 2Q^2/(\pi aT)$$

The displacement given by $s = 1$, which is a lateral displacement without deformation of the circular section, is now unstable. When there is no current flowing the equilibrium is neutral for displacements of this type. If Q is sufficiently large, other (integral) values of s may give unstable modes. Taking $Q = 100$ amperes $= 10$ C.G.S. units, $a = 0{\cdot}2$ cm and $T = 550$ dynes per cm, the value of $2Q^2/(\pi aT)$ is about $0{\cdot}6$; so that for values of s greater than unity the oscillations are stable. If, however, the current becomes as great as 220 amperes, the radius being the same, the oscillations corresponding to $s = 2$ are unstable. These oscillations make the cross-section of the jet elliptical.

Case (II).—Oscillations in planes through the axis.—Here $s = 0$, and the cross-sections remain circles but of varying radii. The condition for stability now gives

$$k^2a^2 > 1 + 2Q^2/(\pi aT)$$

or, using the same figures as before, $ka > 1{\cdot}3$. Thus the wavelength $(2\pi/k)$ must be less than $0{\cdot}8$ times the circumference of the section. It should be noted that if the current is not distributed uniformly over the section, the effect will be to modify the coefficient of Q^2 somewhat. For example, if the current at distance r from the axis is assumed to be proportional to r^n, where n is positive, the coefficient of Q^2 has to be multiplied by $(2 + n)/(2 + 2n)$. The conditions for stability are then slightly modified in form, but are not altered essentially.

[The author's reply to this discussion will be found on page 978.]

NORTH MIDLAND CENTRE, AT LEEDS, 11TH FEBRUARY, 1930.

Mr. W. W. E. French: I am taking part in the London discussion (see page 969) and I therefore propose to confine my present remarks to general considerations. While the fundamental principle—the jet-wave itself—was first conceived in 1907, the complete rectifier did not appear as an engineering fact in the Northern Cable and Wire Works until about 1925. The jet-wave rectifier was demonstrated in this country for the first time in

---

* RAYLEIGH: "Scientific Papers," vol. 1, pp. 366 and 377, and vol. 3, p. 594.

1927, in the Electrical Engineering Department of the University of Leeds. A 200-kW rectifier for experimental and demonstration purposes has been installed in Bradford during the last week, and it is hoped that it will go into traction service within the next few days. This achievement, I hope and believe, will stand in the future to the credit of our Chairman, Mr. T. Roles. Thus, after 20 years of patient work, the author is satisfied that he has produced a rectifier which will do its work successfully, and I am sure that the reticence of the inventor is in itself an indication that it will be a good and reliable apparatus. I believe that the development of rectifiers is the beginning of a new era for the "Cinderella" of electrical engineering—direct current. A little consideration leads to the discovery, or rediscovery, that direct current is the most universally applicable form of electrical energy available, and it is certainly the most elastic in its industrial application. In this connection I need only remind you of electric traction, and recall the persistent efforts which have been made for the past 18 years to design a good a.c. motor for traction service. This period has ended in the vindication of the high-tension series d.c. motor for 1 500 to 3 000 volts. It is, I believe, now universally accepted that the series d.c. motor is the traction motor *par excellence*. Generally speaking, through the introduction of the commutation pole the operation of the d.c. machine has been perfected, and since reactance voltage is no longer the limiting consideration and heating only is the limit in the design problem, the d.c. machine can be built almost as cheaply as the induction motor, the only exception being the squirrel-cage type. The much-abused commutator has been adopted in a.c. machines for speed control and for power-factor correction even by the most ardent advocates of alternating current. The great obstacle to the extension of d.c. engineering has been the inflexibility of the d.c. distribution system. The alternating-current transformer substation is a simple, convenient and reliable means of providing feed points and regularizing the voltage on far-flung networks. Hitherto, the provision of equally serviceable feed points has been the difficulty with direct current since the substations or feed points must contain rotating machinery, which is expensive and needs constant supervision. During the past 10 years, however, mercury-arc and jet-wave rectifiers have been developed and brought to a high pitch of perfection, and it seems to me that the jet-wave rectifier, with its immunity from the harmful effects of short-circuits, is an important apparatus. It will, I think, prove to be suitable for use in the kiosk type of substation so much needed in the d.c. distribution system. In view of the present perfection of rectifiers, it appears to me that the wholesale scrapping of d.c. machinery is becoming progressively less justifiable. It is my considered opinion that if the present users of d.c. power realized the extent of the unnecessary expense and inconvenience to which they and the nation as a whole are put, they would rise in revolt and, I think, in justifiable revolt. I should like to refer to the comparative expenditure on copper in the various systems. In the statements for relative weights it is rarely mentioned that the section of the conductor increases in inverse proportion to the square of the power factor. Taking the most unfavourable condition for direct current, namely the 2-wire unearthed system, and the most favourable for 3-phase power, that is the 4-wire and the 4-wire earthed neutral, the relative weights for the same power and the same transmission losses are 100, 86·6 and 58·6 for the d.c. 2-wire, the 3-phase 4-wire and the 3-phase 4-wire earthed neutral, respectively. But if we introduce and consider a power factor of 0·80 a figure which is a common average, the corresponding figures are 100, 136 and 92, respectively. If I had taken an earthed return on the direct-current system, the relative weight figure would have fallen to well below that of the 3-phase system, which always has been considered to be inherently more economical in the outlay of copper. Another matter to which I would refer is that the total current and voltage change in an a.c. system is $2\sqrt{2}$, that is to say 2·82, or 282 per cent. This change takes place 100 times per second, or 8 640 000 times per day. In which of the two systems, I would ask, are the electrical stresses likely to be the larger? In the d.c. system, with no change at all (apart from a slow load change), or in the a.c. system, which has a change whose magnitude is 282 per cent—a change which takes place more than 8 million times per day? With regard to the possibility of high-tension d.c. transmission, I believe it is here that the jet-wave rectifier will establish its superiority over any system which I now know in commercial use, because the jet-wave commutator is pre-eminently suitable for the production and generation of high d.c. voltages. The paper states that it is possible to deal with 500 volts per jet, and in my opinion this is a conservative estimate as 1 000 volts can be safely negotiated in the jet if the manifold cutting device is used. Assuming that a 100-kV set is required, it appears from what I have said that 100 jets would suffice. If a jet can carry a normal current of about 200 amperes there at once arises the possibility of a 20 000-kW set which would occupy a small space compared with its output. For the same voltage transaction the "Highfield" transverter would require well over 2 000 sections or commutation bars. From what I saw at the Wembley Exhibition a 20 000-kW "Highfield" transverter would be an enormous machine: the one shown there was designed for about 2 000 kW, and it occupied a considerable space. According to the author, the jet-wave rectifier will not only convert alternating to direct current but will also perform the reverse process, as is naturally to be expected if the apparatus is a true commutator, and the device can thus be used as an inverted rectifier. Up to the present, high-tension direct-current transmission has suffered, apart from the problem of the generation of high-tension direct current, from the difficulty of inverse rectification. This obstacle has now been removed by what I would call the jet-wave inverter, and there is, to my mind, no valid reason why high-tension direct-current transmission should not become an accomplished fact within a very short space of time, if only the same technical and financial energy as has been given to the development of the a.c. systems is devoted to it. It will be, I think, superior to a.c. transmissions of 300 miles and over, and at least equally good for smaller distances. I should like to ask for some further information regarding voltage regulation, and also regarding the possibilities of automatic operation of the rectifier. I should further be interested to know whether the commutation problem is more difficult when the jet wave is used for inverted rectification.

Prof. E. L. E. Wheatcroft: I can find little to criticize in the author's calculations, but I should like to refer to the resistance of the jet [sections (6) and (7)]. If I have read the calculations of the wave-form correctly the front of the wave is essentially circular and, as the author himself said in commenting on the photograph, the stretching of the mercury jet from the straight line is $2\frac{1}{2}$ times the actual original length. If the average length has a ratio of $2\frac{1}{2}$, the "stretch factor" of the extreme end will probably be about 5 times. It is remarkable that the mercury can be stretched to a ratio of 5, and this can, I take it, only take place provided that the cross-section is correspondingly reduced. Does formula 27 (page 954) allow for the apparent reduced cross-section of the jet, as well as for the increase in length? From the point of view of the current, I imagine that the cross-section of the jet is not circular as it travels along, but that it is altered to an elliptical form by the twisting effect of the magnetic field. Three factors must, therefore, enter into the calculation of the effective resistance. The increased length (i.e. the curvature of the path), the decreased cross-section and the alteration of the shape of the cross-section must all be considered. From the point of view of design, this was the only topic on which I could find any basis for discussion. With regard to operation, I should like to refer to the oscillograms on page 967, and to what might be called the pseudo-oscillograms on page 968. The particular feature of this rectifier as distinct from mercury arcs is, I think, the clean-cut way in which the wave is switched over from one polarity to the other. The angle of overlapping between the two half-waves is kept down to a minimum by the designer—a feature which has the definite advantage of reducing the losses inside the rectifier itself and thus improving the efficiency. Its one disadvantage, however, is that the wave-form of the alternating part of the current is essentially of a very square shape. This is shown on page 967, Fig. 33 (*b*), which is an actual oscillogram. The effect of the square wave on the alternating line-current is seen in any of the parts of Fig. 34, where the current has essentially a form very far removed from that of a sine wave.

Mr. F. S. G. Hinings: The principle of the jet-wave rectifier presents some good features which differ radically from those of any other rectifier. With regard to the constant velocity of the jet, the statement on page 946 suggests that the pumping system may be a source of weakness, since the velocity in this system has to be kept within fine limits. In other words, the correct velocity in the pipe system seems to be at a point of almost unstable equilibrium, since departure from this velocity in either direction will cause serious, if not disastrous, failures. I should like to ask the author whether it will not be possible at this part of the apparatus to fit some protective device dependent on the velocity, and so ensure the isolation of the plant should the pumping system fail or be unable to maintain the correct velocity. On page 948 mention is made of air bubbles in the jet; such air could only be present through a defect in the piping of the system. Could this not be overcome by running the pumping system under an oil seal? With regard to the statement on page 967: "It may be noted that the loss of hydrogen to which inevitable leakages give rise may easily be made quite negligible," what are these leakages, and why do they occur? Leakages of hydrogen are dangerous, and this fault may militate against the use of the rectifier in certain places. The experience of the author with regard to short-circuiting, given on page 967, is very important as regards continuity of supply, especially in traction and railway services. The author indicates that the development stage is not wholly passed, and I should therefore be interested to know whether further developments are in his mind and, if so, whether they are radical, or only refinements of the existing systems. Such information is important from a commercial aspect, as people will not buy apparatus that is still in the early stages of development. On page 968 it is stated, regarding the various connections of transformers, that the star connection on the primary cannot be used with the series rectifier, owing to the fact that periodic flux is set up. I think that this remark would apply more especially to the 3-phase shell type than to the core type. Star-star connection with a tertiary winding and the normal connection as mentioned by the author are suitable. On page 969 the author states that he is convinced that the rectifier will produce direct current at pressures of 100 kV or more. This is a bold statement, and Mr. French seems to be confident that jet-wave rectifiers can be used in series to obtain 100 kV. I should like to ask the author whether he would propose to use the transformers in cascade, or to employ a number of transformers in parallel on the supply side with increasing insulation on the low-tension side. It would be interesting to have information as to the method of solving the transformer problem. Apart from the rectifier problem for this high voltage, the transformer problem would require special attention and, so far as one can see, it can only be solved economically by the principle of the cascade winding. In any case, for such high pressures the installation would be very bulky and expensive. The following points with regard to the jet-wave rectifier are open to criticism: (1) the length of life of the commutating knives; (2) the risk of explosion (there is a risk, and one would like to know more about it); (3) the insulation of the live parts when used in series for high voltages; (4) the small tolerance of cycle variation for any particular frequency; and (5) the limitation of output due to the heat generated in the jet.

Mr. A. N. Aikman: As yet it is too early to visualize the full extent of the utility of the jet-wave rectifier, for complete technical data, together with confirmation as to the reliability of the parts which make up the complete unit, are necessary if a correct estimate of its value is to be made. Of the auxiliaries—the excitation, pump, and hydrogen supply—the latter is, in my opinion, the weakest link, and its use precludes automatic working, a necessary feature of any new traction station. Whilst the spark-quenching potentialities of hydrogen are somewhat remarkable, the danger of explosion which attends the use of the latter must not be overlooked. In view of the numerous openings to the main body of the rectifier, the question of making all the joints leak-proof is of great importance, and it would be of interest to learn what is the best type of packing for this purpose. Any leakage in the packing may create conditions resulting in an explosion. The efficiency curve is much flatter than for the rotating machine, but it does not reach the higher figure usually given for a rotary convertor. Actually, the numerous leads between the transformer and the rectifier can be expected to result in a considerable drop in the commercial efficiency, just as in the case of rotary convertors; experience has shown that these have little gain in efficiency over, say, a motor convertor, although the individual efficiency of each machine is considerably higher. Having seen the jet-wave rectifier now under test in this country, I would suggest that finality in the arrangement is by no means reached and that attempts to simplify the control and arrangement of the low-tension switchgear are desirable. How often do the curry-combs require adjustment, and is the mercury liable to oxidation, thus necessitating frequent cleaning? Some explanation of the shaded area in Fig. 9 seems to be necessary.

Mr. F. N. Rendell-Baker: As a supply engineer, I am naturally interested in this rectifier. At present, systems are changing over from direct current to alternating current—a very costly process—and in this connection, having worked a 460-kW rectifier for the last 2 years, I have been led very seriously to consider whether supply authorities are justified in spending so much money on the change. Mr. French has already referred to direct current, and has rightly drawn attention to the comparative merits of d.c. and a.c. distribution. The rectifier which I have been operating is not of the same make as the one described by the author, but it appears to me to be rather more simple. In view of the use of motors, pumps, etc., any one of which may break down, I am afraid that the jet-wave machine may give trouble. It is interesting to note that the mercury rectifier requires just 5½ seconds to switch on. Years ago I was interested in motor convertors and remote-control substations, but it is well known that relays and similar devices are expensive, and some of them are not self-controlled. In my opinion, there should be no difficulty in going forward with the development of d.c. distribution using rectifiers. I would not consider the use of rotary plant in preference to rectifiers after my experience during the last 2 years. I think that the d.c. side of electrical engineering has been too easily passed over in order to go on to the more modern a.c. distribution with all its supposed efficiency, and I am of opinion that the same results can be obtained with much less cost by d.c. distribution. I think there is little doubt that Mr. Chattock has proved this to be the case with the many rectifiers which he installed at Birmingham. The cost of rectifiers at the present time is between £5 and £6 per kW. The rectifier at Halifax with which I am associated is self-controlled by a time switch, and it is inspected once a month. Can such results be obtained with any rotary substation? The rectifier is always found to be in order: it goes on load at 5.30 a.m. and cuts off at 11 p.m., for tramway operation. It has been working now for 2 years, and it once ran for 2½ months without a stop. With regard to the question of the spark on the jet-wave rectifier, this is by no means negligible at low loads, and the author gives its value as nearly 5 per cent. This appears to me to be rather a large quantity, as the efficiency of the rectifier substation at Halifax at a quarter of normal load is 90 per cent.

Mr. R. M. Longman: I am glad to know that d.c. supply is not yet obsolete, and that new ideas are still being introduced to assist it. I gather that the efficiency of the rectifier is in the neighbourhood of 95 or 96 per cent, but if transformers are necessary as well this figure will be reduced and the cost increased. With due respect to Mr. French's faith in the jet-wave rectifier and its use in the inverted fashion, I recommend the author to concentrate his energies on applying the equipment to d.c. supplies for lighting, power and traction. It is likely that d.c. networks will be kept going by means of such recent inventions as the mercury-arc rectifier and, now, the jet-wave rectifier. One of the reasons for effecting the change-over from direct current to alternating current is the fact that the condition of cables prevents them from carrying direct current. On the other hand, Mr. French states that a.c. cables are subject to changes in electrical stress which occur 8 million times per day; when cables have been changed over from direct current to alternating current, however, they have been able to stand these stresses, and such cables have operated satisfactorily for many years. There are numerous difficulties in the way of conversion by means of jet-wave rectifiers to high-voltage direct current for transmission. Mr. Hinings has referred to difficulties in connection with the transformers which are apparently necessary, and the only advantage to be derived from direct current when once the high voltage has been obtained is that transmission lines are simpler and cheaper. With regard to the experiment (page 967) of having a few heavy short-circuits on the high-tension lines in order to observe the effect upon the system, it is stated that the jet-wave rectifier carried on but that the remainder of the converting plant was thrown out of action. I am glad that some people are able to make such tests, although in this country it is difficult to carry them out unless they are made to appear as complete accidents. Practical experience of this new rectifier is, of course, what is required.

Mr. R. G. Ward: Are any great difficulties, such as require expert attention, experienced when starting up the apparatus, and does this operation take a long time? Regarding noise, is the apparatus of the type which has to be placed in a cellar or sound-proof chamber? Does the apparatus generate a large amount of heat when working, thus making it necessary to have a cooling device to keep the rectifier within reasonable limits of temperature? Also, is it a difficult matter to adjust the apparatus? The author's remarks suggest that some of the adjustments are of a very fine character and I should like to know whether, when once these are effected, there is any possibility of the machine getting out of adjustment. Some information as to the extent of the running repairs would be welcome, as these appear to me to form one of the principal items in connection with such a piece of apparatus as this, and on them depends its successful working. I should like to support Mr. French in his praises of direct current, as I feel sure that what he said was quite correct. Speaking from practical experience, I have not yet been able to satisfy myself that direct current has any rival for the purposes of speed variation and regulation on motors for driving machine tools and similar apparatus.

Mr. W. A. Crocker: It has been my privilege to help the author and his assistant in the installation of the 200-kW plant in Bradford, and I hope the author will allow me to explain a few of the practical points raised by previous speakers. With regard to automatic operation, after only 3 days' experience the whole installation appears to me to be remarkably simple. Mr. Rendell-Baker has mentioned that the switching-on period for a mercury-arc rectifier is about 5½ seconds, and my estimate of the time required for the operation on the jet-wave rectifier is practically the same. The necessary operations are to close the high-tension switch (making sure that the hydrogen content is correct), and then to start the mercury pump. The motor-generator immediately energizes the d.c. magnets and the mercury is raised to a certain head in the stand-pipe, where there is a reservoir and a float. This, incidentally, clears up Mr. Hining's point as regards making sure that there is a proper circulation of mercury, for the float could be fitted with a couple of contacts to ensure the existence of this head before the procedure is continued. The mercury jet is sent into wave form immediately, and it is then only necessary to close the low-tension main circuit-breaker and the main d.c. circuit-breaker. There are thus but few operations, and I consider that it compares favourably with a motor-convertor or rotary convertor in this respect. With regard to leakage of hydrogen, this appears to be one of the difficult problems, for the leakage takes place, I understand, through the pores of the cast-iron chamber as well as through the joints. The author is concerned with this problem, and he has considered spraying the chamber with molten nickel. The hydrogen leakage is made up from a cylinder which passes a small amount of gas, day and night. The oxygen content of the chamber must not exceed 5 or 6 per cent, otherwise the mixture is explosive, although the only effect of an explosion is to blow out the mica windows of the chamber and temporarily to deafen anyone present. In practice, it is easy to limit the content of oxygen to 1 per cent, this being the percentage in the commercial product, and such a proportion is quite safe as regards risk of explosion. Unless the leakage of hydrogen and the corresponding replacement is very small, this amount of oxygen will oxidize the mercury and necessitate frequent cleaning of the whole of the mercury circuit—pump, stand-pipes and chamber. It will be necessary, therefore, either to reduce the leakage or the oxygen content of this hydrogen.

Mr. I. S. Mackenzie: I should like to bear out what Mr. Rendell-Baker has said. Such experience as I have had of mercury-vapour rectifiers has been quite satisfactory. I do not entirely agree with Mr. French's opinion of the merits of direct current. I have a great many motors at Staveley and, whilst admitting the figures as to distribution, I submit that the cost of maintaining d.c. motors, even of the most modern types, is far greater than the cost associated with a.c. motors. We must move forward, however, and I believe, as did Dr. Ferranti, that there is a great future before high-tension d.c. transmission. It may take a long while to work out all the details of insulation, to overcome transformer difficulties, etc., but I think that these will be overcome, and I feel that perhaps Dr. Ferranti was right in this matter, as in so many others. If so, d.c. transmission at hundreds of thousands of volts will be the rule, with freedom from the present surge troubles.

Mr. T. Roles: The question raised by Mr. French and others with regard to the use of direct current is interesting. Years ago, when I was at Poplar, the then chief engineer decided to put down a high-tension direct-current system to meet a certain set of circumstances. It was in respect of its details rather a novel system, and Lord Kelvin, who came down to see some of his instruments which were not altogether giving satisfaction, evinced much interest in the scheme and ventured the opinion that direct current would eventually be the form of electrical energy most generally used. From his remarks on this occasion it was gathered that he had no great faith in the future of 3-phase and other alternating-current systems of electricity. It is interesting to note how, during different periods, the vogue has changed from d.c. to a.c. systems and from a.c. back to d.c. systems. I am therefore in agreement with the remark that we should not be too quick to abandon direct current. In many cases, however, it is necessary to consider changing over because of the expense involved in supplying the d.c. network. The use of rectifiers, therefore, becomes an economic question, and their adoption will largely depend upon their efficiency and the cost at which they can be supplied. Direct-current apparatus is extremely useful in cases where the demand is for ease of speed regulation. Although alternating-current motors which do very well in this respect have now been developed, the direct-current motor is, I consider, still pre-eminent for variable-speed work. Such being the case, the future of this rectifier will be followed closely. As Mr. French and others have stated, a 200-kW rectifier of this type has been installed in Bradford, and within the past few days it has been coupled up and switched into circuit. Fortunately, I have a number of assistants who are very keen on carrying out pioneer work, and they, I am sure, will give the apparatus every attention. I therefore think that the author will have no cause to regret its having been installed in a substation of the Bradford Corporation Electricity Department.

THE AUTHOR'S REPLY TO THE DISCUSSIONS.

Prof. J. Hartmann (*in reply*): The discussions have raised a multitude of questions, most of which may, however, be co-ordinated in groups dealing with more or less definite problems. In general, therefore, my reply will take the form of a series of brief treatments of these problems. I am glad that the discussion gives me this opportunity of supplementing the paper itself—dealing with the design of the rectifier—with information which, while it cannot well be grouped under this heading, has an important bearing on the jet-wave rectifier as an engineering proposition. I refer especially to the possible future applications of the jet-wave principle.

The Electromagnetic Pressure inside a Jet carrying an Electric Current.

Prof. Marchant has raised the question of the effects of the current on the stability of the jet, and Mr. Street has dealt with it in a valuable contribution to the discussion and may add an experimental result from my laboratory.

The internal pressure set up by the mutual attraction of the layers of a current-carrying cylindrical jet of radius r_0 at the distance r from the axis of the jet is expressed by

$$p_r = \frac{I^2}{100\pi r^4}(r_0^2 - r^2)\text{(dynes/cm}^2\text{, amps., cm)} \quad . \quad (a)$$

I being the value of the current in amperes. The average value taken over the cross-section of the jet is

$$p_a = \frac{I^2}{200\pi r_0^2}\text{(dynes/cm}^2\text{, amps., cm)} \quad . \quad . \quad (b)$$

With a cylindrical jet the internal pressure to which the surface tension C gives rise is

$$p_c = \frac{C}{r_0}\text{(dynes/cm}^2\text{, cm)} \quad . \quad . \quad . \quad . \quad (c)$$

The effect of both pressures is to reduce the velocity of the jet, the pressures p_a and p_c acting against the (geometric) head of the jet. A proof of this is given in Fig. E. Here the ordinate is the square of the volume V discharged per sec., while the abscissa is the geometric head. With a cylindrical jet the curve corresponding to a currentless jet should intersect the axis of the abscissa at a point determined by the counter-pressure (*b*), i.e. at the point $\Delta h_c = (C/r) \,.\, 1/(\rho g)$, ρ being the density of the liquid. As a matter of fact it has been proved that Δh_c assumes this value, which means that the surface tension of a liquid can be determined by means of such an experiment.* The horizontal distance between the two parallel curves of Fig. E is due to the electromagnetic counter-pressure. In the case considered the diameter of the jet was about 0·13 cm. From the exact value of the diameter of the orifice the value 0·235 cm was calculated for $\Delta h_a = p_a/(\rho g)$ by means of equation (*b*). The observed value is 0·239 cm.

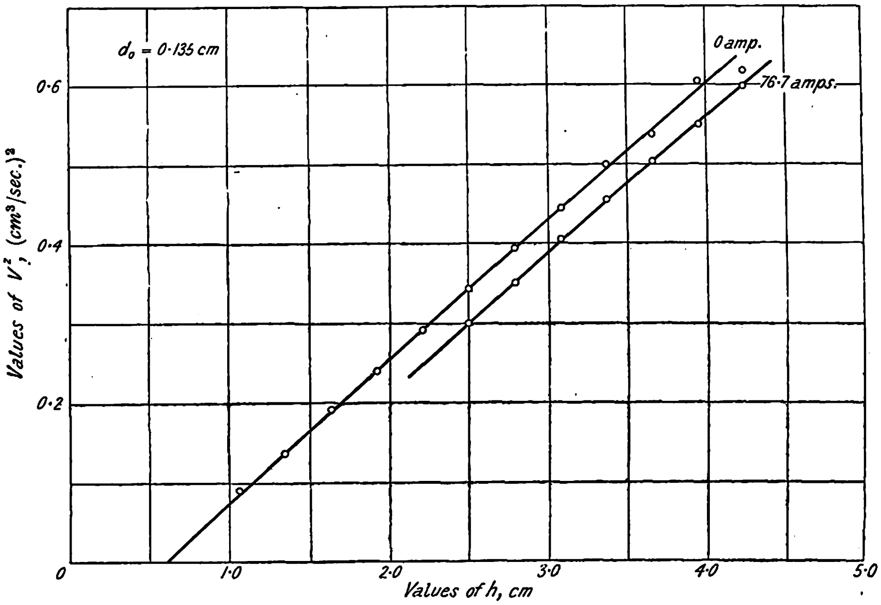

FIG. E.—Effect of electromagnetic pressure on the discharge of liquid in a jet.

Now in order to see whether the electromagnetic pressure is likely to break up the jet wave, let us consider the wave of an ordinary 33·3-kW, 180-V, 50-cycle commutator. This wave may have the constants $d_0 = 3\cdot 8$ mm, $a'(= \sin\theta_m) = 0\cdot 447$ ($\lambda = 12$ cm), and the main electrode may be placed at the distance $\beta = 1\cdot 8$ from the centre of the field. In the theory of the jet wave it is shown that the area of cross-section S of the jet wave in the axis is determined by

$$S = \frac{S_0}{\sqrt{[1 + \pi^2(a')^2\beta^2]}} \quad . \quad . \quad . \quad . \quad (d)$$

S_0 being the cross-section of the non-undulating jet. In the case considered $S = 0\cdot 367$, $S_0 = 4\cdot 16 \times 10^{-2}$ cm² for $\beta = 1\cdot 8$, i.e. just above the knife of the commutator. With 100 per cent overload the current which this part of the jet will have to carry is about 400 amperes. The electromagnetic pressure in it is thus, by equation (*b*), $p_a = 16 \times 10^4/(200 \times 4\cdot 16 \times 10^{-2}) = 1\cdot 92 \times 10^4$ or 1·45 cm of mercury. If there be a not too pronounced contraction on the wave, due for instance to the teeth of the curry-comb, pressure differences of about this order may occur between adjacent parts of the wave. *A priori* it would seem unlikely that such differences could break down the wave in the course of the few thousandths of a second during which they are in play, and as a matter of fact they do not. It would appear to be of great interest to study the question of the development of a deformation under the influence of pressure differences due either to surface tension or to the " pinch " effect of the current. The otherwise highly interesting analyses of Lord Rayleigh and Mr. Street do not, as far as I can see, throw light on this question.

---

* "The Influence of Surface Tension on the Efflux of a Liquid in Jet Form," *Physical Review*, 1922, vol. 20, p. 728.

The main jet and the jet wave are thus not likely to be destroyed either by the heating or by the "pinch" effect of the current. Other elements, occasionally used, are more sensitive, e.g. the so-called jet-comb electrodes. In this electrode a " comb " of tiny jets was employed for tapping the rectified current. With a comb of jets of 0·75 mm diameter and a velocity of 250 cm per sec. it appeared that the rectified current could not be raised above 200 amperes without causing the comb-jets to evaporate. This effect could be predicted, for from formula (32) on page 955 a rise of temperature per cm of 414 deg. C. with the current in question is derived, and the length of the comb-jets was about 0·8 cm, giving a rise of temperature of 330 deg. C., nearly the boiling temperature. The effect of evaporation was very definite and manfested itself in a sudden increase of the pressure-drop of the commutator when a current between 200 and 220 amperes was reached. Further, the evaporation and pinch effects undoubtedly make themselves felt in the commutation process, as they both tend to break down the " strings " between the wave and the knife at the extreme end of the interval of metallic short-circuiting.

Deformation of the Jet-Wave due to Mechanical Disturbances.

It is a well-known fact that a liquid jet is highly sensitive to any contact. This explains the great difficulties met with in the development of the auxiliary electrodes, especially the tapping electrode. These difficulties were, however, finally overcome completely through the invention of the curry-comb and certain other electrodes. Otherwise the jet wave is an extremely stable system. From instantaneous photographs of waves used in the ordinary high-capacity commutators it is seen that such waves continue far beyond the part utilized. Hence, under ordinary conditions, the question of the stability of the jet and the wave has, as a matter of fact, but little bearing on the practical commutator. If, however, for any reason high-frequency vibrations, say of 1 000–2 000 cycles per sec., are likely to be set up in the jet-producing system, a different state of affairs exists, for the jet is highly sensitive to such vibrations. The effect of the vibrations has been thoroughly studied by means of instantaneous photographs. Three cases are illustrated in Fig. F(1, 2 and 3). The vibrations are in the direction of the axis of the jet pipe, and as a rule only such vibrations are dangerous. On the non-deflected jet, Fig. F(1), they give rise to prominences and contractions. When the jet is deflected by means of a constant field *F*, interacting with a direct current, the jet assumes the grotesque aspect shown in Fig. F(2). On the inner side a regular series of protuberances appear, the height of which increases steadily with the distance from the field. They of course originate from the prominences on the undeflected jet, these prominences suffering a smaller deflection than the contracted parts owing to their greater mass. In the jet-wave, finally, the same protuberances are seen on the inner side of the wave-tops [Fig. F(3)] and here only. It will be understood that the deformations in Fig. F(3) may endanger the safe contact between the wave and a curry-comb electrode. High-frequency vibrations, especially in the direction of the jet pipe, should therefore be avoided. So far, however, it has never been necessary to take any precautions against them, not even with rectifiers set up in a room together with other rotating machinery such as turbo-generators. On the other hand, high-frequency vibrations are the only disturbances to be feared when a rectifier is mounted in a railway carriage (see page 985).

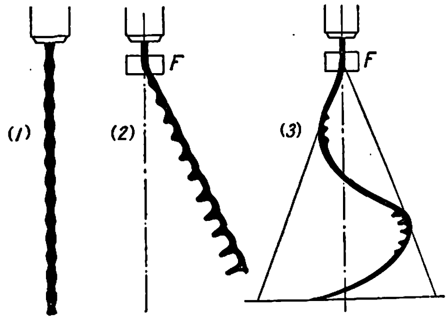

FIG. F.—Effect of high-frequency vibrations on jet and jet-wave.

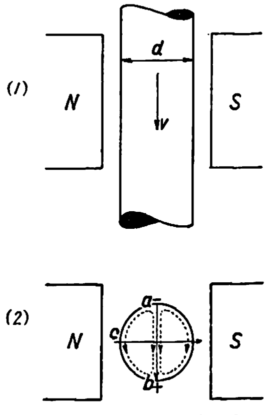

FIG. G.—Electromotive forces induced in the jet.

In connection with this subject I may answer a question raised by Prof. Thornton. Let us consider a disc-shaped element of the jet between two cuts perpendicular to the axis. During the passage of the field of this disc an e.m.f. is set up as shown in Figs. G(1 and 2). If the diameter of the jet is d cm, its velocity v cm per sec. and the field intensity H gauss, the e.m.f. between the points " a," " b " is

$$e = 10^{-8} \times dvH \text{ volts.}$$

With $d = 0{\cdot}4$ cm, $v = 500$ cm per sec., $H = 10\,000$ gauss, $e = 20 \times 10^{-3}$ volt. If two light contact-pieces are so arranged that they touch the jet at the points "a" and "b," the e.m.f. can easily be measured by means of a simple millivoltmeter. The jet with the contact-pieces thus constitutes a magnetometer. The latter has been developed in connection with the rectifier and, due to the small dimensions of the moving conductor, i.e. the disc, it has proved an excellent means for the survey of abruptly varying fields. The question raised by Prof. Thornton is whether circulating currents such as those indicated by the dotted curves in Fig. G will not flow. Obviously they will not, for the sum total of e.m.f.'s induced in any circuit situated in the plane of the disc is nil or, in other words, the e.m.f. along the diameter "a b" is exactly counterbalanced by the e.m.f. in any curved line from "a" to "b," say the line "a c b."

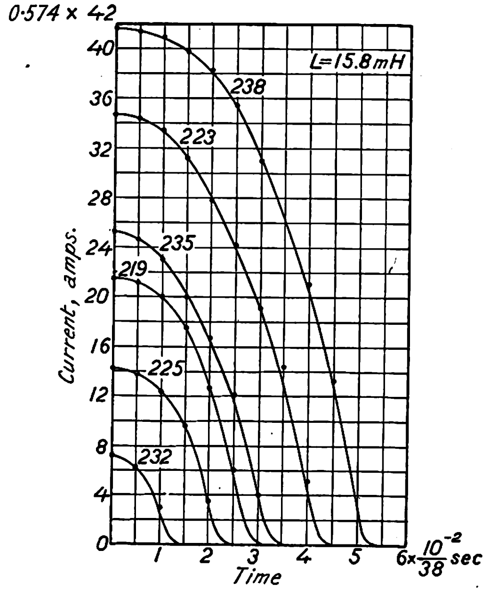

FIG. H.—Spark-current curves.

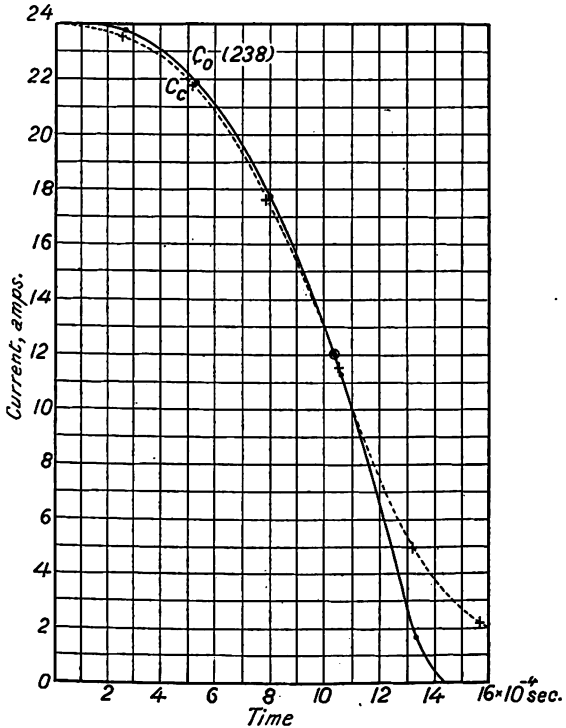

FIG. J.—Representation of the spark-current curve by $i = i_0 \varepsilon^{-yt^3}$.

Theory of Commutation.

Mr. French has, by his qualitative analysis based on a knowledge of the current/voltage characteristic of the commutation spark or arc, introduced into the discussion the question of the commutation. The theory of commutation has only been hinted at in the paper because it has but slight bearing on the problems of the design, and because the whole question of this theory is such a vast one that it requires—and deserves—special treatment. The subject is, however, hardly ripe as yet for such treament, since rather elaborate investigation is still pending. It may, however, prove of some interest to survey the problem in order to see how it may be tackled. Some years ago an investigation on the commutation spark was carried out by means of the jet-wave commutator. Some of the experimental results were obtained with an artificial circuit containing a constant e.m.f. and an ironless self-inductance. Oscillograms of the current through the commutation spark and of the voltage across the same were taken, and at the same time the spark power was measured by means of a wattmeter. Similar observations were taken with a com-

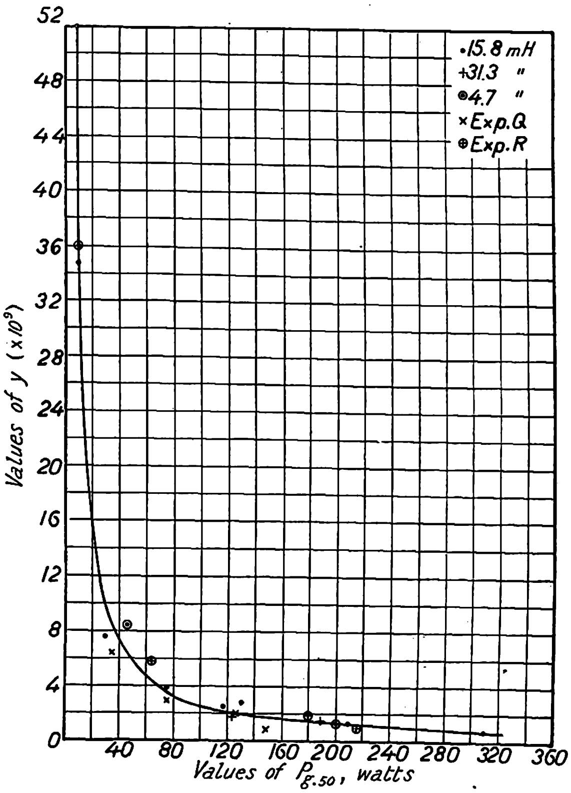

FIG. K.—Relation between spark-current constant, y, and spark power.

mutator in a 6-phase series rectifier. Attention was drawn to the fact that the spark-current oscillograms were normally of a characteristic regular shape, as illustrated in Fig. H. Attempts were made to find an analytic expression suitable for the representation of the current, and it was found that the formula

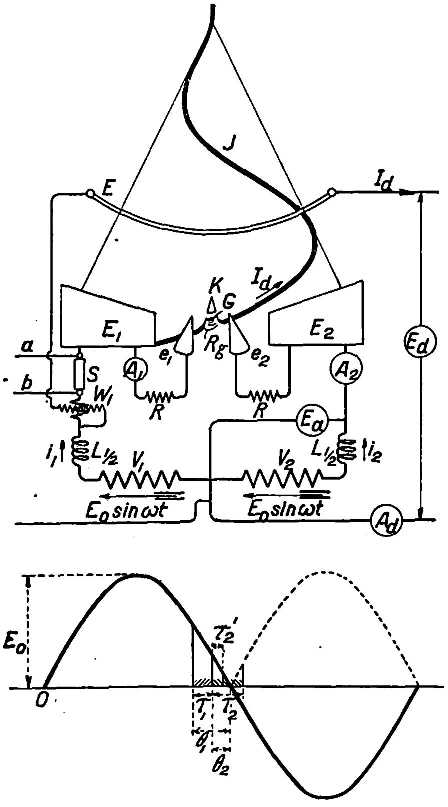

FIG. L.—Commutation diagram.

$$i = i_0 \epsilon^{-yt^3} \quad . \quad . \quad . \quad . \quad . \quad . \quad (e)$$

where i_0 is the initial value of the current, gave a good approximation, as will appear from Fig. J. Here C_0 is the actual oscillogram, while C_c is a curve of the type (e) determined in such a way that C_c and C_0 coincide for $i = \frac{1}{2}i_0$. The constant y characterizing the oscillogram was co-ordinated with the spark power $P_{g.50}$ corresponding to 50 commutations per sec. and a very simple relation was found, namely

$$y = \frac{c}{P_{g.50}} \quad . \quad . \quad . \quad . \quad . \quad (f)$$

c being a constant. In Fig. K a graphic representation of the y–$P_{g.50}$ relation is given, and in Table A (A) the numerical test of equation (f) is made.

The same simple law was found to hold good with oscillograms from a 33·3-kW, 180-V commutator in a 100-kW, 550-V rectifier [Table A (B)]. The value of $y \cdot P_{g.50}$, however, differs widely from that of the small plant. Obviously c depends on the characteristics of the plant, but the connections have so far not been explored.

The knowledge reviewed above was made the basis of a theory of commutation. In the first instance certain general relations may be derived from it. Thus, for instance, if we cut the wave by two knives instead of one, we get two sparks, each with half the spark power. Hence we conclude that the constant y for each spark must be twice that of a single spark. This means that the spark interval τ_2 is reduced in the ratio $\sqrt[3]{2}$ (= 1·26) to 1. With three knives the factor of reduction should be $\sqrt[3]{3} = 1 \cdot 44$, and so on. Again, an attempt was made to predict the spark power with a given plant, it being assumed that the numerical value of the constant c was known for that plant. The commutator in Fig. L was considered, and an expression was derived for the spark power P_g. It should be understood that during the interval τ_2' the right-hand resistance is inserted in series with the spark G, while during the rest of the spark-interval τ_2 this resistance is short-circuited. During the interval τ_2 the current relations in the short-circuited secondary transformer are obviously determined by

$$2E_0 \sin \omega t - L_{\frac{1}{2}} \frac{di_1}{dt} + L_{\frac{1}{2}} \cdot \frac{di_2}{dt} = i_1 R_g - i_2 R \quad . \quad (g)$$

R_g being the resistance of the spark.

If the rectified current I_d is completely smoothed out, then

$$i_1 + i_2 = I_d \quad . \; . \quad . \; . \; . \quad (h)$$

By eliminating i_2 we get

$$2E_0 \sin \omega t - 2L_{\frac{1}{2}} \,.\, di_1/dt = i_1 R_g + (i_1 - I_d)R \quad . \quad (j)$$

The spark power is now

$$P_g = 2p \int_0^{\tau_2} i_1^2 R_g \, dt, \quad . \; . \; . \; . \; . \; . \quad (k)$$

$2p$ being the number of commutations per sec. Hence

$$P_g = 2pL_{\frac{1}{2}}\bar{i}_1^2 + 2p \,.\, 2E_0 \int_0^{\tau_2} i_1 \sin \omega t \, dt$$
$$- 2pR \int_0^{\tau_2} (i_1 - I_d) i_1 \, dt \quad . \quad (l)$$

where $\bar{i}_1$ is the value of i_1 at the commencement of the spark interval. This value is $I_d + i_c$, where i_c is the short-circuit current which has been increasing during the overlapping interval τ_1. Expression (l) is of some interest. The first term on the right-hand side is twice the electro-kinetic energy stored up in the inductance shown on the left in Fig. L. The second term denotes the increase of the spark power due to the transformer voltage. It may be negative if the greater part of the spark interval is situated to the right of the zero point of the voltage in Fig. L. The third term represents the reduction of the spark power due to the electrode resistance R, in which a certain part of the electro-kinetic energy may be absorbed. It is, however, not certain that the reduction is positive, as will appear from equation (l). At no load, $I_d = 0$, it is always positive, i.e. the resistance always tends to extinguish the arc in this case.

Now, in order to predict the spark power, $\bar{i} = I_d + i_c$ must be known. It is a simple matter to derive expressions for i_c and therefore for $\bar{i}$. During the overlapping interval τ_1 the current relations are determined by equations (g) and (h), the term $i_1 R_g$ being omitted from the former. For the commutator in Fig. L the following expression is derived:—

$$\bar{i} = I_d + \frac{E_0}{R/2}\left[\sin\left(\pi \frac{\vartheta_1 - \tau_1}{\mathbf{T}/2} + \phi\right) \right.$$
$$\left. - \epsilon^{-\frac{\pi}{\tan\phi} \cdot \frac{\tau_1}{\mathbf{T}/2}} \sin\left(\pi \frac{\vartheta_1}{\mathbf{T}/2} + \phi\right) \right] \Big/ \sqrt{[1 + \tan^2 \phi]} \quad (m)$$

where $\tan \phi = \dfrac{\omega L_{\frac{1}{2}}}{R/2}$.

Then, again, the determination of P_g [eqn. (l)] requires a knowledge of the variation of the spark current i_1 with time. The latter, however, depends mainly on the spark power to be determined. Hence the problem must be solved by approximation. This was done in the following way.

The first term $P_{g.0} = 2pL_{\frac{1}{2}}\bar{i}_1^2$ [cf. eqn. (l)] was used as an approximate value for P_g. From this the expression

$$i_1 = \bar{i}_1 \epsilon^{-yt^3} \quad . \; . \; . \; . \; . \; . \quad (n)$$

where

$$y = \frac{c}{P_{g.0}} \quad . \; . \; . \; . \; . \; . \quad (o)$$

was derived and taken to represent the variation of the spark current with time. Then the two last terms of (l) were calculated by numerical integration and so a first value of P_g was found. By replacing $P_{g.0}$ in (o) by this value and by repeating the numerical integrations a new and improved value for P_g could be computed. It was generally found, however, that the first and second values of P_g were practically identical. The method was tested on a series of commutations for which the spark losses were observed. The knowledge of the commutation constants τ_1 and τ_2' was hardly good enough for a complete test, but at any rate a certain agreement was established. Moreover, the method was found to be suitable for an *a priori* survey of the variation of the spark power with the commutation constants and the constants of the electric circuit, such as $\tan \phi$. The method furnishes not only a value of P_g but also an approximate picture of the variation of the spark current, namely that of equation (n) (with y calculated from the value found for P_g). It should be noted that the method depends on a knowledge of one numerical constant only, the constant c, which, as mentioned, seems to be characteristic of the plant, i.e. of the transformer constants.

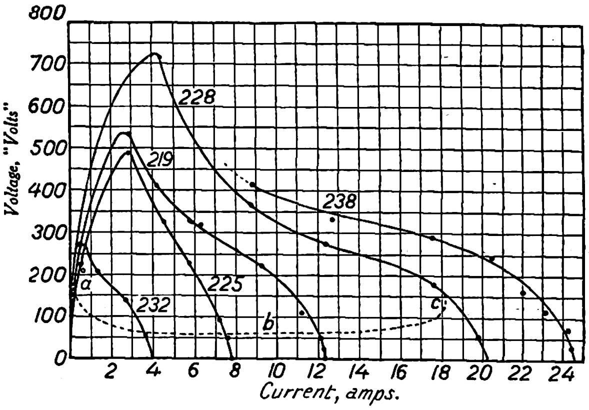

FIG. M.—Voltage/current characteristics.

It is interesting to contrast Mr. French's method with that indicated above. His is based on a knowledge of the voltage/current characteristic of the commutation spark. This characteristic is, however, by no means common to all sparks or plants. It is just as individual as the current/time curve (the spark-current oscillogram). For the sparks which were considered in Fig. H the voltage/current characteristics are represented in Fig. M. Attempts have been made to derive a general expression for these characteristics. If this is achieved the commutation problem can be solved graphically and, possibly, analytically. It may be mentioned that systematic experimental investigations have now been planned as a basis for the complete solution of the commutation problem with the jet-wave commutator.

The Jet-Wave Inverter, the Jet-Wave D.C. Transformer and the Jet-Wave Frequency-Changer.

Mr. French desires information with regard to the inverse rectifier, "the inverter" and related jet-wave apparatus. When used in the ordinary way, the rectifier conveys electrical energy from the a.c. mains to the d.c. busbars. If, however, the voltage of the latter is raised above that of the rectifier, energy will be transmitted in the opposite direction, the complete electric system being reversible, if it is not made irreversible by suitable means. Preliminary investigations on inverse rectification have been carried out with a laboratory plant of about 7 kW and it has been proved that, apart from the direction of the various currents, the current relations are identical with those of the same system used for rectification. There is, however, a very interesting difference between the rectifier and the inverse rectifier, and this is illustrated in Fig. N. If, with a rectifier, the commutation could be delayed until after the voltage had changed its sign [Fig. N(2)], a reduced spark loss would ensue owing to part of the electro-kinetic energy being absorbed by the transformer voltage. The scheme cannot, however, as a rule be realized, because the delay would make the commutation unstable. With the inverse rectifier or "inverter" the current is in the opposite direction with regard to the transformer voltage [Figs. N(3) and N(4)]. It means that part of the electro-kinetic energy is normally absorbed during the overlapping interval and that the commutation should be precipitated in order to reduce the spark loss [Fig. N(4)]. There is nothing to prevent this; on the contrary the process of commutation is made more stable. The inverse rectifier therefore provides an effective spark damper.

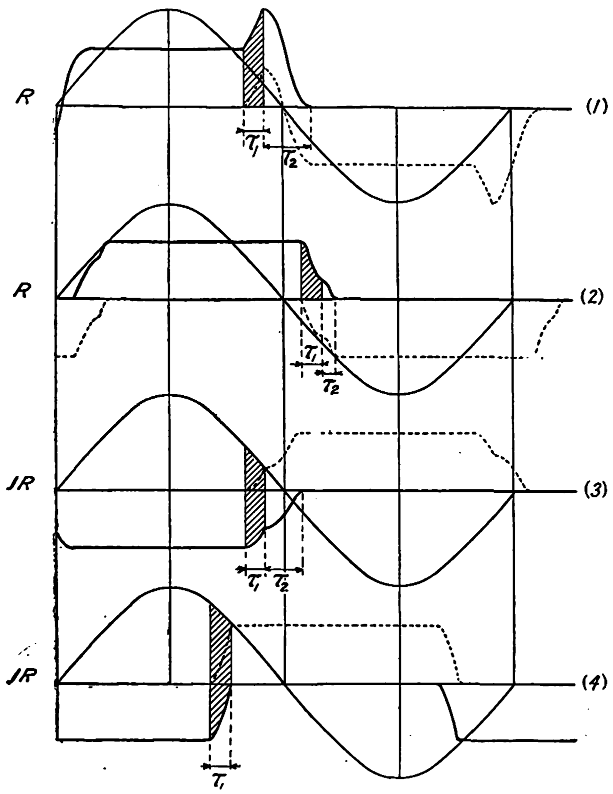

FIG. N.—Commutation with rectifier (1 and 2) and with inverse rectifier (3 and 4).

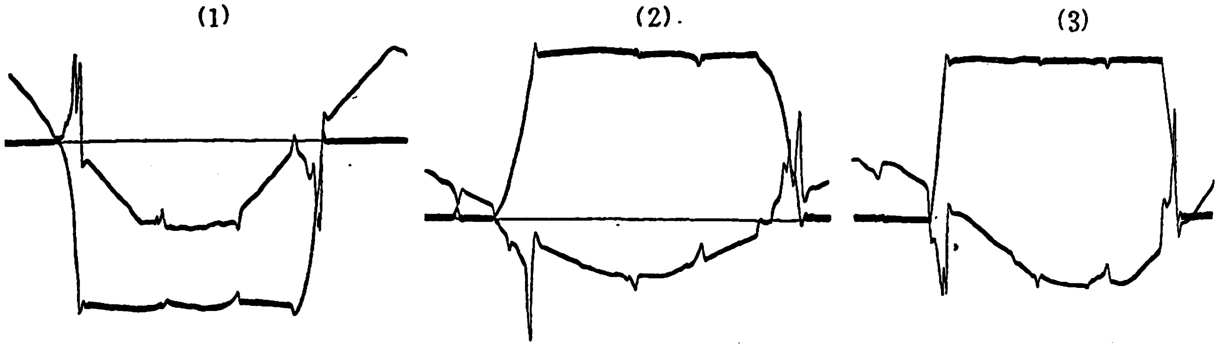

FIG. O.—Oscillograms of rectifier and inverter.

This spark-damping is seen in the oscillograms, Fig. O, which all represent the current flowing in a secondary half-phase of the transformer of the 6-phase series system. Fig. O(1) corresponds to rectification ($I_d = 25$ amperes, $E_d = 242$ volts) with t_1 (Fig. 17) equal to 2 per cent of the half-period. In Fig. O(2) inverse rectification ($I_d = 25$ amperes, $E_d = 202$ volts) with $t_1 = 2$ per cent is represented. Finally Fig. O(3) again corresponds to inverse rectification ($I_d = 25$ amperes, $E_d = 202$ volts), but now t_1 is 12 per cent. It is clearly seen that the current falls off much more steeply in Fig. O(3) than in Fig. O(2), owing to a pronounced reduction of the commutation spark.

When inverse rectification is possible it is safe to say that step-up or step-down transformation can also be carried out by means of jet-wave commutators. This application has been studied on a small scale and found to be a promising technical proposition. Fig. P is a diagram of a 6-phase system. The 3-phase transformer is furnished with 3 sets of windings per phase, the S_I–S_{II} and P windings in Fig. P. Two 6-phase series jet-wave systems I and II are connected to the S_I and S_{II} windings of the 3 phases as shown. The P windings are connected in delta to an auxiliary 3-phase source N which is also assumed to supply the exciting currents for the two sets of commutators. In the d.c. transformer plant the primary d.c. source E_I now supplies energy to N, the 6-phase system I acting as an inverse rectifier. N, however, again supplies the same energy to the secondary side of the d.c. transformer (E_{II}), the 6-phase system II acting as a rectifier. It will thus be seen that the source N and the windings P need only be designed for a small fraction of the power dealt with in the transformation. The transformation ratio is determined by the ratio of turns of the S_I and S_{II} windings, as in the case of the ordinary a.c. transformer.

If the commutators II in Fig. P are removed, the rest of the plant constitutes an inverter, i.e. a d.c.–a.c. transformer. The frequency of the a.c. voltage produced is determined by that of the auxiliary a.c. source N. The system here considered is the inverter in its most general form, while the ordinary rectifier plant, used inversely, is only suited for the transmission of energy from a d.c. line to an a.c. line under voltage. With the latter system the transformer flux necessary for the transmission of the energy may be regarded as being produced partly by the a.c. voltage. In the general solution of the inverter problem the flux is to a certain degree produced by the auxiliary a.c. source N, Fig. P, and it is possible to choose any frequency whatever.

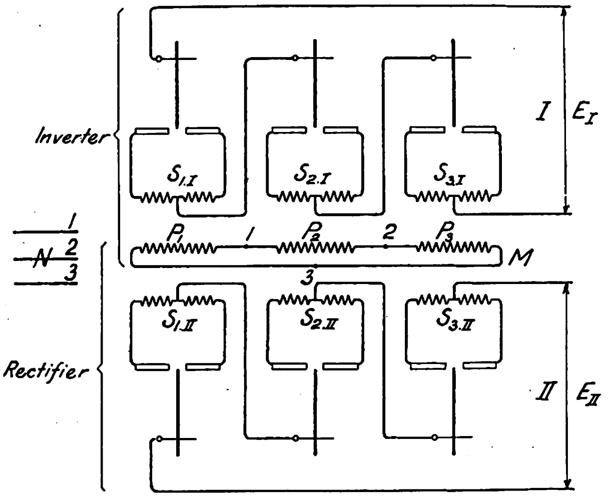

Fig. P.—Diagram of d.c. "transformer."

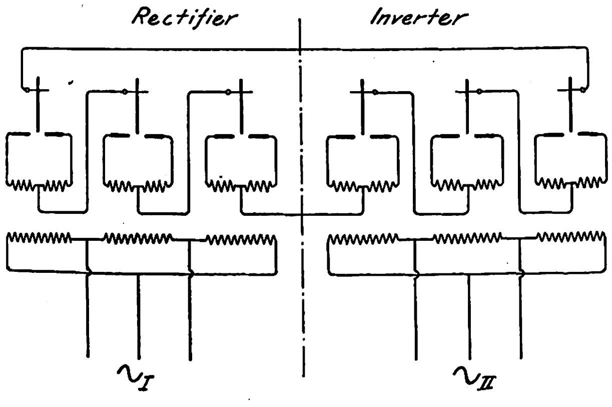

Fig. Q.—Frequency-changer.

Finally, it will be gathered that a frequency-changer may be produced by means of a rectifier in combination with an inverter. By means of the rectifier, the action of which is governed by the primary a.c. voltage, this voltage is changed into a d.c. voltage. The latter is again changed into an a.c. voltage by means of the inverter. If the frequency-changer is to form a bridge between two networks of different frequencies $\sim_I$ and $\sim_{II}$, the frequency-changer assumes the simple symmetrical form shown in Fig. Q.

An argument which has been advanced against the scheme of d.c.–a.c. transformation indicated above is that the wave-shape of the a.c. voltage deviates considerably from that of a sine curve. This is generally true, as will be understood, for instance, from Fig. 34 of the paper. By means of special transformer connections, however, the wave-shape can be made to approximate more closely to a sine curve. Another method is to use 12-phase instead of 6-phase commutator systems.

High-Tension D.C. Transmission.

This scheme has been referred to by Mr. Bartlett, Mr. Hinings and Mr. Longman. Its realization requires means for the production of a high d.c. voltage (e.g. 100 kV) and means for stepping it down. Owing to the comparatively high voltages for which the jet-wave commutator can be built, I am of the opinion that it yields the simplest available means for the production of such high d.c. voltages. I fail to see why the transformer problem, which, it is true, has so far not been seriously discussed, should prove so difficult as Mr. Hinings seems to think. I am also confident that the jet-wave principle will furnish the necessary means for dealing with the high d.c. voltage when once produced. On the whole I consider the applications of the jet-wave principle to the proposed scheme of high-tension d.c. transmission to be very promising, since this principle seems to furnish nearly all that is necessary to enable the scheme to be carried out.

The Jet-Wave Rectifier as a Means for Railway Traction.

So far the chief applications of the jet-wave rectifier have been to tramway traction and to the operation of motors in a factory, and, apart from a few slight objections, it has undoubtedly proved suitable for these purposes. As far as I am able to judge, a very promising future field of application is that of railway traction, because the jet-wave rectifier is reversible and because it seems suitable for installation in trains. I assume that the best system for railway electrification is that in which the electrical energy is transmitted to the train in the form of high-tension alternating current, transformed in the train itself to direct current at, say, 1 500 volts, and utilized in a d.c. series motor. This scheme can in all probability be realized by means of the jet-wave rectifier, but it seems doubtful whether the mercury-arc rectifier will operate safely in a running car. At any rate the latter rectifier is not reversible. The reversibility of the jet-wave rectifier implies that regenerative braking can be used. According to electric railway authorities * this form of braking may result in a saving of approximately 15 per cent of the total power required and, especially in connection with heavy passenger or freight service on mountain grade sections, in considerably increased safety, reduced wear on equipment, and increased comfort to passengers. I have not yet been able to install a jet-wave rectifier in a running railway carriage, but the effect of the accelerations by which the jet is likely to be influenced in the train has been carefully discussed, and it has been found that the accelerations or decelera-

* Cf. A. S. Rickey: "Electric Railway Handbook" (New York, 1924).

tions caused by starting, braking, passing of sidings, or driving in curves, are quite harmless, or at any rate easy to counteract by means of springs. The same is true for the vertical accelerations set up by irregularities in the rail joints. The only point on which there may still be a slight doubt is the possibility of the high-frequency vibrations referred to earlier in my reply, but if they occur they can undoubtedly be eliminated by springs in connection with some damping device.

The Jet-Wave Rectifier in Automatic Substations.

Mr. Ward raises the question of the attention required for starting up the jet-wave rectifier. This gives me an opportunity of furnishing some information with regard to this starting and also with regard to the use of the rectifier in automatic substations, a field of application for which the rectifier would seem especially suitable.

With an ordinary non-automatic plant the rectifier is started in the following way: (1) The oil switch is closed; (2) the pump is started; (3) when the mercury has reached the normal height in the reservoirs the combined exciting-current and magnetizing-current switch is closed; and (4) the commutators are connected to the main transformer by closing either a separate switch for each commutator or a common 6-pole switch. The complete starting of the rectifier can be performed in from 10 to 15 sec. when done in this way, and it requires no kind of expert attention. It is, however, interesting to note that the whole operation can be done by simply pressing the button of the oil switch, provided certain simple automatic devices are employed, and, furthermore, provided the rectifier can remain permanently connected to the d.c. busbars. The first effect of connecting the plant to the a.c. mains is that the pump is started, and at the same time the small d.c. generator supplying current to the magnets, if such a generator is used, is also started. (The power necessary for the operation of the pump and generator is so small that a simple squirrel-cage asynchronous motor without any starting device may be employed.) When the mercury has reached the normal height in the reservoirs the exciting-current circuit is automatically closed by the mercury proper and, as the magnets are already excited, the rectifier will start to supply current to the d.c. busbars. As a rule it does not matter, with rectifiers of moderate size, how large the load is at the moment the rectifier starts operation. If the pump motor should fail, all that will happen is that the d.c. voltage will disappear. When, owing to a deficiency in the supply, the mercury sinks in the reservoir, the exciting-current circuit will first be broken, the immediate effect of which will be that the jet will no longer undulate. This means that, owing to the design of the main electrode, the a.c. side of the plant is automatically cut off from the d.c. side. The same effect is produced by the failure of the exciting current or the magnetizing current of any of the three commutators or set of parallel commutators of a 6-phase series rectifier.

Considering now the question of automatic plants, it would seem, from what has been stated, that the arrangements must be simpler with the jet-wave than with the mercury-arc rectifier, in that plants of the latter type must generally include automatic devices for the starting, exciting and vacuum-pump elements. Also, as artificial cooling is not necessary with the jet-wave rectifier, the corresponding automatic starting devices are also eliminated. Generally the jet-wave plant is now provided with a 3-pole overload circuit breaker inserted in three of the 6 wires between the main transformer and the three commutators. This circuit breaker protects the plant not only against short-circuits on the d.c. side, but also against internal short-circuits. So far it has been found necessary only to use quite ordinary types of circuit breakers and not (as with the more delicate mercury-arc system) special high-speed breakers. In automatic plants the overload circuit breaker—like the corresponding breaker in the mercury-arc plant—must be combined with a relay for switching it in again a definite number of times after an interruption has occurred. In d.c. lighting plants an automatic regulation of the d.c. voltage must of course be provided with both types of rectifiers. The jet-wave rectifier plant is, as already stated, reversible, while the arc rectifier plant is not. In cases where this quality is not desirable, the jet-wave rectifier plant must be furnished with an automatic reverse-current switch.

The Jet-Wave Rectifier compared with the Mercury-Arc Rectifier.

The jet-wave rectifier and the mercury-arc rectifier have been compared several times in the course of the discussion, notably by Prof. Thornton, Mr. Bartlett and Mr. Rendell-Baker. I think Mr. Bartlett is perfectly right in saying that it has been much easier to gain insight into the nature of the jet-wave rectifier than into that of the mercury-arc rectifier. The jet-wave rectifier is a purely mechanical device, and is much simpler than its competitor. Knowing the difficulties to which the development of the former system has given rise, I therefore fully appreciate the achievement of those who made the mercury-arc rectifier the practical engineering proposition it certainly is to-day. I admit that, at present, the capacity of the latter rectifier is greater than that of the jet-wave rectifier. I am, however, convinced that the jet-wave rectifier, when its manufacture has been rationalized, will soon gain upon its competitor and finally overhaul it. I trust I have made it fairly clear that there is nothing to prevent practically all sizes of jet-wave rectifiers for practically all voltages being made, and I shall endeavour to sum up the facts upon which I base my opinion with regard to the final outcome of the competition between the arc rectifier and the jet-wave rectifier (or rectifiers of substantially the same qualities).

The efficiency of the jet-wave rectifier is, at medium voltages (550 volts), practically identical with that of the arc rectifier, while at lower voltages it is higher. Hence, while an economical rectifier of the arc type cannot be built for voltages below 220, and with difficulty for even that voltage, economical jet-wave rectifiers can be produced for voltages down to 110 and most likely for still lower voltages. In this connection it may be mentioned that serious consideration has been given to the possibility of developing low-voltage jet-wave rectifiers for the chemical industries. In connection with the question of efficiency I should like to say a few words about the glass-bulb rectifier. I suppose that Mr. Rendell-Baker's experiences refer to this type of rectifier, which undoubtedly yields a wonderfully simple means for a.c. rectification, although in my opinion a rather costly one. The price of a glass-bulb rectifier plant for 550 volts, 400 amperes (the size of the jet-wave rectifier installed in Bradford) is stated in the catalogue of a leading Continental manufacturing company to be 12 880 reichsmarks (£630), not including the main transformer or means for voltage regulation. The plant comprises two glass bulbs, each for 200 amperes and 501–600 volts. The two bulbs cost £124 6s., to which must be added a transport insurance of 10 per cent, or £12 8s. The total price is thus £136 14s. Now the average life of such bulbs is on an average 8 000–10 000 hours. Using the latter figure we find that 3·27d. must be set aside per hour for renewal. Let us assume that the plant is running on full load. Then the d.c. energy produced per hour is about 200 kWh. At 0·35d. per kWh for the a.c. energy, the raw material for the production of the 200 kWh of d.c. energy has cost 5s. 10d. Hence the 3·27d. represents a percentage loss in the production amounting to $3 \cdot 27 \times 100/5 \cdot 8 \times 12 = 4 \cdot 6$ per cent. This loss may be given other names, but actually it is equivalent to a reduction of the efficiency by 4·6 per cent. With the jet-wave rectifier there is no corresponding loss.

I have tried to convey an idea of how simple a matter the operation of a jet-wave rectifier is. As stated, the rectifier can be started within 10 sec., even with the present low-tension switchgear, which Mr. Aikman quite correctly thinks can be simplified. The simplicity in operation of the rectifier has been considered a prominent feature of the new apparatus by all who have had experience of it, and it has been suggested that it lends itself better than the arc rectifier for use in automatic substations. I fail to see why the quite harmless circumstance that hydrogen is used as a medium of commutation should preclude automatic working, as suggested by Mr. Aikman. Again, by all who have had experience in its use the jet-wave rectifier has been considered well able to stand all kinds of rough treatment. As far as I can see, it is superior in this respect to the arc rectifier, the operation of which is still in a rather obscure way threatened by the phenomenon of backfiring. Mr. Bartlett states that the modern arc-rectifier equipment is called upon to stand larger overloads than those claimed in my paper for the jet-wave rectifier. This is true, but what percentage overload a plant will stand obviously depends solely on what is taken to be the normal load. With 33 per cent reduction of the nominal value of this load the overload capacity of any plant will be doubled, and with the jet-wave rectifier this reduction would leave the efficiency at full load unaltered.

In a comparison between the mercury-arc and the jet-wave rectifier great stress must be laid on the fact that the latter is a reversible system. This quality, which the mercury-arc rectifier in its ordinary form does not possess, opens up great fields of applications for the jet-wave principle—as already indicated in my reply.

It may be questioned whether the arc rectifier or the jet-wave rectifier is the simpler, but I know that the manufacture of large jet-wave rectifiers is now, and will be especially in the future, a very much simpler process than that of arc rectifiers. Therefore the cost of production cannot fail to be much smaller for the former than for the latter. It has been mentioned in the discussion that a 200-kW/550-V jet-wave rectifier plant has recently been installed at a substation in Bradford. This rectifier was manufactured under very unfavourable conditions in Copenhagen, in a workshop not in the least equipped for the purpose. The whole low-tension switchgear, together with the auxiliary transformer, had to be bought at the full list price from various firms. Notwithstanding these drawbacks the whole plant, apart from the main transformer but including the low-tension switchgear, has cost us only what a glass-bulb mercury-vapour plant of the same size delivered by one of the leading Continental firms would have done. Since that time the jet-wave rectifier has been greatly simplified. The rather expensive slide arrangement for setting the main electrodes has been discarded and the velocity of the jet changed from 6 to 5 metres per sec., which results in a reduction of the mercury content of the rectifier by about 30 per cent. It would therefore seem that the commercial production of the new rectifier is almost sure to be a good business proposition.

Various Subjects.

The discussion contains a great number of suggestions and questions, with some of which I shall now deal. Prof. Thornton suggests that the large pulsations in the current supplied by the jet-wave rectifier when operated in parallel with a constant-voltage source are characteristic of this rectifier while they are absent from the mercury-arc rectifier as " the resistance of the arc circuit stabilizes the current flow." I fail to see how any resistance could have such an effect, and I am convinced that the current fluctuations are practically identical in the two rectifiers. Mr. Bartlett states that he based his early unfavourable view in regard to the jet-wave rectifier on the fact that I was " at that time using only about 150 volts " per jet whilst he believed " a voltage of 600 to 1 000 to be the least which would justify the use of a rectifier." I regret that his views are based on a complete misconception. It is true that, at the time referred to, commutators for 183 volts only were used, but as our aim was to construct a 550-volt rectifier for tramway traction, and as such a rectifier must consist of 3 commutators in series, each commutator had to be designed for 550/3 = 183 volts. It would seem that Mr. Bartlett has confused the two terms " commutator " and " rectifier " in my paper.

The floor space required by large-power jet-wave rectifiers is likely to be $0 \cdot 125\ \text{m}^2$ per 100 kW.

Mr. Stevens asks me how I came upon the idea of the jet-wave principle. The first jet-wave apparatus was a periodic interrupter. In February 1907 I was working at certain problems in connection with the radiation of electricity from needle points, and found that none of the interrupters for inductor operation known at that date was satisfactory. A few months before, when taking my degree of Master of Science at the University of Copenhagen, I had been set the problem of determining the mass-charge ratio of the particles of a cathode ray by the method of magnetic deflection. In searching for a new principle for an interrupter it now occurred to me that the analogical deflection of a mercury jet in a magnetic field could probably be used for this purpose, and a preliminary estimate at once showed that the scheme was quantitatively sound. Such was the origin of this idea. All the constructive suggestions given by Mr. Stevens have been considered and some of them have been realized. Thus a rotating-field commutator has been built. A serious drawback with this commutator is, however, that the exciting current for the production of the wave must be a direct current of rather great intensity, though of course of small voltage, and such a current is comparatively expensive. I am doubtful whether the use of a water jet-wave and the application of an electrostatic field for the production of the wave would be sound propositions. An inductive load is on the whole an advantage in that reactance in the d.c. circuit means a smoother rectified current but no increase of the spark-loss (cf. description of commutation process). Hydrocarbon (illuminating gas) has been used as a medium for the commutation, but its use has now been discontinued on account of the carbon deposits to which it gave rise. Experiments have been carried out with hydrogen at pressures up to about 20 atmospheres. The pressure has of course no effect on the spark loss. Probably the spark interval τ_2, Fig. 17, decreases with increasing pressure, which would mean a greater stability. This question, however, has not yet been finally settled. It appears that the commutation spark does not give rise to any serious radio disturbances and, as regards the disturbances to be expected from the rectified current proper in telephone circuits, it would seem that they must be of the same intensity and character as those due to currents from a mercury-vapour rectifier, seeing that the currents from the two types of rectifier are practically identical.

Prof. Wheatcroft asks whether all changes occurring with the jet when transformed into a jet wave have been taken into account in the building-up of the formula for the resistance of the latter. I trust they have, but I confess that I fail to see how " the alteration of the shape of the cross-section " can have any appreciable effect on the resistance. The complete theory of the jet wave has been given in a treatise issued by the Danish Royal Society,* to which treatise I would refer inquirers for information with regard to the mathematical treatment of the problems. I do not think that the wave-form with the jet-wave rectifier is on the whole more square-shaped than that with the mercury-arc rectifier. At any rate we possess means for varying the width of the spark interval within wide limits, though so far we have always deemed it an advantage to make the interval as short as possible.

Mr. Aikman touches the question of oxidation of the mercury, and Mr. Crocker has very correctly stated the effect of such oxidation, which is a soiling of the pipe system, necessitating periodical cleaning. The oxidation in the jet-wave rectifier is due to the small amount of oxygen (about 0·5 per cent) generally contained in the commercial hydrogen used for filling the chamber. Owing to leakage at the packings of the connecting bolts the flow of hydrogen past the chamber, and therefore the oxidation, has so far been greater than it should be. Owing to the introduction of a special type of packing the leakage will be reduced to at least one-tenth of what it was, i.e. the consumption of hydrogen, the oxidation and the soiling will become quite negligible.

It has been stated in the course of the discussion that a 200-kW, 550-V rectifier plant has been installed in a substation for tramway traction at Bradford. I take this opportunity of thanking Mr. Roles for giving facilities for installing the rectifier in England for demonstration purposes. I also desire to thank Mr. Roles's collaborators and engineers, Mr. Dundas, Mr. Aikman, Mr. Bramwell and Mr. Crocker for their interest and kind assistance during the test. I very much appreciate the trouble which they have taken to subject the apparatus to a complete test. Finally I beg to express my gratitude to the Institution for giving me an opportunity of discussing my work with eminent British electrical engineers.

THE NATURE AND EXTENT OF THE OSCILLATIONS PRODUCED IN A ROTARY CONVERTOR ON FLUCTUATING LOADS AND ON SHORT-CIRCUIT.[*]

By H. COTTON, M.B.E., D.Sc., Associate Member.

(*Paper first received* 3*rd May*, 1928, *and in final form* 5*th April*, 1930.)

SUMMARY.

The following investigation is concerned with the operation of a rotary convertor during conditions of abnormal loading, such as violent fluctuations occurring at definite intervals or during short-circuit conditions. In the former case the rotary convertor, being an oscillatory system having a natural period of its own, behaves just like any mechanical oscillatory system which is subjected to uniformly timed impulses. It is shown that when the natural and the forcing periods synchronize, resonance takes place and very large displacements may be set up, not only with the fundamental period of the disturbance but also by selective resonance with any harmonics which may be present. Methods of determining the natural period of the convertor and of calculating the amplitude of the oscillations set up under specified conditions are given, the methods being verified by experimental results.

The second part of the investigation deals with the motion of the rotor when the machine is subjected to a short-circuit of short duration. The mechanical analogy is in this case a ballistic pendulum, and expressions are developed which enable the displacement and slip velocity to be determined at the moment the short-circuit is cleared, and also the motion subsequent to clearing. These expressions also are verified by experiment, and considerable light is thrown on the requirements of the quick-acting circuit breakers which are commonly used on the d.c. side of rotary convertors.

The research has, of necessity, been conducted on a small experimental machine, but the theoretical and experimental investigations are found to be in reasonably close agreement and, in the case of the operation under short-circuit conditions particularly, it is possible that some other investigator having the necessary facilities may be induced to repeat the investigation on a machine of commercial size.

LIST OF SYMBOLS.

$\mathbf{T}_m$ = maximum value of synchronizing torque, in lb.-ft.;
$\mathbf{T}_l$ = load torque, in lb.-ft.;
$\mathbf{T}_i$ = induction-motor torque, in lb.-ft.;
$\mathbf{T}_s$ = total synchronizing torque = $F(\theta)$;
$\mathbf{T}_d$ = torque due to damping winding;
ρ = ratio of load torque to synchronizing torque;
p = $180/T$, where T = duration of short-circuit;
$\mathbf{I}$ = moment of inertia of armature;
T, T' = time periods;
g = acceleration due to gravity;
ω = slip, in mechanical radians per sec.;
$p\omega$ = slip, in electrical radians per sec.;

LIST OF SYMBOLS—*continued.*

E = applied p.d. per phase;
R = resistance, per phase, of the stator;
Z = impedance, per phase, of the stator;
θ = angular distance between stator and rotor fluxes, in electrical radians;
m = ratio of power of synchronous motor to maximum theoretical power.

(1) GENERAL CONSIDERATIONS OF THE EQUATION OF MOTION.

When a rotary convertor is working in the normal manner, that is, converting from alternating to direct current, it behaves on its a.c. side exactly like any other synchronous machine, the fundamental features of its operation not being affected by the internal reactions due to the d.c. load. Thus the machine constitutes an oscillatory system having a definite frequency of its own, and it is with the nature and extent of these oscillations that this research is concerned.

The problem of the oscillation of a synchronous motor with smooth-cored rotor has been considered in detail by Carr, the present author and others,[*] the behaviour of the machine while oscillating having been based on the equation

$$-\rho\mathbf{T}_m + \mathbf{T}_m \sin\theta + \frac{\rho\mathbf{T}_m}{p\omega}\cdot\frac{d\theta}{dt} + \frac{\mathbf{I}}{p}\cdot\frac{d^2\theta}{dt^2} = 0$$

This is the equation of motion of a mechanical model consisting of a heavy disc of moment of inertia $\mathbf{I}/p$ which can rotate about a horizontal axis (Fig. 1). If the disc is considered as having unit radius then the various components of the equation have the following derivation. The term $-\rho\mathbf{T}_m$ is the uniform torque due to a massless weight of $\rho\mathbf{T}_m$ hanging from a string passing round the periphery of the disc; $\mathbf{T}_m \sin\theta$ is the sinusoidal torque set up on displacement from the equilibrium position by a massless weight $\mathbf{T}_m$ which is secured to the periphery of the disc; the term $\rho\mathbf{T}_m/(p\omega) \,.\, (d\theta/dt)$ is a frictional torque which is proportional to the speed of the disc $d\theta/dt$, and therefore represents a torque such as is set up in an induction motor, or the damping windings of a rotary convertor when slip takes place. Finally, the term $\mathbf{I}/p \,.\, (d^2\theta/dt^2)$ represents the torque required to produce acceleration of the disc.

In the present investigation the rotary convertor is initially running at synchronous speed under zero external load, so that the initial conditions of the model of slip motion are that $\mathbf{T}_m$ is present but the weight $\rho\mathbf{T}_m$ suspended from the string is absent; the disc will thus be at rest with the weight $\mathbf{T}_m$ at the bottom position A. (Actually ρ will have a small value ρ_0 because of the friction and iron losses in the machine; the disc will, however, still be at rest, but with the weight $\rho_0\mathbf{T}_m$ displaced a small distance from A.) The next step is to imagine that a load is thrown on the d.c. side of the machine, the weight $\rho\mathbf{T}_m$ in the model therefore becoming suddenly established. There are three cases to consider.

(1) *A load of fixed value* $\rho\mathbf{T}_m$ *is suddenly thrown on, and is subsequently kept constant.*—If we imagine that the weight $\rho\mathbf{T}_m$ is suddenly hung from the string wound round the disc, it is easy to see that motion in a clockwise direction will take place, and that owing to the inertia of the disc the weight $\mathbf{T}_m$ will be carried beyond the position B, of stable equilibrium. Then if the velocity is brought to zero before $\mathbf{T}_m$ reaches the position C (of unstable equilibrium), damped oscillations about the position B will take place, the disc finally settling down with $\mathbf{T}_m$ at B. This corresponds to the angular shift of the rotor of the machine which takes place when a load is put on, the angle α representing the angle through which the armature rotating field moves backwards in space relative to the fixed magnetic field of the magnet system.

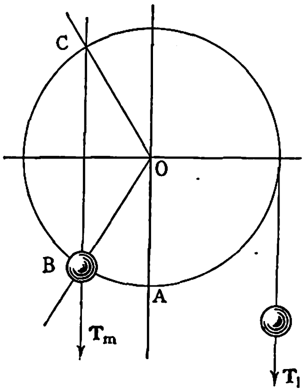

FIG. 1.—Mechanical model to illustrate the slip motion.

If $\rho\mathbf{T}_m$ is so large that the weight $\mathbf{T}_m$ is carried round beyond the position C of unstable equilibrium, then the disc will continue to make whole revolutions and will never come to rest. This corresponds to an overload being switched on to the machine beyond its pull-out capacity.

(2) *The load* $\rho\mathbf{T}_m$ *being a fluctuating quantity. In this case, provided the machine is not pulled out of step, oscillations will be maintained, the nature of the oscillations depending on the manner in which* $\rho\mathbf{T}_m$ *varies with time.*—This aspect of the problem represents a convertor subjected to a fluctuating load on its d.c. side. This form of load is very common since all machines subjected to industrial loads or traction loads, especially the latter, have to withstand very intense, and often very rapid, changes in the magnitude of the load. If the load is fluctuating in a very irregular manner the problem presents little of interest, because in such a case the forced oscillations to which the machine will be subjected will, in all probability, not reach any great amplitude and the machine will continue to run in a normal manner. If, however, the fluctuations in the load occur at sensibly equal intervals, the resultant oscillations will be more definite in character. In the particular case in which the load fluctuations synchronize with the natural period of oscillation of the machine, resonance will take place, and then the amplitude of the oscillation may become very large even if the machine is not overloaded from the point of view of the magnitude of the load fluctuations.

This phenomenon must be of very common occurrence, since even with a very irregular load an examination of the chart from a recording instrument will often show that for a few seconds the peak loads were more or less evenly distributed.

(3) *The load* $\rho\mathbf{T}_m$ *is again suddenly established, but only for a small instant of time, this corresponding to a severe overload or to a short-circuit lasting for a fraction of a second only, until the circuit-breaker trips.*—In this case, provided the duration of the overload is not sufficiently long to pull the machine out of step, a sudden oscillation which is very quickly damped down again will be set up, and the most important point in the investigation of this case is the change in kinetic energy which has taken place, to find out how much of the energy of the short-circuit is derived from the rotational energy of the machine, and how much is derived electrically from the alternating-current side. This is a very important problem in connection with rotary convertors which may be frequently short-circuited, as for example when working on traction duty, since it determines very largely the nature of the overload protection used on the alternating-current side, and, more particularly, the setting of the overload trips.

(2) CONSTANTS OF THE TEST MACHINE.

The whole of the experimental work was performed on a small 3-phase rotary convertor rated as follows:—

Output:—3·5 kW.
A.C. voltage:—100 at frequency 50.
D.C. voltage:—165 at no load.
Full-load current on the d.c. side:—21 amperes.
No. of poles:—4.
Speed:—1 500 r.p.m.

Armature Resistance.—This was measured on both d.c. and a.c. sides, the measurement including brush contact-resistance and the resistance of the leads to the machine terminals. It was made by the ammeter and voltmeter method immediately after a full-load run.

Resistance on d.c. side, 0·235 ohm.

Resistance on a.c. side, measured between each pair of terminals in turn, (1) 0·190 ohm, (2) 0·208 ohm, (3) 0·202 ohm; mean 0·200 ohm.

As the armature of a rotary convertor is essentially mesh-connected, the resistance per phase is $1\frac{1}{2}$ times the above value, namely 0·30 ohm.

Armature Reactance and Impedance.—The machine was belt-driven by a motor and run at its normal speed of 1 500 r.p.m., and the voltage on the d.c. side was measured for different values of the excitation. Where the speed deviated slightly from the normal value the necessary correction was applied instead of attempts being made to maintain the speed absolutely constant. The a.c. voltage was then calculated by multiplying by the transformation ratio of 0·612 for a 3-phase convertor, a check reading showing that this was actually the ratio for the machine. This method was adopted in order to obtain accurate readings of the voltage right down to low values of the excitation, so that the open-circuit characteristic could be drawn accurately over the whole range. The three terminals on the a.c. side were then short-circuited and excitations over a restricted range applied, the external short-circuit current being measured by a single ammeter constituting one of the short-circuit paths. The armature impedance and reactance were then worked out by the Behn-Eschenberg method, the values so obtained taking account of armature reaction, and therefore being applicable with little error to the case of a salient-pole machine.

FIG. 2.—Blondel diagram of experimental machine.

During the experimental work the excitation was maintained constant at 1·51 amperes, the corresponding reactance of the armature per phase therefore being 0·78 ohm, and the impedance 0·836 ohm. This value of the excitation was chosen because it gave a power factor of unity on steady full load when working normally.

Iron and Friction Losses.—While still hot from a load run, the machine was run light as a d.c. motor, the applied voltage being adjusted to give the normal speed of 1 500 r.p.m. with the normal excitation of 1·51 amperes. The armature intake was measured on a wattmeter, and after correcting for armature copper-loss and brush contact-loss the iron and friction losses were found to be 550 watts.

Pull-out Torque.—The magnitude of $\mathbf{T}_m$ was determined from the Blondel diagram, as this was the most satisfactory method for the present investigation. The diagram is drawn to scale in Fig. 2. The base OA is equal to the a.c. voltage, E, per phase, namely 100, while each slant side is equal to

$$\frac{2Z}{R} \times E = \frac{2 \times 0{\cdot}836}{0{\cdot}3} \times 100$$
$$= 558 \text{ volts}$$

Now the total mechanical output of the motor, including iron and friction losses, is represented on the diagram by a series of concentric circles having their centre at O′. Again, the maximum power corresponding to any given excitation is defined by the point of intersection of the locus of the back-e.m.f. vector AB and the slant side O′A, namely the point C in the figure. But the length AB is equal to 100 and therefore

$$\text{O'C} = 558 - 100 = 458$$

It can be shown * that

$$\frac{\text{O'C}}{\text{O'A}} = \sqrt{(1 - m)}$$

where m is the ratio of the power represented by the circle passing through the point C to the maximum possible power (not to be confused with the power corresponding to the pull-out torque).

$$\because \sqrt{(1 - m)} = \frac{458}{558} = 0{\cdot}824$$
$$\therefore m = 0{\cdot}325$$

Again, the maximum possible power per phase is equal to $E^2/(4R)$, so that for the machine under test this is

$$\frac{100^2}{4 \times 0{\cdot}3} = 8\,350$$

∴ Power corresponding to pull-out torque

$$= m \times \frac{E^2}{4R} = 2\,710 \text{ watts per phase}$$

We have now to find the normal full-load power per phase. This is the sum of the output and the iron and friction losses.

Total power developed at normal full load by all three phases = 3 500 + 550 = 4 050 watts.

∴ Power developed per phase = 1 350 watts.

As the machine runs at a constant speed these powers are proportional to the corresponding torques. Hence when working on full load

$$\rho = \frac{1\,350}{2\,710}$$
$$= 0{\cdot}497$$

From $$\mathbf{T} = \frac{33\,000 \times \text{watts}}{2\pi N \times 746}$$

we have for the pull-out torque

$$\mathbf{T}_m = \frac{33\,000 \times 3 \times 2\,710}{2\pi \times 1\,500 \times 746}$$
$$= 38{\cdot}5 \text{ ft.-lb. units}$$

---

* See H. COTTON: "The Graphical Theory of the Polyphase Synchronous Motor," *World Power*, 1926, vol. 5, p. 315, and vol. 6, p. 33.

Moment of Inertia.—The armature moment of inertia was obtained by removing the armature and timing the period of small oscillations made when it was suspended by means of a long bi-filar suspension. With the shaft fittings used during the experimental work the value was

$$\mathbf{I} = 10{\cdot}8 \text{ ft.-lb. units}$$

Knowing **I** it is possible to determine the time of free oscillation, the calculation being made in the next paragraph.

(3) FREE OSCILLATIONS.

In the experiments to be described, and which were made to determine the operation of the machine on fluctuating load, the number of large single oscillations per second was found to be of the order of 4·6 when the natural period synchronized with the forcing period. This gave a half-period of

$$\frac{T'}{2} = \frac{1}{4{\cdot}6} = 0{\cdot}218$$

$$\therefore\ T' = 0{\cdot}436 \text{ for large oscillations}$$

When breaking a current of 10 amperes in such a manner that the period of forced oscillations was made to coincide with the natural period of oscillation of the machine, the period was 0·218 sec., as above, the maximum displacement of the rotor being 82 electrical degrees. Regarding this load as equivalent to a sinusoidal load of amplitude 5 amperes superposed on a steady load of 5 amperes, the corresponding amplitude of swing as reckoned from the mean position is 41 electrical degrees. The actual period for small oscillations is, therefore, obtained from the pendulum correction for large angles. For a pendulum of length l we have

$$T = 2\pi\sqrt{\left(\frac{l}{g}\right)} \text{ for small oscillations}$$

and $$T' = 2\pi\sqrt{\left(\frac{l}{g}\right)} \times \frac{2}{\pi}\int_0^{\pi/2} \frac{d\phi}{\sqrt{(1 - \sin^2 \frac{1}{2}\alpha \,.\, \sin^2 \phi)}}$$

for large angles, α being the displacement from the mean position. In the above case $\alpha = 41°$.

$$\therefore\ \frac{2}{\pi}\int_0^{\pi/2} \frac{d\phi}{\sqrt{(1 - \sin^2 \frac{1}{2}\alpha \,.\, \sin^2 \phi)}} = 1{\cdot}032^*$$

$$\therefore\ T = \frac{T'}{1{\cdot}032}$$
$$= 0{\cdot}424 \text{ second}$$

Damping Constant.—In the general equation of motion all the constants have now been determined with the exception of the coefficient of $d\theta/dt$, this coefficient depending on the extent of the damping. In the present case the damping was produced only by eddy currents induced in the pole-faces, and as these are not amenable to convenient mathematical solution it was necessary to determine the damping in an indirect manner.

When there is no load on the machine, the equation of motion becomes

$$\mathbf{T}_{\mathbf{m}} \sin\theta + \text{const.} \times \frac{d\theta}{dt} + \frac{\mathbf{I}}{p}\frac{d^2\theta}{dt^2} = 0$$

or $$b\sin\theta + c\frac{d\theta}{dt} + d\frac{d^2\theta}{dt^2} = 0$$

where $b = 1$

c is unknown

$$d = \frac{\mathbf{I}}{gp\mathbf{T}_{\mathbf{m}}}$$
$$= 0{\cdot}0041$$

Hence $$\sin\theta + c\frac{d\theta}{dt} + 0{\cdot}0041\frac{d^2\theta}{dt^2} = 0$$

or $$\frac{d^2\theta}{dt^2} + 245c\frac{d\theta}{dt} + 245\sin\theta = 0$$

Now so long as θ is not greater than about half a radian, there is very little error in assuming that $\sin\theta = \theta$, the equation for small amplitudes then becoming

$$\frac{d^2\theta}{dt^2} + 245c\frac{d\theta}{dt} + 245\theta = 0$$

From the nature of the free oscillations it is known that $245 > \frac{1}{4} \times (245c)^2$, since the motion is not aperiodic. The solution is therefore

$$\theta = ae^{-122\cdot 5ct}(\cos nt + \epsilon)$$

where the period is

$$\frac{2\pi}{n} = \frac{2\pi}{\sqrt{(245)} \times \left\{1 - \frac{(245c)^2}{4 \times 245}\right\}^{\frac{1}{2}}}$$

Actually the quantity within the brackets will not differ greatly from unity, and we can write

$$\frac{2\pi}{n} \approx \frac{2\pi}{\sqrt{(245)}}$$

or $$n \approx \sqrt{(245)} \approx 15{\cdot}65$$

This gives for the period

$$T \approx \frac{2\pi}{15{\cdot}65} \approx 0{\cdot}4 \text{ second}$$

which is in reasonably close agreement with the experimentally observed period (when corrected to small oscillations) of 0·424 second.

So long as the motion is not aperiodic, the above differential equation is the equation to a damped oscillation, and the values of θ for which $d\theta/dt = 0$ will become progressively smaller. If we put

$$\frac{d^2\theta}{dt^2} + k\frac{d\theta}{dt} + \mu\theta = 0$$

where $k = 245c$ and $\mu = 245$, it follows that the ratio of one maximum swing in a given direction to the next maximum in the opposite direction is $e^{-\frac{1}{2}k\pi/n}$. Hence if the amplitudes of the successive swings could be observed this ratio could be determined, and the damping constant thus calculated. Actually it was impossible to observe the amplitudes of successive swings because the period was too small. Another method had therefore to be tried.

The function $d\theta/dt$ is also a simple harmonic function of continually diminishing amplitude, the form of this function, and the nature of its decay, being identical with those of θ. It thus follows that the ratio of successive maxima of the velocity curve is also equal to $e^{-\frac{1}{2}k\pi/n}$.* This suggested the following method of determining the changes in motion after throwing off the load. An insulated wire was stretched across one pole-face in a direction parallel to the shaft of the machine, so that when phase swinging took place one pole of the magnetic field set up by the armature currents oscillated across the wire. In this way, when the machine was executing damped oscillations, a damped alternating e.m.f., which was at any instant proportional to the velocity with which the flux moved across the wire, that is, to $d\theta/dt$, was induced in the wire. The induced e.m.f. obtained in this way was too small to operate the oscillograph, so it was amplified by means of a thermionic valve, the type of valve used being a Marconi L.S.5 working with an anode voltage of 400. No transformer was used as the slowness of the oscillations did not render this necessary. In order to operate the oscillograph satisfactorily it was found necessary to use two such valves in parallel.

---

* From tables of elliptic integrals.

The record obtained is shown in Fig. 3, from which it will be seen that the fundamental voltage wave due to oscillations of the main flux has a second harmonic superposed on it. This harmonic is due to changes in magnitude of the flux accompanying the changes in position, and, therefore, the changes in the reluctance of the air-gap traversed by the flux. This effect, although large, has no direct bearing on the problem of the phase-swinging of an undamped or lightly damped rotary convertor, but it is obviously of importance in connection with the design of the damping grids for a commercial machine, since these grids will carry an appreciable double-frequency current in addition to the fundamental current.

To find the ratio of successive maxima in the induced e.m.f. curve, a portion of the film was placed between two lantern-slide covers and projected on to a large sheet of squared paper, on which the enlarged curve was then drawn. As the damping was small the curve was drawn for 15 oscillations, the ratio of the positive swings of the first and fifteenth being equal to 2·7. Hence,

$$\frac{\theta_2}{\theta_1} = \frac{\theta_3}{\theta_2} = \frac{\theta_4}{\theta_3} = \ldots = e^{-\frac{1}{2}k\pi/n}$$

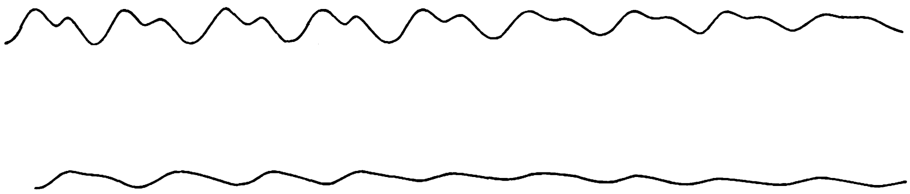
$$\frac{\theta_3}{\theta_1} = \frac{\theta_5}{\theta_3} = \frac{\theta_7}{\theta_5} = \ldots = e^{-k\pi/n}$$

For 15 complete oscillations there will be 14 terms in the above series, so that, multiplying all these terms and substituting the above ratio, we have

$$e^{-14\pi k/n} = \frac{1}{2\cdot 7} = 0\cdot 37$$

$$\therefore\ e^{-\frac{44\times 245c}{245\sqrt{(1-\frac{1}{4}c^2)}}} = 0\cdot 37$$

The solution of this is $c = 0\cdot 023$, showing that in the present case the damping is small.



Induced e.m.f. when executing free damped oscillations

Induced e.m.f. when executing forced oscillations at resonance frequency

FIG. 3.

Equation of Motion of Test Machine with Experimentally Determined Constants.—The complete equation of motion is, therefore,

$$\frac{d^2\theta}{dt^2} + 5\cdot 6\frac{d\theta}{dt} + 245\sin\theta = 0$$

when executing free oscillations.

(4) FORCED OSCILLATIONS OF THE ROTARY CONVERTOR.

A. *Theoretical Considerations.*—The above investigation shows how the damping factor for a rotary convertor can be determined experimentally, the method being applicable to a large commercial machine as well as to a small experimental machine. From the point of view of performance under actual working conditions it is also of importance to investigate the nature of the forced oscillations to which the machine will be subjected when severe fluctuations in the load take place, and these fluctuations occur for a short period at sensibly equal intervals of time. In such a case the load can be regarded as periodic, and unless the damping is very effective very large amplitudes can be set up in a very short time. If we assume a sinusoidally varying load of maximum value $\mathbf{T}_l = \rho\mathbf{T}_m$, then on putting $-\rho = a$ we have for the equation of motion

---

* See Appendix 2.

$$d\frac{d^2\theta}{dt^2} = -b\sin\theta - c\frac{d\theta}{dt} + \rho\cos(pt+\epsilon)$$

Writing this in the general form, we have

$$\frac{d^2\theta}{dt^2} = -\mu\sin\theta - k\frac{d\theta}{dt} + f\cos(pt+\epsilon)$$

same as that of the forcing system, the fluctuating load in the present case, and the amplitude of which is equal to A. The damping coefficient k is relatively small, and therefore A is greatest when the denominator of A is least, that is, when

$$p^2 = \mu$$

We then have for the maximum amplitude

$$A = \frac{f}{kp} = \frac{f}{k\sqrt{\mu}}$$

Using the simplification $\sin\theta = \theta$, which, although not accurate for large oscillations, will give an idea of the order of the magnitudes involved, the solution for the maximum amplitude is

$$A = \left[\frac{f^2}{(\mu - p^2) + k^2p^2}\right]^{\frac{1}{2}}$$

and for θ is

$$\theta = A\cos(pt - \epsilon - \epsilon_1)$$

where $\tan\epsilon_1 = kp/(\mu - p^2)$.

This is a forced oscillation the period of which is the

Substituting the numerical values of the constants we thus have

$$\begin{aligned} A &= \frac{114}{5{\cdot}6 \times \sqrt{245}} \\ &= 1{\cdot}32 \text{ radians} \\ &= 76 \text{ degrees, or a total swing of 152 degrees.} \end{aligned}$$

For different values of p either greater than or less than $\sqrt{\mu}$ the amplitude falls away rapidly after the well-known manner of the resonance curve. The numerical calculation indicates that if the period of the fluctuations in the load coincides with the natural period of oscillation of the rotary convertor, then very violent oscillations may be set up, which, if they do not actually pull the machine out of step, will yet cause very severe fluctuations in line current, and in the power factor. This effect will be greater the smaller the degree of damping in the machine.

B. *Test Results with Sinusoidal Currents.*—In order to investigate this effect the machine was subjected to a d.c. load which varied in a very nearly sinusoidal manner. To accomplish this, a liquid resistance was made up with one electrode fixed and the other capable of rotation about a horizontal axis. This electrode was fixed eccentrically, its shape being such that the area of electrode immersed in the liquid was a sinusoidal function of the angular position of the electrode. In one position the electrode only just touched the electrolyte, so that, although the circuit was not actually broken, the current fell to a very small value. An oscillograph test showed that the current was very nearly sinusoidal. With the rotating electrode in the position giving maximum current, this maximum current was adjusted to a certain value by altering the strength of the electrolyte, since it was essential to keep the level constant in order that the minimum current should be close to zero. The electrode was then rotated by means of a small motor, and the amplitude of phase swing was determined as a function of the speed of the electrode. The amplitude of swing was determined by the stroboscopic method as follows. A disc was mounted on the convertor shaft, and two black patches were painted on at the opposite ends of a diameter. A small induction motor was mounted with its shaft in line with the convertor shaft, and on this was mounted a disc having two narrow slits cut in, also at opposite ends of a diameter. The induction motor was run up to speed in the usual way and then synchronized by switching direct current into the rotor circuit, and it then ran throughout at synchronous speed. Light from an arc lamp was directed through the slits on to the disc on the convertor shaft, the observed motion of the pattern then being a reproduction of the phase-swinging of the convertor. In order to measure the amplitude of phase-swing, a scale was fixed behind the disc, its graduations being in electrical degrees. Owing to the fairly rapid motion of the pattern it was rather difficult to read off the position just at the extremity of a swing, and, therefore, in order to facilitate this measurement, two small sliders were so arranged that they could be placed in any position of the scale. These were so adjusted that the black patch just touched them at each extremity of swing, this being much more accurate than the reading of the amplitude without their aid. Since the rotary electrode threw out a little

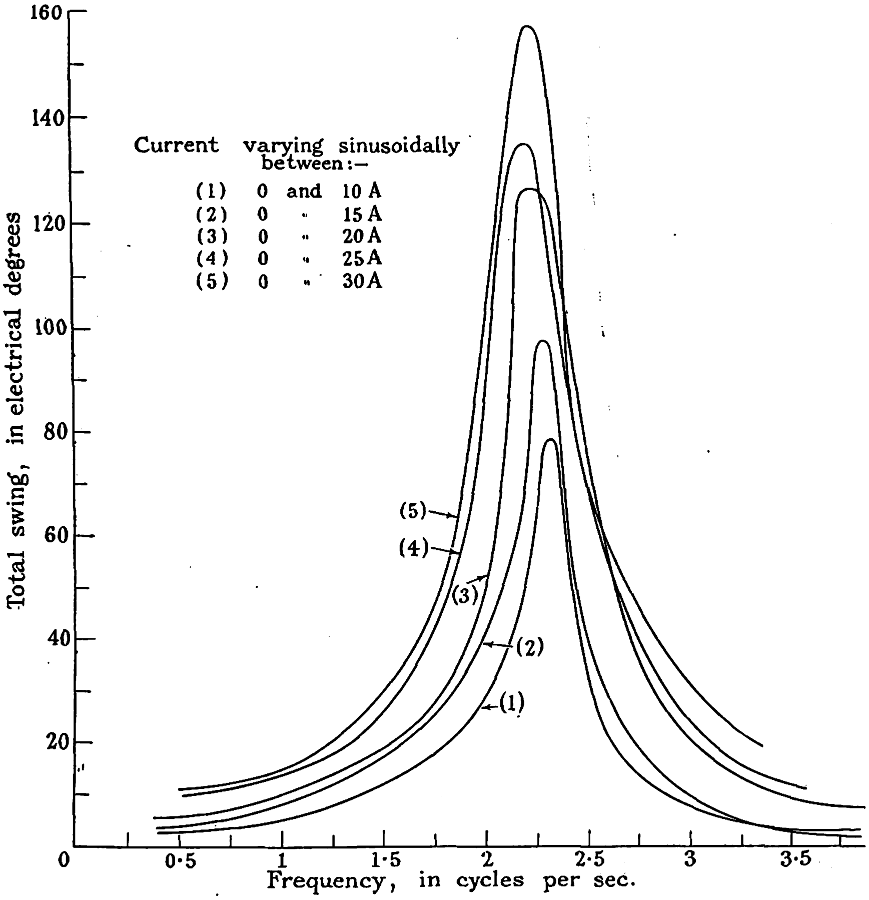

FIG. 4.—Forced oscillations with sinusoidal load current.

water it was necessary to make up the level from time to time, although this was minimized as far as possible by fixing over the disc a cowl which directed any water back into the tank. The maximum value of the current was also occasionally checked. Experiments were made with maximum currents of 10, 15, 20, 25 and 30 amperes, the results being given in Table 1 and plotted in Fig. 4.

It will be seen that they are of the same form as the curve obtained from purely dynamical considerations, showing that the performance of the machine can be predetermined with reasonable accuracy by these methods. The tabulated swings are all of twice the amplitude as measured from the mean position. The remarkable feature of the curves is the sharpness of the resonance peak, although this is to be expected since the damping is very small. It shows that such a machine will attain a large amplitude of swing in a very short time, if the frequency of the load fluctuations is correctly timed. This was shown to be the case, since if the speed of the rotating electrode was adjusted to give resonance, and the load then suddenly thrown on by closing the main switch on the d.c. side, the maximum amplitude appeared to be attained practically instantaneously.

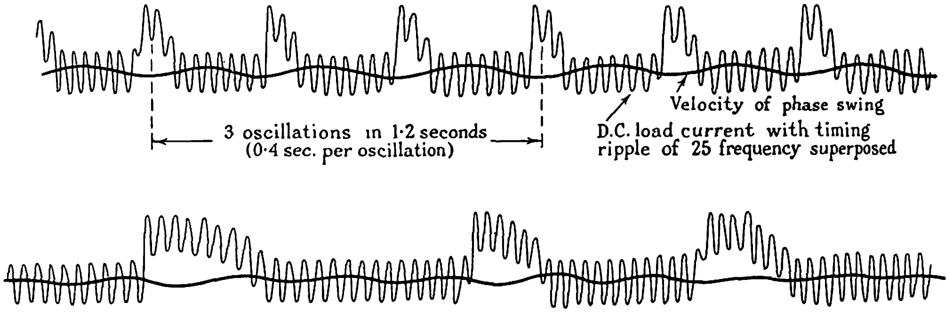

FIG. 5.—Oscillograms of fluctuating load current (with 25-cycle timing ripple superposed) and corresponding slip velocity. The upper oscillogram gives the conditions of resonance.

As previously pointed out, it was not possible to obtain the velocity of phase-swing under actual experimental conditions by the rotating disc method, and in the case of operation under fluctuating load the additional load imposed by the eddy current in the disc was such as to pull the machine out of step. In order to obtain a record of the nature of the motion, however, a few such speed determinations were made, with a fluctuating load both of resonance and of non-resonance frequency, and its maximum adjusted to a low value so that the machine was able to keep in step. The curves are reproduced in Fig. 5, from which it will be seen that the motion appears to be approximately sinusoidal at resonance. It was not thought necessary to calibrate this curve, since it was not obtained under the conditions used in the theoretical and experimental investigations. There does not appear to be any second harmonic present in the motion, and the resonance curves also do not exhibit any trace of the presence of such a harmonic, from which it can be concluded that in the case of the machine under investigation the double-frequency component of the torque due to the salient poles is negligible in its effect, thereby justifying its omission from the equation of motion.

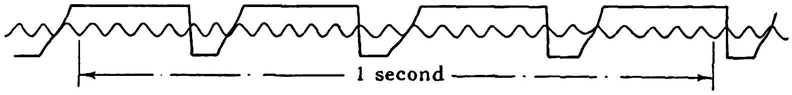

FIG. 6.—Oscillogram of fluctuating load current given by motor-driven rotary switch.

C. *Test Results with Intermittent Currents.*—Since it is very improbable that any rotary convertor will, under actual operating conditions, be subjected to a sinusoidally varying load, a second experimental load was arranged to reproduce the sudden changes which are more likely to occur in practice. When violent loads are imposed on a machine they are, as a rule, maintained for a small fraction of a second, so that a load consisting of a series of sudden peaks and sudden falls, with peak value of the current maintained for a short interval of time, would be more likely to reproduce actual conditions. Such conditions are obtained by alternately making and breaking a load of constant resistance. For this purpose the water load was again used, but this time the electrodes were kept in a fixed position, except that from time to time a little adjustment was necessary to keep the steady value of the current constant. The switching off and on was done by means of a rotary type of switch which was directly coupled to a d.c. motor. In order to obtain a sufficiently good contact between the fixed and rotating parts it was necessary to adjust the tension springs of the fixed contacts fairly tight, with the result that, while contact was made, a considerable load was imposed on the motor, this being increased by the fact that it was necessary to make use of a whole row of six contacts to save the switch from premature destruction by burning out. The result of this was that the periods of load were longer than the periods of no-load, but as the operation under such a load is not amenable to convenient mathematical analysis this was considered of no importance. An oscillogram of the current curve so obtained is given in Fig. 6, and owing to the fact that the periods of load and of no-load are not equal there are even as well as odd harmonics present in the analysis into sinusoidal components. Denoting the fundamental component by unity, the first five components are as follows:—Fundamental 1·0, 2nd harmonic 0·679, 3rd harmonic 0·304, 4th harmonic 1·21, 5th harmonic 0·0539.

The maximum value of the current was adjusted to a series of values, as before, and the amplitude of phase-swing determined as a function of the frequency of the load fluctuations, the results being given in Table 2 and plotted in the curves of Fig. 7.

—	—	—	—	—	—	—	—	3·27	21

The results of this series of experiments show that resonance can take place with each harmonic, and that, particularly in the case of the third harmonic, the amplitude obtained may be very nearly as large as that given by the fundamental. It is thus obvious that if a load is fluctuating at such a rate that a prominent harmonic is in synchronism with the natural period of the convertor, then a large amplitude of swing may again be produced. The shape of the curves shows that the resonance peaks with the harmonics are very sharply defined, this also being due to the small amount of damping. The equation of motion with such a load is of the form

$$\frac{d^2\theta}{dt^2} = -\mu\theta + k\frac{d\theta}{dt} + f_1 \cos(pt + \epsilon_1) + f_2 \cos(2pt + \epsilon_2) + f_3 \cos(3pt + \epsilon_3) + \ldots$$

and, as is well known, if k is small the amplitude at resonance with any one of the components is due to that component only, the others being of negligible effect. Denoting these amplitudes by A_1, A_2, A_3, etc., the relation

$$A_1 : A_2 : A_3 : \ldots = f_1 : f_2 : f_3 : \ldots$$

should hold. It was found impossible to identify the peaks due to harmonics higher than the third, because they come so close together that the slighest variation in the time of revolution of the switch caused the motion to change completely and to become very complex. From the analysis of the wave-form we have

$$f_1 : f_2 : f_3 = 1\cdot0 : 0\cdot679 : 0\cdot304$$

while from the experimental results we have

$$A_1 : A_2 : A_3 = 1\cdot0 : 0\cdot772 : 0\cdot891$$

when the maximum current was 30 amperes

$$A_1 : A_2 : A_3 = 1\cdot0 : 0\cdot455 : 0\cdot75$$

when the maximum current was 25 amperes

$$A_1 : A_2 : A_3 = 1\cdot0 : 0\cdot481 : 0\cdot58$$

when the maximum current was 20 amperes

$$A_1 : A_2 : A_3 = 1\cdot0 : 0\cdot296 : 0\cdot426$$

when the maximum current was 15 amperes

and $A_1 : A_2 : A_3 = 1\cdot0 : 0\cdot415 : 0\cdot805$

when the maximum current was 10 amperes.

Since the changes in load were sudden, and not gradual as with the sinusoidally varying load, points corresponding to a frequency of fluctuation of zero were obtained by taking the swing when the load was suddenly switched on, these being the initial points on the curves.*

Under actual working conditions, it is more probable that the magnitude of the fluctuations will be less than 100 per cent of the maximum current. Another series of experiments was therefore made with two loads in parallel, one of them kept permanently in circuit, and the other switched in and out by the rotary switch as before. The maximum current in the second resistance was made equal to the current permanently flowing in the first, so that the percentage fluctuation of the load was now 50 per cent, or some other value, instead of 100 per cent. The maximum current taken by the whole load was given a series of values as before, this time 31, 30, 24 and 24 amperes, the minimum values being 10, 15, 12 and 8 amperes, respectively. The four curves, along with the experimental points, are plotted in Fig. 8, and it will be seen that the results are sensibly the same as before, except that with very large amplitudes the machine pulled out of step. At first sight it might appear that the machine should carry such a load more easily than a load in which the fluctuations were 100 per cent of the maximum, but the reason is probably due to the fact that the mean load is now three-quarters of the maximum, instead of one-half, the angular position of the rotor at this mean load, therefore, being considerably nearer to the position of instability.

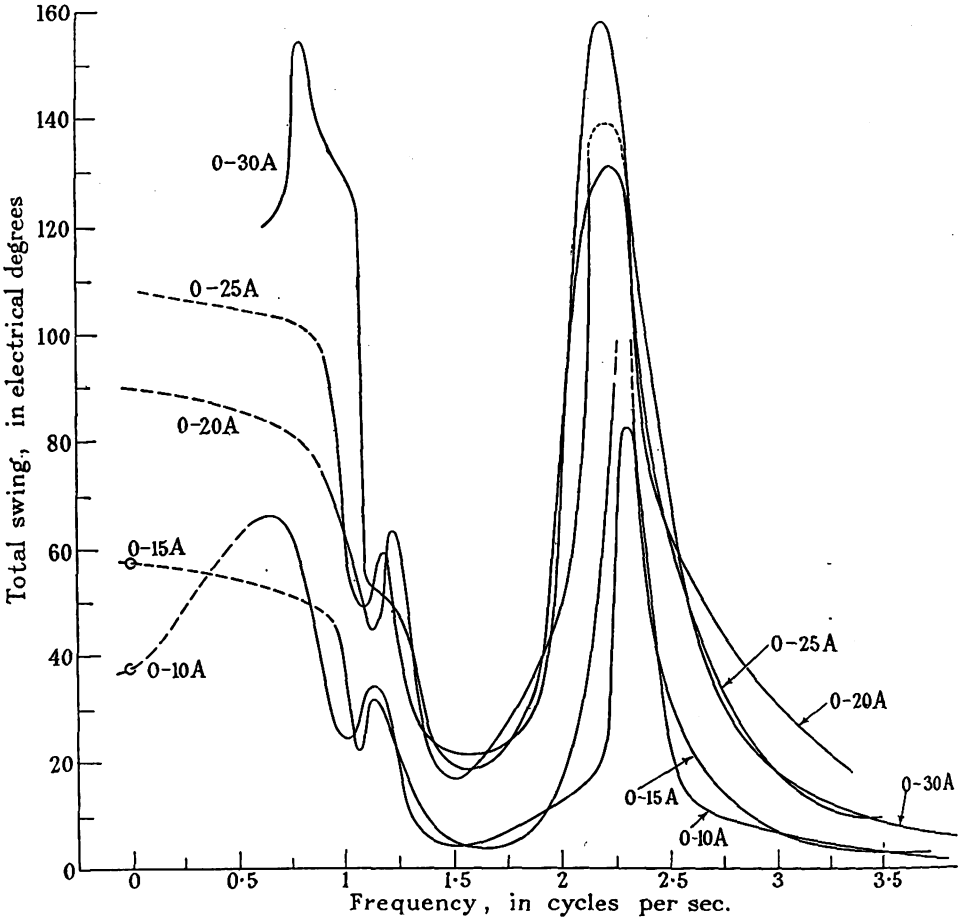

FIG. 7.—Forced oscillations with non-sinusoidal current.

While these experiments were in progress it was suggested to the author that the operation of a rotary convertor under such conditions as explained above would be, of necessity, somewhat inconsistent, and that quite different results would be obtained if identical tests were carried out at different times. To test this the rotary switch was arranged to switch on and off a load of 15 amperes and observations were made by several observers at a very large number of speeds of the switch. The experimental points obtained are plotted in Fig. 9, from which it will be seen that for speeds not less than that corresponding to the third harmonic the points are grouped about a curve identical with the corresponding curve of Fig. 7. At speeds less than third-harmonic speed it was certainly impossible to obtain any definite information.

A final series of tests with fluctuating load was made with different excitations of the machine. It was found that the excitation made very little difference to the operation unless it was reduced to such an extent that the power factor on steady load was as low as about 0·7, when the machine very readily fell out of step. It has, therefore, not been considered necessary to give actual experimental data for these tests as they do not give any additional information.

---

* Actually the wave-form changed with speed of the switch because of the slowing-down effect when the switch closed, this effect naturally being much greater as the speed decreased. Agreement between the experimental peaks and the analysed wave could therefore hardly be expected.

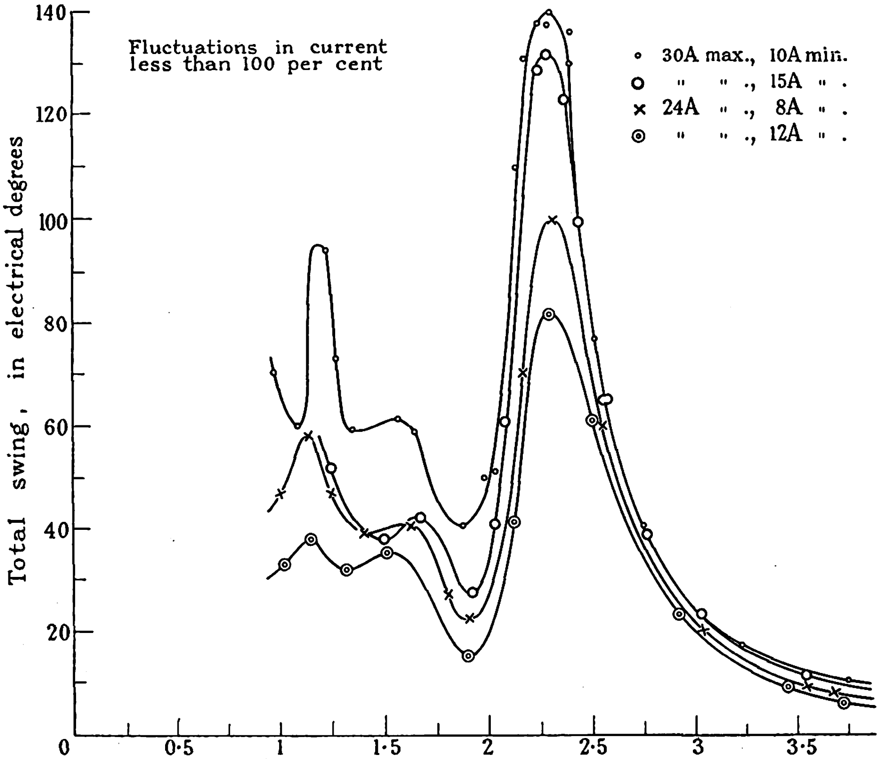

FIG. 8.—Forced oscillations with load fluctuations of less than 100 per cent.

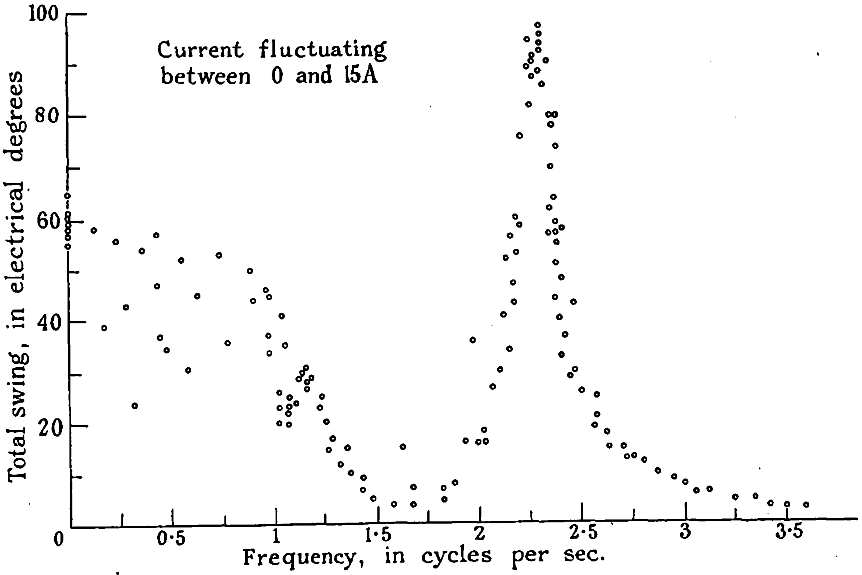

FIG. 9.—Results obtained by several independent observers.

(5) BEHAVIOUR UNDER SHORT-CIRCUITS.

A. *Theoretical Considerations* (*undamped*).—In this section of the investigation, the changes in motion and in phase position of the rotor are determined for violent overloads of short duration, such as may frequently take place in the case of a rotary convertor operating on a traction load. This case also can be studied by means of the mechanical model previously referred to.

Suppose that the machine is initially on no-load, the weight $\mathbf{T}_m$ attached at B then being in the bottom position $\theta = 0$ and the weight $\rho\mathbf{T}_m$ equal to zero; that is, $\theta = 0$ if we neglect the iron and friction losses taking place at no load. This is justifiable in the present case because the opposing torque due to these losses will be exceedingly small when compared with that due to an overload approaching the short-circuit value. To represent the short-circuit, imagine that the weight $\rho\mathbf{T}_m$ is suddenly attached to the string: also imagine that this weight remains operative for only a very short interval of time, which, in practice, is determined either by the duration of the overload, if this is exceedingly brief, or by the time taken for the circuit breaker on the d.c. side to open. In practice the opening of the d.c. breaker, and not the oil circuit-breaker on the a.c. side, is assured by the use of very quick-acting breakers which have been recently developed for use with rotary convertors.

It is very easy to see in a general way what changes will take place during such a short-circuit. The ratio ρ may, of course, be greater than unity, so that for a sustained short-circuit there is no position of equilibrium of the model, either stable or unstable, which means that the model will continue to rotate through whole revolutions at gradually increasing speed, this corresponding to the case of a convertor falling out of step.

If the short-circuit is only of very short duration, then two things can happen. First, the point B (Fig. 1) will have been carried to some angular position less than 180° by the time the short-circuit has cleared, and, furthermore, the disc will not have attained a sufficiently high velocity for the inertia to carry this point B as high as the position $\theta = 180°$. Strictly speaking, this critical position will be the position of unstable equilibrium defined by the value of ρ corresponding to the iron and friction losses, but, as stated above, this will be very little short of 180° in practice.

Secondly, the point B will have reached or passed the position $\theta = 180°$ by the time the short-circuit has cleared, or the velocity attained during this time will be such that the inertia of the disc will carry the point beyond the position $\theta = 180°$.

In the first case the rotary convertor will not fall out of step, whereas in the second case it will, even though the duration of the short-circuit is less than the time taken for the disc to swing from the position $\theta = 0°$ to the position $\theta = 180°$. It therefore follows that for a given circuit breaker having a given minimum time of clearing the circuit, there is a maximum short-circuit current which a given convertor can withstand without falling out of step, and an examination of the operation of a machine under such conditions is, therefore, of extreme practical, as well as theoretical, value.

Consider, then, the mechanical model of the motion of the machine. Since the operation is being worked out as a problem in mechanics the following symbols will be used:—

$\mathbf{I}$ = moment of inertia of the disc in ft.-lb. units, i.e. not including g,
W = weight attached to B and producing the synchronizing torque $T_m \sin\theta$,
F = weight attached to the end of the string, and producing the load torque $\rho\mathbf{T}_m$,
a = radius of disc, in feet.

Then for the equation of motion we have

$$\mathbf{I}\frac{d^2\theta}{dt^2} = (F - W\sin\theta)ag$$

where θ is any angular displacement. This gives

$$\begin{aligned}\mathbf{I}\left(\frac{d\theta}{dt}\right)^2 &= 2Fag\theta - 2Wag(1-\cos\theta)\\ &= 2Fag\left[\theta - \frac{W}{F}\left\{1-\left(1-\frac{\theta^2}{2!}+\frac{\theta^4}{4!}-\frac{\theta^6}{6!}\cdots\right)\right\}\right]\\ &= 2Fag\theta\left\{1-\frac{W}{2F}\left(\theta-\frac{\theta^3}{12}+\frac{\theta^5}{360}-\frac{\theta^7}{201\,060}\cdots\right)\right\}\end{aligned}$$

$$\therefore \frac{d\theta}{dt} = \left[\frac{2Fag\theta}{\mathbf{I}}\left\{1-\frac{W}{2F}\left(\theta-\frac{\theta^3}{12}+\frac{\theta^5}{360}-\frac{\theta^7}{201\,060}\cdots\right)\right\}\right]^{\frac{1}{2}}$$

This enables the angular velocity $d\theta/dt$ to be determined in terms of θ.

In order to find the relationship between t and θ there are two methods available.

(1) *Graphical Method.*

We have

$$\int\frac{dt}{d\theta}\cdot d\theta = \int dt$$
$$= t + C$$

Hence, if the reciprocal of the velocity, namely $dt/d\theta$, is plotted against θ, the areas under the curve between the limits $\theta = 0$ and θ equals a series of values, will give the times corresponding to these values of θ. The constant of integration, C, will be zero, since when $\theta = 0$, $t = 0$.

(2) *By Calculation.*

From the equation for $d\theta/dt$

$$\frac{d\theta}{dt} = \sqrt{\left[\frac{2ag}{\mathbf{I}}\right]}\sqrt{[F\theta - W(1-\cos\theta)]}$$

we have

$$t = \sqrt{\left[\frac{\mathbf{I}}{2ag}\right]} \times \int_0^\theta \frac{d\theta}{\sqrt{[F\theta - W(1-\cos\theta)]}}$$

If, now, the short-circuit current is exceedingly large, as might happen if the short-circuit occurred right up to the machine, we could neglect W in comparison with F, and obtain for an approximate solution

$$\begin{aligned}t &= \sqrt{\left[\frac{\mathbf{I}}{2agF}\right]} \times \int_0^\theta \theta^{-\frac{1}{2}}\,.\,d\theta\\ &= \sqrt{\left[\frac{\mathbf{I}}{2agF}\right]} \times 2\sqrt{\theta}\end{aligned}$$

$$\therefore\ \theta = \tfrac{1}{2}\frac{Fag}{\mathbf{I}}\,.\,t^2$$

This shows that the angular displacement attained by the end of the short-circuit varies as the square of the time, thus showing the necessity for a very quick-acting breaker if the machine is not to be pulled out of step.

If the short-circuit is not so intense that the above approximation is justifiable, then we have

$$t=\sqrt{\left[\frac{\mathbf{I}}{2agF}\right]}\int_0^{\theta}\frac{d\theta}{\theta^{\frac{1}{2}}}\left\{1+\frac{W}{4F}\left(\theta-\frac{\theta^3}{12}+\frac{\theta^5}{360}\cdots\right)\right\}$$

$$=\sqrt{\left[\frac{\mathbf{I}}{2agF}\right.}\left[\left\{2\theta^{\frac{1}{2}}+\frac{W}{4F}\left(\frac{2}{3}\theta^{3/2}-\frac{2}{7}\cdot\frac{\theta^{7/2}}{12}+\frac{2}{11}\cdot\frac{\theta^{11/2}}{360}\cdots\right)\right\}\right.$$

From this expression we can plot a family of curves of θ against t, each curve corresponding to a given value of F, and from these we can read off directly what will be the angular displacement at the moment of clearing the short-circuit. The value of t calculated for this value of θ will also enable the change in kinetic energy of the rotor to be made, and this energy will have been fed into the fault, the supply, therefore, having been relieved of a corresponding amount.

If the convertor is already on load at the moment the short-circuit takes place, then, owing to the fact that the initial angular position is no longer $\theta = 0$, but is now $\theta = \theta'$, where θ' is the steady displacement corresponding to the load, the conditions for just remaining in step will be modified, although not to any great extent, since θ' will, for normal loading, only be of the order of 3° or 4°.

In this case we have

$$\mathbf{I}\left(\frac{d\theta}{dt}\right)^2 = 2Fag\theta + 2Wag\cos\theta + C$$

To determine the new value of C, we have $d\theta/dt = 0$ when $\theta = \theta'$, which gives

$$C = 2ag\left[F\theta' + W\left(1 - \frac{(\theta')^2}{2!} + \frac{(\theta')^4}{4!}\cdots\right)\right]$$

Neglecting terms in θ' of orders higher than the second we have

$$C = 2ag\left[W + F\theta' - \tfrac{1}{2}W(\theta')^2\right]$$

Hence, generally,

$$\mathbf{I}\left(\frac{d\theta}{dt}\right)^2 = 2Fag\theta + 2Wag(1-\cos\theta) - 2ag\left[F\theta' - \tfrac{1}{2}W(\theta')^2\right]$$

$$= 2Fag\theta\left[1 - \frac{W}{2F}\left(\theta - \frac{\theta^3}{12} + \frac{\theta^5}{360}\cdots\right)\right] - 2ag\left[F\theta' - \tfrac{1}{2}W(\theta')^2\right]$$

The curve of $d\theta/dt$ against θ can thus be determined in the manner previously described. The effect of the initial displacement will be very small for intense short-circuit conditions, and can be neglected, but it may not be negligible if the overload is only two or three times the normal full load.

To convert the equations to a form comparable with those used in the previous parts of the investigation substitute

$\frac{\mathbf{I}}{p}$ for $\mathbf{I}$; $\quad \mathbf{T}_m$ for Wa

$\mathbf{T}_l$ for Fa; $\quad \rho$ for F/W

Before applying the above method to the particular machine under investigation it is of value to study the problem from another point of view. If Ω is the synchronous angular velocity of the machine, then the armature will possess an amount of stored energy U given by

$$U = \tfrac{1}{2}\mathbf{I}\Omega^2$$

If any change in the conditions of load takes place, there will be a momentary change in the angular velocity of, say, $\delta\Omega$, which will bring about a change in kinetic energy equal to

$$\delta U = \Omega\mathbf{I} \times \delta\Omega \div g \text{ ft.-lb.}$$

Suppose that this change has taken place in an interval of time of δt seconds, then the slowing down will be equivalent to an average power output of

$$\frac{\Omega\mathbf{I} \times \delta\Omega}{550 \times \delta t \times g} \text{ h.p.}$$

or

$$\frac{\Omega\mathbf{I} \times \delta\Omega}{732 \times \delta t \times g} \text{ kW}$$

For the experimental machine we have

$\mathbf{I} = 10{\cdot}8$ ft.-lb. units.

$\Omega = 157$ radians per sec., corresponding to a speed of 1 500 r.p.m.

Suppose we take a change in angular velocity of 4 per cent, that is $\delta\Omega = 6{\cdot}3$, and an interval of $0{\cdot}015$ sec., this being the order of time taken by a quick-acting circuit breaker to clear a short-circuit. Then for the average power given up due to the slowing down of the rotor we have

$$\frac{157 \times 10{\cdot}8 \times 6{\cdot}3}{732 \times 0{\cdot}015 \times 32{\cdot}2} = 29{\cdot}7 \text{ kW}$$

This is 8·5 times the normal output of the machine, and corresponds, in fact, to the amount of power which would flow into a short-circuit. We are, therefore, led to the conclusion that when a rotary convertor is subjected to a momentary short-circuit, practically the whole of the energy flowing into the short-circuit may be derived from the slowing down of the rotor, and that only a very small proportion will be drawn from the a.c. supply.* This is a very important consideration from the practical point of view, since it ensures that the onus of clearing the fault can be safely left to the quick-acting breaker on the d.c. side, and that the construction of the breaker on the a.c. side, and the setting of its trip coils and relays, need not be different from those adopted where the possibilities of frequent severe short-circuits do not arise. This, of course, necessitates that the d.c. breaker shall clear the fault before there is any falling out of step, otherwise there will be flashing-over at the commutator, and a transference of the short-circuit conditions to the a.c. side as well. On the other hand, if the d.c. breaker clears the fault before the position $\theta = 180°$ is reached, but the velocity attained is such that the machine falls out of step, the a.c. breaker will operate, but not under severe conditions.

---

* See also *Brown Boveri Review*, 1924 vol. 11, p. 9.

B. *Effect of Damping.*—Now consider the effect of a damping winding during the change in speed. The torque due to this winding is directly proportional to the slip and can be written

$$\mathbf{T}_d = K \times \frac{d\theta}{dt}$$

where K is a constant.

Suppose that if, when the machine is run as an induction motor with this winding acting as the squirrel-cage winding, the slip at normal full-load torque is 4 per cent, this being the order of magnitude of the slip in a commercial machine when run in this manner, then if we apply this to the experimental machine for which the normal full-load torque is

$$\begin{aligned}\mathbf{T}_l &= \rho\mathbf{T}_m \\ &= 0{\cdot}464 \times 41{\cdot}2 \\ &= 19{\cdot}1 \text{ lb.-ft.}\end{aligned}$$

the torque for any percentage slip σ is

$$\begin{aligned}\mathbf{T}_l &= \frac{19{\cdot}1 \times \sigma}{4} \\ &= 4{\cdot}8\sigma\end{aligned}$$

Hence with the previously assumed slip of 4 per cent

$$\mathbf{T}_d = 19{\cdot}1 \text{ lb.-ft.}$$

The speed attained when the torque has reached this value is 96 per cent of Ω, namely 1 440 r.p.m. Hence power of the damping winding at this instant

$$\begin{aligned}&= \frac{2\pi \times 1\,440 \times 19{\cdot}1}{33\,000} \text{ h.p.} \\ &= 5{\cdot}25 \text{ h.p., or } 3{\cdot}91 \text{ kW}\end{aligned}$$

The mean power will then be approximately one-half of this, say 2 kW. This is so very small compared with the power given up by the decelerating armature that we can conclude that while the short-circuit is taking place the effect of the damping winding on the operation of the machine is quite negligible. On the other hand its effect on holding the machine in step after the fault has been cleared is very important, and it is obvious that the greater the degree of damping the greater can be the velocity at any given angular position which can be brought to zero before the position of instability is reached. This point is considered in the next section.

The power corresponding to the synchronizing torque is even smaller than that due to the damping torque. We have

$$\begin{aligned}\mathbf{T}_s &= \mathbf{T}_m \sin\theta \\ &= \mathbf{T}_m\theta \text{ for small values of } \theta \\ &= 41{\cdot}2 \times \theta \text{ ft.-lb. units.}\end{aligned}$$

For the previously assumed values of $\delta\Omega = 6{\cdot}3$ radians per sec., and $\delta t = 0{\cdot}015$ sec., the displacement at the end of the interval will be approximately

$$\begin{aligned}\tfrac{1}{2}\delta t \times \delta\Omega &= \tfrac{1}{2} \times 0{\cdot}015 \times 6{\cdot}3 \\ &= 0{\cdot}047 \text{ mechanical radian} \\ &= 0{\cdot}094 \text{ electrical radian}\end{aligned}$$

in the case of a 4-pole machine.

$$\begin{aligned}\therefore \mathbf{T}_s &= 41{\cdot}2 \times 0{\cdot}094 \\ &= 3{\cdot}87 \text{ lb.-ft.}\end{aligned}$$

Power due to this torque

$$\begin{aligned}&= \frac{2\pi \times 1\,440 \times 3{\cdot}87}{33\,000} \\ &= 1{\cdot}065 \text{ h.p., or } 0{\cdot}8 \text{ kW}\end{aligned}$$

The synchronizing torque will, of course, continue to increase, after the instant the short-circuit is cleared, up to the displacement $\theta = 90°$ provided the inertia of the armature carries the displacement so far, but the asynchronous torque will begin to decrease from the same instant, since the slip velocity will decrease.

The above calculations are approximately correct, since in an actual machine θ does not reach large values, and they are valuable because they indicate in a simple manner the relative magnitudes of the quantities involved.

C. *Motion after Removal of Short-Circuits.*—The next step is to determine whether the velocity is such that the machine will fall out of step, in spite of the fault having been cleared before an angular displacement of $\theta = 180°$ is attained. Suppose the fault is cleared at the instant the displacement is equal to θ'', then the angular velocity attained at this instant must be such that the velocity must fall to zero at some further angular position situated between $\theta = \theta''$ and $\theta = 180°$. Now after the fault is cleared, the motion of the convertor when the damping is light is similar to that of a pendulum swinging through a large arc, and the critical case will be defined by the motion of the pendulum which just makes whole revolutions, i.e. the angular velocity of which is zero at the position $\theta = 180°$. Again, for a pendulum swinging under such conditions the linear peripheral velocity at any position is equal to the velocity which would be attained by the bob if it were allowed to fall freely under gravity through a height equal to the vertical distance between the position $\theta = 180°$ and the position in question. Thus for a simple pendulum of length l if the bob is at any angular position θ this height is

$$h = l(1 + \cos\theta)$$

Hence the peripheral velocity is

$$\begin{aligned}v &= \sqrt{[2gh]} \\ &= \sqrt{[2gl(1 + \cos\theta)]}\end{aligned}$$

The angular velocity is therefore

$$\frac{d\theta}{dt} = \frac{v}{l} = \sqrt{\left[\frac{2g(1 + \cos\theta)}{l}\right]}$$

In the case of the rotary convertor, the equation of free oscillations is

$$\frac{\mathbf{I}}{p} \cdot \frac{d^2\theta}{dt^2} = -\mathbf{T}_m \sin\theta$$

and comparing this with the equation of motion of a simple pendulum of length l we see that the length of the simple equivalent pendulum is given by

$$l = \frac{\mathbf{I}g}{\mathbf{T}_m p}$$

(Note that $\mathbf{I}$ is now in ft.-lb. units.)

Hence the critical angular velocity at any position θ is given by

$$\left(\frac{d\theta}{dt}\right)_{max.} = \sqrt{\left[\frac{2(1 + \cos\theta) \times \mathbf{T_m}p}{\mathbf{I}}\right]}$$

If the velocity attained at the moment of the clearing of the fault is less than the above, then the machine will remain in step, while if it is greater it will fall out of step. For the machine under investigation this critical velocity reduces to

$$\left(\frac{d\theta}{dt}\right)_{max.} = 3{\cdot}91\sqrt{[1 + \cos\theta]}$$

It is plotted against θ in Fig. 10.

The case of a heavily damped machine is more difficult and it cannot be solved in the above manner. With finite damping the equation of free oscillation is

$$\mathbf{T_m}\sin\theta + \frac{\rho\mathbf{T_m}}{p\omega}\cdot\frac{d\theta}{dt} + \frac{\mathbf{I}}{p}\cdot\frac{d^2\theta}{dt^2} = 0$$

which can be written in the form

$$\sin\theta + c\cdot\frac{d\theta}{dt} + d\cdot\frac{d^2\theta}{dt^2} = 0$$

By putting $y = d\theta/dt$ this can be transformed in the usual way into the following differential equation of the first order:—

$$\sin\theta + cy + d\,.\,y\frac{dy}{d\theta} = 0$$

or

$$\frac{dy}{d\theta} = -\frac{\sin\theta}{d\,.\,y} - \frac{c}{d}$$

The method of solution by taking increments of θ has already been given in detail by Carr and the present author, and it is, therefore, unnecessary to give it again.

D. *Experimental Results* (*undamped*).—In order to verify the above theory the rotary convertor was subjected to a series of short-duration short-circuits of graded severity, the extent of the phase-swing being determined by the stroboscopic method, and the energy fed into the short-circuit being calculated from oscillograph records of the current and voltage on the d.c. side. In the case of a large commercial machine it is usual to carry out such short-circuit tests by means of a quick-acting circuit breaker, but in the present case this was quite out of the question and fuses were used instead. In fact it is probable that fuses were preferable to a circuit breaker, since it is very doubtful whether a breaker would give consistent results in a series of tests. On the other hand, fuses were found to be exceptionally consistent, the amount of the phase-swing on closing the circuit through a given low resistance and a fuse of given size being practically the same each time the test was made, the fuse being placed inside a large box so as to exclude draughts.

It was found that for these experiments the use of a stroboscopic disc driven by a synchronous motor was inadmissible because the reaction of the rotary convertor on the alternator caused a momentary swinging in this motor, which gave a false reading. This was overcome by using a Crompton-Robertson electrically driven tuning-fork and projecting the light from a lantern through the slots on to a disc mounted on the shaft of the convertor. A scale was placed behind this disc so that the position of the pattern could be easily read off. The difficulty presented by this method was that of holding the alternator speed absolutely constant; in fact it was impossible to do this, but if all the machines had been running on steady load for several hours before carrying out the tests, conditions had then become so constant that it was possible to hold the speed steady while making a test. Only those observations were recorded for which the pattern on the disc remained stationary after the blowing of the fuse; if the pattern rotated slowly, as sometimes happened, especially with the large fuses, the observation was rejected.

The current and voltage records were taken on cinematograph film by means of a Duddell two-element oscillograph, and, since the speed of the film had to be known in order that the energy in the short-circuit could be calculated, it was necessary to arrange for a timing ripple in addition. This was done by controlling the current vibrator with a two-pole throw-over switch by means of which this vibrator could be connected to a low-voltage supply of known frequency both just before and just after the test. Since it is possible that others may wish to carry out similar tests a diagram of connections is given in Fig. 11. This should be self-explanatory.

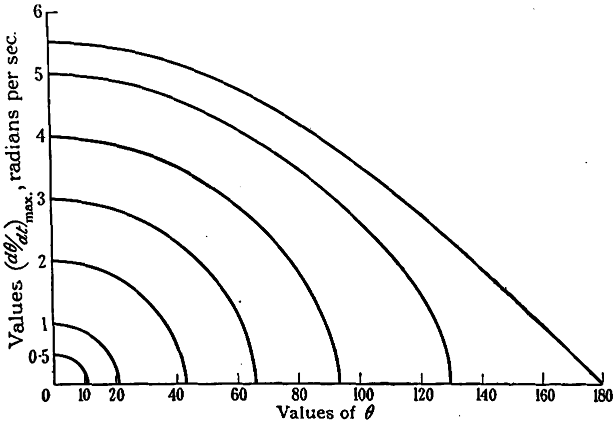

FIG. 10.—Curves of maximum angular velocity for the test machine to remain in step.

The voltage records verified a phenomenon which is of very great importance in connection with the breaking of the circuit of an overloaded rotary convertor, i.e. that if the cut-off is too rapid the self-induction of the circuit will set up an e.m.f. which may cause the e.m.f. across the brushes to become much larger than the normal machine voltage, and a rise in pressure with its attendant risk of breakdown may therefore be set up by the very appliance which is installed to do away with this risk.*

The rise of current will follow approximately the exponential law

$$i = \text{const.} \times (1 - e^{-at})$$

* See also R. TOWNEND: "1 500-Volt, 50-Cycle Traction Rotary-Convertor Equipments," *Metropolitan-Vickers Gazette*, 1927, vol. 10, p. 184.

and the decay of current, if over-voltages are to be prevented, should obey the complementary law

$$i = \text{const.} \times e^{-at}$$

If the decay of current is greater than that given by the above law, e.g. by the blowing of a fuse with explosive violence, or the operation of a quick-acting circuit breaker with too rapid a break, then rises of pressure of possibly serious proportions may be set up.

In the experimental observations on the small rotary convertor there were a good many cases in which the above phenomenon masked the true drop in voltage due to the ordinary working characteristics of the machine, and therefore when calculating the output of the machine during any particular test the voltage corresponding to a steady current equal to the mean current was taken.

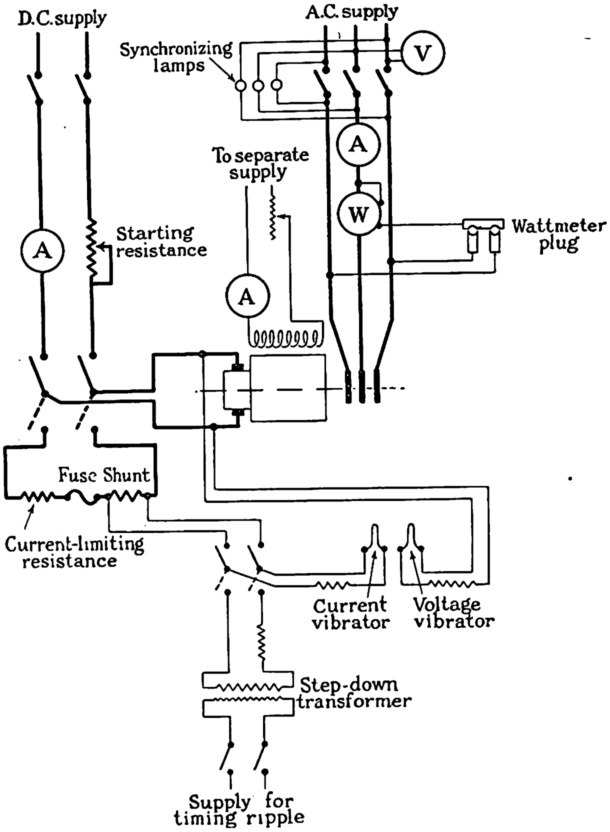

FIG. 11.—Connections for short-circuit tests.

The current and voltage curves were projected by means of a lantern on to a screen so as to give a magnified image, and were then re-drawn on squared paper so that the change in the output over the short-circuit period could be calculated and the mean output then determined. Suppose that this mean output is W_s watts, then, since the power of the machine corresponding to its pull-out torque is 2 710 watts per phase, or

$$3 \times 2\ 710 = 8\ 130 \text{ watts altogether,}$$

the corresponding value of ρ is

$$\rho = \frac{T_l}{T_m} = \frac{W_s}{8\ 130}$$

TABLE 3.

Fuse	Total rotor displacement on short-circuit (4 observations)	Duration of short-circuit	Maximum value of short-circuit current	Mean value as determined from oscillogram	Mean value of d.c. voltage during short-circuit	Mean output	Mean armature I^2R loss	Mean power during short-circuit	ρ	Displacement attained at moment of clearing, electrical degrees	Velocity attained at moment of clearing, electrical radians per sec. In the application of the previous analysis it was assumed that the actual short-circuit was equivalent to this average ρ applied for the whole time of the short-circuit, as determined from the oscillograms. Altogether, tests were made with 12 different sizes of fuse, the results obtained being given in Table 3.

E. *Types of Deceleration Laws* (*undamped*).—The next step was to determine whether the mean or some other value of the current should be adopted, and to investigate the errors involved in the various possible assumptions. An examination of the current oscillograms shows that where the time of short-circuit is very short the current curve is roughly in the form of a triangle, whereas when the time is relatively long the curve is rectangular. With the latter form it is sufficiently accurate to determine the area under the curve and to take the average height as being the magnitude of the absolutely steady current which produces the same effect in the same time. With the triangular shape this may not be permissible, and it may be necessary to adopt some more accurate method. This is especially important in view of the fact that the short-circuits of commercial machines are almost invariably of this form.

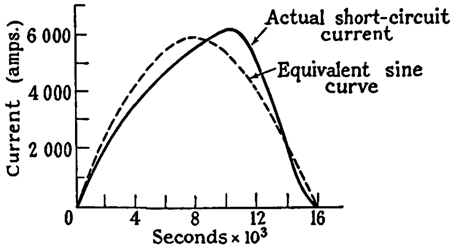

FIG. 12.—Short-circuit current of large machine.

In a paper entitled "The Generating Effect in Rotary Convertors on Short-Circuit"* the actual curve is replaced by the equivalent sine curve, and for the example given there the sine curve fits the actual curve reasonably closely. Adopting this approximation, we can write

$$\mathbf{T}_1 = m \times \mathbf{T}_1' \sin pt$$

where $\mathbf{T}_1'$ = max. value of load torque corresponding to the max. current in the equivalent sine curve,

$p = 180/T$, where T = duration of short-circuit,

m = ratio of terminal voltage during short-circuit to the no-load voltage. This correction is necessary since there is a very appreciable voltage-drop, especially if the convertor is used with a transformer, as is generally the case.

In the mechanical model of the slip motion we can, therefore, assume that the suspended weight is allowed to act for a time T seconds, and that its magnitude varies according to the above sinusoidal law. Again, since T is very short for those cases which admit of this method of treatment we can neglect the effects of both synchronizing and damping torques, and assume that the disc is acted on only by the torque $\mathbf{T}_1$. In order to investigate the degree of the error made by replacing an actual current curve by some simple equivalent form amenable to mathematical analysis, consider the curve of Fig. 12 which is taken from the article in the *Brown Boveri Review* quoted above.

Neglecting all torques but that due to the load, the equation of motion becomes

$$\frac{\mathbf{I}}{p} \cdot \frac{d^2\theta}{dt^2} = \phi(t)$$

or $$\frac{d^2\theta}{dt^2} = F(t)$$

since in a comparison of this kind it is not necessary to insert the constants of the machine, and values of $d\theta/dt$ and θ in arbitrary units are sufficient.

(1) Use the equivalent sine curve.

Then $$F(t) = 5\,950 \sin\left(\frac{\pi}{0 \cdot 016} \times t\right)$$

$$\therefore \frac{d^2\theta}{dt^2} = +\,5\,950 \sin (196t)$$

At the end of short-circuit, $t = 0 \cdot 016$.

$$\therefore \frac{d\theta}{dt} = 30 \cdot 4(1 - \cos \pi) = 60 \cdot 8 \text{ arbitrary units}$$

$$\theta = -\,0 \cdot 155 \sin \pi + 0 \cdot 486 = 0 \cdot 486 \text{ arbitrary units}$$

(2) Use the equivalent constant current.

Its value will be the mean height of the short-circuit current curve, namely 3 800.

$$\therefore \frac{d^2\theta}{dt^2} = 3\,800$$

Hence at the end of short-circuit, when $t = 0 \cdot 016$

$$\frac{d\theta}{dt} = 3\,800 \times 0 \cdot 016 = 60 \cdot 9$$

$$\theta = 1\,900 \times 0 \cdot 000256 = 0 \cdot 486$$

(3) Use the equivalent linear current curve.

Its peak value will be $2 \times 3\,800 = 7\,600$ amperes, so that

$$\frac{d^2\theta}{dt^2} = 7\,600 \times \frac{t}{0 \cdot 016} = 475\,000t$$

Hence at the end of short-circuit, when $t = 0 \cdot 016$

$$\frac{d\theta}{dt} = 288\,000 \times (0 \cdot 016)^2 = 74 \text{ arbitrary units}$$

$$\theta = 0 \cdot 394 \text{ arbitrary units}$$

(4) Use the actual current curve or a more accurate equation.

It is possible to proceed by a step-by-step method or to find two curves which fit the curve closely. The former method is laborious, and therefore the latter method is here adopted, especially as it is possible to make a very close approximation to the actual curve. The first part of the curve is obviously that of the rise of current in an inductive circuit, so that the equation is

$$i = \mathbf{I}(1 - e^{-at})$$

---

* *Brown Boveri Review*, 1924, vol. 11, p. 9.

From the curve we have

$$i = 4\,350 \quad \text{when} \quad t = 0\cdot005$$

and $$i = 6\,170 \quad \text{when} \quad t = 0\cdot01$$

$$\therefore \frac{6\,170}{4\,350} = \frac{1 - e^{-0\cdot01a}}{1 - e^{-0\cdot005a}}$$

$$1\cdot42 = 1 + e^{-0\cdot005a}$$

$$\therefore a = 174 \quad \text{and} \quad \mathbf{I} = 7\,500$$

As a check, if the above constants are correct, the current should be 0·6321 × 7 500, namely 4 741 amperes in 1/174 or 0·00575 sec. This point is actually on the curve, showing that the first part of the curve is fitted exactly by the equation for i. This portion holds from $t = 0$ to $t = 0\cdot0105$, the current then having risen to 6 250 amperes. It is sufficient to take the second part as being a straight line, falling from $i = 6\,250$ at $t = 0\cdot0105$, to $i = 0$ at $t = 0\cdot016$, since this will be more accurate than another exponential curve, owing to the inflection in the actual curve.

The calculation of $d\theta/dt$ and θ at the end of short-circuit is made in two parts as follows, the first of which is strictly accurate, while the second is approximate with a probable error of negligible order.

$$\frac{d^2\theta}{dt^2} = 7\,500(1 - e^{174t})$$

$$\frac{d\theta}{dt} = 7\,500t + \frac{7\,500}{174}e^{-174t} + A$$

and $$\theta = 3\,750t^2 - \frac{7\,500}{174^2}e^{-174t} + At + B$$

when $t = 0$, $d\theta/dt = 0$, and $\theta = 0$.

$$\therefore A = -43\cdot0, \quad \text{and} \quad B = 0\cdot248$$

∴ $d\theta/dt = 42\cdot75$ arbitrary units, $\theta = 0\cdot17$ arbitrary units, at the end of the first step.

Take $t = 0$ at the commencement of the decay of the current. Then

$$\frac{d^2\theta}{dt^2} = 6\,250 - \frac{6\,250}{0\cdot0055} \times t$$

$$\frac{d\theta}{dt} = 6\,250t - 568\,750t^2 + A$$

$$\theta = 3\,125t^2 - 189\,600t^3 + At + B$$

when $t = 0$, $d\theta/dt = 42\cdot75$, and $\theta = 0\cdot17$.

$$\therefore A = 42\cdot75 \quad \text{and} \quad B = 0\cdot17$$

Hence when the current has finally died down to zero, $t = 0\cdot0055$.

$$\therefore \frac{d\theta}{dt} = 59\cdot8 \text{ arbitrary units}$$

$$\theta = 0\cdot493 \text{ arbitrary units}$$

A check by the step-by-step method gave almost identical results. These values are given in Table 4.

TABLE 4.

$F(t)$	$d\theta/dt$	θ	Percentage error in $d\theta/dt$	Percentage error in θ
1. Sinusoidal	60·8	0·486	1·7 % high	1·4 % low
2. Constant	60·9	0·486	1·85 % high	1·4 % low
3. Linear	74·0	0·394	23·75 % high	20 % low
4. Combination of exponential and linear	59·8	0·493	—	—

It will be seen that for the particular short-circuit current curve investigated there is very little to choose between the various functions, except No. 3, which has a considerable error. Nos. 1 and 2 give slightly high values for $d\theta/dt$ and slightly low values for θ, with the result that if they are used in the determination of the motion subsequent to the clearing of the short-circuit, the errors in this calculated motion will be even less than those tabulated. This is because after clearing, $d\theta/dt$ diminishes with increase in θ. It thus follows that the error will be very small if either the first or the second function is used. The table shows very clearly that the effect on the machine depends not only on the energy in the short-circuit, which was the same in all four cases, but also on the shape of the current curve, and that this should be determined very carefully, particularly if the time taken to decay to zero is a very short fraction of the whole period of short-circuit, as is sometimes the case, since then the curve more closely approximates to the linear function of t than to either No. 1 or No. 2.

In working out the displacement from the oscillograms it will be seen from Table 3 that the average value of the current has been taken, and this value has been assumed to be operative throughout the whole of the short-circuit period. This average value was determined by means of a planimeter from the enlarged curves which are reproduced in Fig. 13. Also a correction for the change in voltage on the d.c. side was, as explained previously, made when calculating the values of ρ. The total displacement which, according to the above theory, should have taken place during each test is worked out in two steps, the second step corresponding to the continued movement following the clearing of the short-circuit, requiring the use of the curves given in Fig. 10. It will also be seen that the values of ρ are, with one exception, all less than unity although all corresponded to an overload. This was necessary because of the small size of the machine under test, coupled with the ease with which it could fall out of step owing to its very small damping.

On comparing the calculated with the observed deflections it will be seen that both are of the same order, which is, perhaps, as much as could be expected from such an investigation. For the small deflections the calculated values are on the small side, while for large deflections the reverse is the case. This is to be expected since, although damping has no appreciable effect so long as the deflection is small, it does have some effect on the magnitude of a large displacement following a severe short-circuit, even though the damping is small as in the present case. Thus in tests 11 and 12 the calculated velocities indicate that the machine should fall out of step because the velocities obtained are greater than the critical velocity for the absolutely undamped machine, namely 5·52 electrical radians per second. Actually, owing to the existence of finite damping the machine showed no indication of falling out of step no matter how many times the fuse corresponding to test 11 was blown, but during test 12 it did fall out of step on several occasions, showing that the velocity attained at the moment of clearing the short-circuit was just about the same as the critical value for that particular angular position of the armature. In Table 3 the figures underlined in col. 2 are the displacements actually observed when the oscillograms were taken: the other figures are displacements observed on blowing the same size of fuse wire, no oscillograms being taken. It will be seen that the method gave quite consistent results.

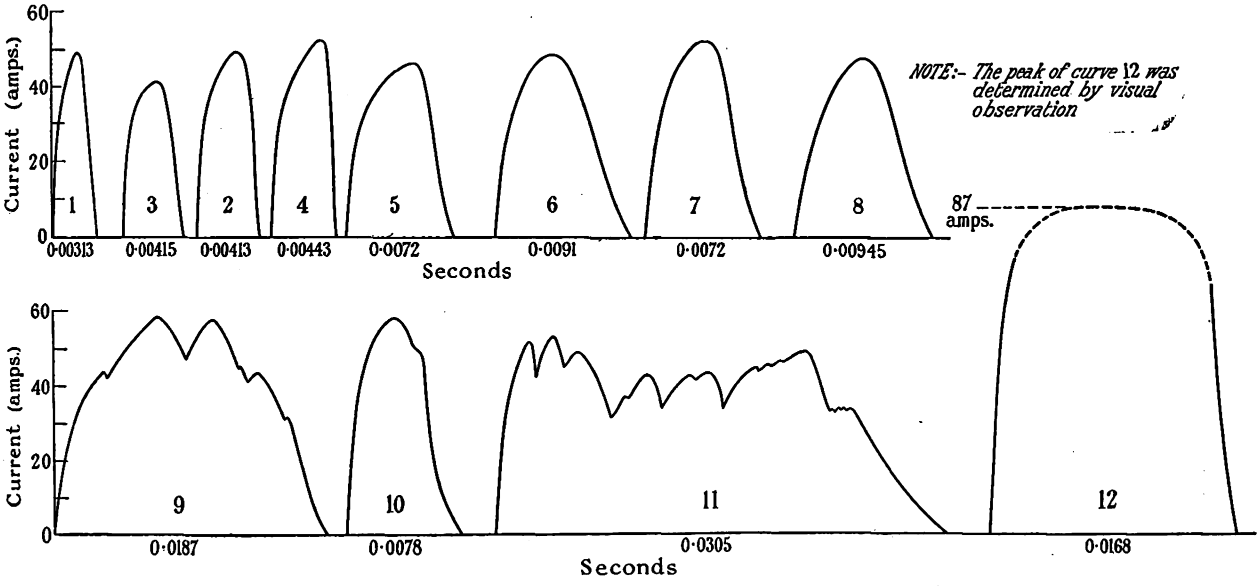

FIG. 13.—Short-circuit currents with small experimental machine.

(6) MOTION OF A DAMPED ROTARY CONVERTOR.

Further Considerations.—The equation of damped motion is

$$\frac{d^2\theta}{dt^2} + k\frac{d\theta}{dt} + \mu\theta = 0$$

and for critical damping we have the well-known relationship

$$k^2 = 4\mu$$

or

$$k = 2\sqrt{\mu}$$

Since $\mu = 245$, the value of k for critical damping is

$$k = 2\sqrt{245} = 31\cdot 3$$

It is doubtful whether the damping in an actual machine can ever be equal to the critical value, and a more representative value of k will be considerably less than the above. The value of 20 has, therefore, been taken so that the equation of motion with the machine under load becomes

$$a + b\sin\theta + c\frac{d\theta}{dt} + d\frac{d^2\theta}{dt^2} = 0$$

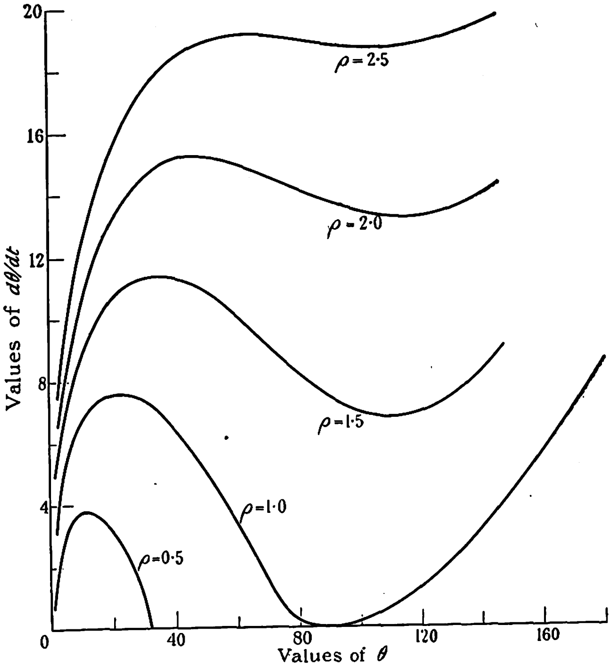

FIG. 14.—Motion of a heavily damped rotary convertor during short-circuit.

where $a = -\rho$
$b = 1{\cdot}0$
$c = k \times d = 20 \times 0{\cdot}0041 = 0{\cdot}082$
$c/d = 20$

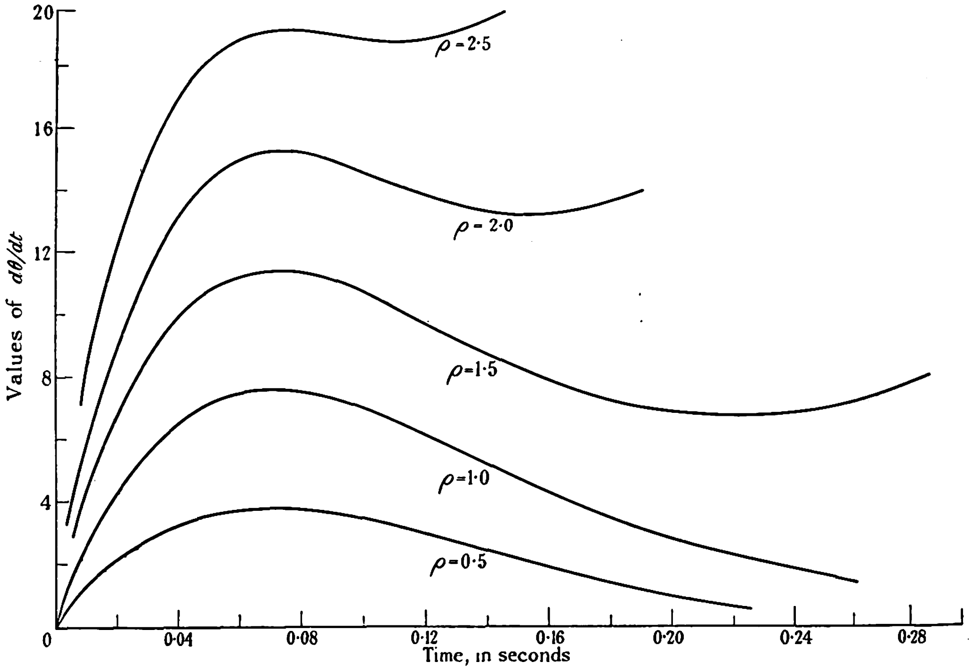

FIG. 15.—Motion of a heavily damped rotary convertor during short-circuit.

The equation with damping can only be solved by the step-by-step method, and the results of the investigation are given in the curves of Figs. 14 and 15. On comparing these curves with those for the same machine without damping (Figs. 16 and 17), it will be seen that for large displacements the damping does limit the displacement as would naturally be expected, but for small displacements produced by a disturbance acting only during a small fraction of a second the damping is practically inoperative since the initial portions of corresponding characteristics are the same both with and without damping. This is a more complete and satisfactory proof of the principle expounded in an elementary manner on page 1002, and it follows that as far as the motion during short-circuit is concerned, that is, not including the continued motion after clearing, it is quite justifiable to neglect the damping, no matter how strong this may be.

The author is glad to make acknowledgments to his colleague Mr. E. W. Golding and to Mr. F. W. Campbell

for assistance in making some of the observations, to Mr. S. A. Swann for assistance with computations, and to the Royal Society for a grant of money with which to purchase certain apparatus.

APPENDIX 1.

A SPECIAL SOLUTION OF THE EQUATION OF MOTION.

If large slip velocities are produced, the criterion for a synchronous machine to be just able to keep in step is that the slip velocity shall be brought to zero at the angular position

$$\theta = \pi - \alpha, \text{ where } \alpha = \arcsin (\mathrm{T_l/T_m})$$

Now the author has found, when making step-by-step solutions of this problem, that the curve of $d\theta/dt$ against θ is very nearly an ellipse. In the limiting case, if ω_0 is the maximum possible slip velocity in mechanical radians per second at the position for the machine just to keep in step, then we can write as a first approximation, putting $\phi = (\pi - \alpha)$,

$$\frac{\theta^2}{\phi^2} + \frac{(d\theta/dt)^2}{\omega_0^2} = 1$$

$$\therefore \left(\frac{d\theta}{dt}\right)^2 = \omega_0^2\left(1 - \frac{\theta^2}{\phi^2}\right)$$

or

$$\frac{d\theta}{dt} = \frac{\omega_0}{\phi}\sqrt{(\phi^2 - \theta^2)}$$

$$\therefore \frac{dt}{d\theta} = \frac{\phi}{\omega_0} \times \frac{1}{\sqrt{(\phi^2 - \theta^2)}}$$

$$\therefore t = \frac{\phi}{\omega_0}\int_0^{\phi}\frac{d\theta}{\sqrt{(\phi^2 - \theta^2)}}$$

$$= \frac{\phi}{\omega_0} \times \frac{\pi}{2}$$

the constant of integration being zero, since when $\theta = 0, t = 0$.

Now this expression for t is the area under the curve of $dt/d\theta$ against θ. It was found that the departure from the pure elliptical form of the curve of $dt/d\theta$ against θ was such that the ratio of the area under the actual curve to the area under the ellipse with the same semi-axes was about 1 to 1·1. Hence a somewhat more correct value for t will be given by taking the ratio of the area under the curve of $dt/d\theta$ to the area under the curve of reciprocals of the ordinates of the ellipse, to be 1·1 to 1. In other words the corrected value for t is

$$t = \frac{\phi}{\omega_0} \times \frac{\pi}{2} \times 1{\cdot}1$$

Now this value of t will be the quarter-period when swinging with an amplitude of 0 to ϕ, plus the quarter-period when swinging from α to ϕ

$$\therefore t = \pi\sqrt{\left(\frac{\mathrm{I}}{\mathrm{T_m}p}\right)} \times k$$

where k is the correction factor for this amplitude.

Equating these two expressions for t, we have

$$\frac{\phi}{\omega_0} \times \frac{1{\cdot}1\pi}{2} = \pi\sqrt{\left(\frac{\mathrm{I}}{\mathrm{T_m}p}\right)} \times k$$

$$\therefore \omega_0 = \frac{1{\cdot}1\phi}{2k \times \sqrt{[\mathrm{I}/(\mathrm{T_m}p)]}}$$

Probably the best illustration of the order of accuracy given by this method is to calculate ω_0 for the data given by Carr * for a synchronous induction motor, namely

$\mathrm{T_m} = 2\,000$ lb.-ft.
$\mathrm{T_l} = 1\,000$ lb.-ft.
$\mathrm{I} = 200$ foot, pound, second, units
$p = 5$

$$\therefore \alpha = \arcsin\frac{1\,000}{2\,000} = 30^\circ$$

and

$$\phi = 150^\circ$$
$$= \frac{150 \times \pi}{180} \text{ radians}$$

k is obviously the mean of the correcting factors for the swing of 0 to α, the position of stable equilibrium, and the factor for the swing from α to ϕ.† The first swing is one of 30°, for which the correcting factor is 1·0174. The second is from 30° to 150°, i.e. 120°, for which the factor is 1·3729. The value of k is therefore

$$k = \frac{1{\cdot}0174 + 1{\cdot}3729}{2}$$
$$= 1{\cdot}195$$

Hence, finally,

$$\omega_0 = \frac{1{\cdot}1 \times 150\pi/180}{2 \times 1{\cdot}195 \times \sqrt{[200/(2\,000 \times 5)]}}$$
$$= 8{\cdot}5$$

as against 8·58 when calculated by the step-by-step method. The agreement is sufficiently close to show that, unless extreme accuracy is required, the above solution of this special problem is sufficient for most purposes, especially as the calculation can be made in a few moments as against an hour or more by the step-by-step method. Also it should be noted that if the motion is such that the curve of $dt/d\theta$ against θ becomes very steep, it is necessary to take very small intervals of θ when using the step-by-step method, otherwise very appreciable errors may be made, and this renders the method extremely laborious.

APPENDIX 2.

The equation for θ can be written

$$\theta = ae^{-kt}\cos nt$$

$$\therefore \theta = \text{Real part of } (ae^{-kt+jnt})$$

$$\therefore \frac{d\theta}{dt} = \text{Real part of } \left\{(-k + jn)ae^{-(k+jn)t}\right\}$$

$$= \text{Real part of } \left\{(-k + jn)ae^{-kt}e^{jnt}\right\}$$

$$= ae^{-kt}\left[\text{Real part of } (-k + jn)(\cos nt + j\sin nt)\right]$$

$$= ae^{-kt}(-k\cos nt + n\sin nt)$$

$$= \frac{a}{\sqrt{(k^2 + n^2)}} \cdot e^{-kt}\cos(nt - \epsilon)$$

where $\tan\epsilon = k/n$.

---

* *Loc. cit.*

† This is not rigorously correct, as the motion is not exactly sinusoidal, but the error introduced will be very small.

THE PRODUCTION OF UNIFORM ILLUMINATION OVER LARGE AREAS.*

By H. R. S. McWhirter, B.Sc.(Eng.), Associate Member.

(*Paper first received* 18*th November*, 1929, *and in final form* 15*th January*, 1930.)

Summary.

It is shown that when planning a lighting system for a large "working plane," using the standardized industrial reflector (B.S.S. No. 232—1926), it is better to place the lamps over the centres of certain contiguous rhombuses than over the centres of contiguous squares of equal area. A new definition is proposed for the term "spacing ratio." A convenient method of drawing isolux diagrams is described and such diagrams are given for the above-mentioned standardized reflector at a spacing ratio of 1·5. It is shown how uniformity of illumination varies with spacing ratio with the above reflector. A plea is made that manufacturers of other reflectors should publish similar information relating to their goods. Finally, some brief practical rules for designers of electrical lighting systems are given, from whose point of view the paper has been written.

Introduction.

There is a widespread belief among engineers, fostered by statements in certain reference books and pamphlets, that to provide the most uniform illumination over a large working plane with a given number of lighting units (i.e. lamps and reflectors) it is best to divide the plane into squares and suspend a unit over the centre of each square. This belief is shown in the paper to be erroneous, and a more correct theory is developed.

When the positions of lighting units are fixed, the present method of fixing their height is to rely on a statement of the reflector manufacturers, that the "spacing ratio" must not exceed a certain maximum. This ratio is taken to be

$$\frac{\text{(Distance apart of lamps)}}{\text{(Height above working plane)}}$$

and for various industrial reflectors it varies between 1 and 2.

The inadequacy of this definition of spacing ratio and of this method of fixing the height of the lamps is shown in the paper, and more satisfactory methods are given.

The subject is dealt with under the following headings:—

(1) General discussion.
(2) Practical rules for the design of electric lighting systems.

(1) General Discussion.

The case considered will be that of a large horizontal plane divided into a number of equal areas of the same shape, which completely cover the plane but do not overlap, the plane being illuminated by direct lighting units suspended one over the geometrical centre of each area, the lighting units being similar to each other in all respects.

If the plane is sufficiently large the distribution of illumination over each area will, in the cases to be discussed, be sensibly the same, except for those areas around the borders of the plane. Neglecting the latter areas for the time being, and assuming that no light is reflected on to the plane from the ceiling, the average illumination over each area will be equal to the lumens emitted in the lower hemisphere by one lighting unit, divided by the value of the area in square feet. The result so obtained will be in foot-candles.

The ratio of the minimum illumination occurring in each such area, to the average, will be referred to in the paper as α. The ratio of the maximum illumination to the average will be referred to as β. Clearly α must be less than unity and β greater than unity.

The values of α and β will depend on the value of each area in square feet, the mounting height of the units in feet, the shape of their polar distribution curve and the geometrical shape of the areas. If, however, the term "spacing ratio" is defined as

$$\frac{\sqrt{\text{(Area under each unit)}}}{\text{Mounting height of unit}}$$

then the values of α and β will depend on only three variables, viz. spacing ratio, the shape of the polar distribution curve of the units, and the geometrical shape of the areas. Hereinafter the term "spacing ratio" will be assumed to be defined as above.

This proposed definition coincides with the generally accepted one (see Introduction) when the units are suspended over squares. The latter definition, however, suffers from the disadvantage that when the lamps are not over squares it is often ambiguous, as the distance between lamps in one direction is greater than the distance between them in another direction.

For a given reflector and spacing ratio, therefore, α and β depend only on the geometrical shape of the area. It is necessary to ascertain what shape of area will make α as high as possible.

The total illumination on an area under one unit is due partly to the unit above it and partly to all the other units. As the spacing ratio is increased, however, the illumination due to the lighting unit above the area becomes an increasingly great proportion of the whole. Assuming that the polar distribution curve of a unit is the same in every plane through the vertical axis of the unit, it is to be expected that, at least for high values of spacing ratio, a would be highest when the area was the nearest possible approximation to a circle.

---

* The Papers Committee invite written communications, with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

A plane, however, cannot be divided into circles which completely cover it without overlapping; the nearest approximation to a circle that can be used is the hexagon. It is therefore to be expected that this shape of area would make a as high as possible.

Fig. 1 shows in small circles the positions of units hung over the centres of hexagons. Three contiguous hexagons are shown in dotted lines on the left of the figure, while on the right are shown four contiguous rhombuses. When they divide the plane into hexagons the lighting units also incidentally divide it into rhombuses of which the acute angle is 60°.

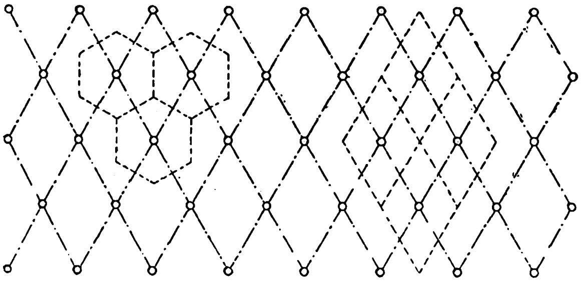

FIG. 1.

The square, however, is only a particular case of the rhombus in which the angle is 90°; and if the value of a is a maximum when the angle of the rhombus is 60° it must be less when the angle is 90°, and there must be another value for the angle, less than 60°, for which the value of a would be equal to that corresponding to 90°. This angle of less than 60° will be referred to as the "critical angle" and the ratio (Major diagonal)/(Minor diagonal) for the rhombus corresponding to it will be referred to as the "critical ratio." The critical ratio is thus equal to the cotangent of half the critical angle. It is desirable to introduce this ratio because in designing lighting systems it is easier to deal with than the angle.

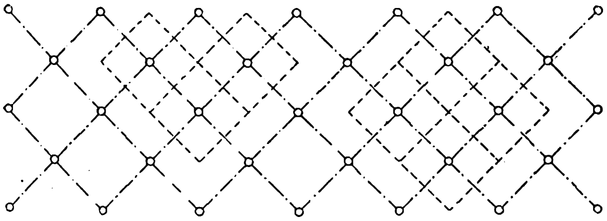

FIG. 2.

If the plane is divided into rhombuses the ratio of whose diagonals is less than the critical ratio but greater than unity, the value of a will be greater than if it is divided into squares of equal area.

Fig. 2 shows a plane divided into squares, and Fig. 3 shows a plane divided into 45° rhombuses, the areas in each case being the same as that of the 60° rhombuses in Fig. 1.

It is interesting to note how the dotted areas in the left of the three figures coalesce into each other as the angle of the rhombus changes. These areas on the left differ from the rhombuses in that they are cyclic, and form the closest approximation to a circle that the respective arrangement of points permits. It is necessary, however, to refer mostly to the rhombuses, in preference to referring to the areas on the left, because in designing lighting systems it is simpler to deal with rhombuses.

The above conclusions can be made of practical use by referring to the lighting distribution curve of what is probably the most widely used reflector in industrial lighting, namely that standardized in B.S.S. No. 232—1926 entitled "Industrial Reflector Fittings for Electrical Lighting (No. 1)." Particulars of this fitting may be obtained from the Specification and from Technical Paper No. 3 of the Department of Scientific and Industrial Research entitled "Light Distribution from Industrial Reflector Fitting No. 1." This latter paper is obtainable at H.M. Stationery Office.

For those unfamiliar with this reflector it may be stated that it is an all-metal bowl fitting, enamelled white inside, and so arranged that the rim of the bowl cuts off all direct light from the filament at an angle of 20° below the horizontal. According to the specification the efficiency of this reflector must not be less than 60 per cent.

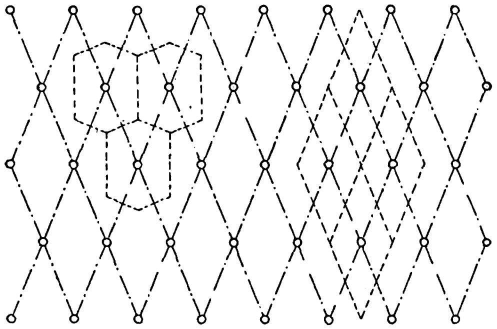

FIG. 3.

In the technical paper referred to, the contour of the reflector and its average polar distribution curve are given. These are reproduced, by kind permission of the Controller of H.M. Stationery Office, as Figs. 4 and 5.

By using a modification of Rousseau's method on Fig. 5 it was found that the mean spherical candle-power of a unit with this polar distribution curve would be 1/4·5 times the radius vector vertically downwards. The reflector efficiency being 60 per cent, it is clear that when a lamp is placed in one of these reflectors the candle-power of the combination vertically downwards is 2·7 times the mean spherical candle-power of the lamp alone. It is stated in the above-mentioned technical paper that the ratio of tip-end candle-power to mean spherical candle-power of ring-filament gas-filled lamps is about 1·25. Therefore when such a lamp is placed in its appropriate reflector of the above type the candle-power in the direction of the tip-end of the lamp is increased in the ratio of 2·16.

The mean spherical candle-power of any standard gas-filled lamp may be obtained from B.S.S. No. 161—

1928, and as the candle-power vertically under such a amp when placed in the appropriate standard reflector may be found by multiplying this by 2·7, the candle-power in any other direction from the combined lamp and reflector may be found by making use of the curve of polar distribution, Fig. 5.

If any number of such lighting units are suspended over a plane the illumination at any point may be found by adding together the illumination at that point due to each lamp taken separately.

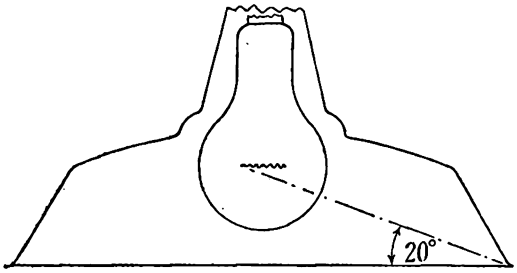

Fig. 4.

If a large number of such calculations are to be made, it is useful to proceed as follows: Lay out on a plan the positions of the units to a suitable scale, and mark on it the point at which the value of illumination is required. Draw, to the same scale on tracing paper, the isolux diagram for one unit, which will consist of a system of concentric circles. Place the centre of the diagram over the point on the plan at which the illumination value is required. For each lighting unit on the plan which falls within the diagram, there will correspond an illumination value which can be read off from the diagram. Add these values together, and the sum will give the total illumination value at the point in question.

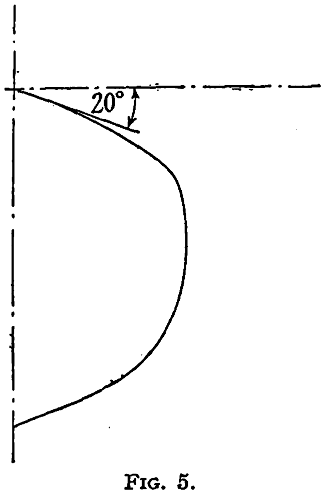

Fig. 5.

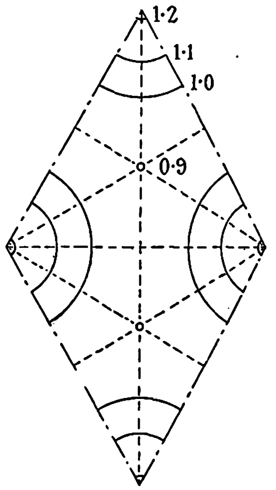
By using such a method the author found the value of α for these reflectors when used at a spacing ratio of 1·5 (which is the value quoted in the Standard Specification). When the lamps were placed in squares the value was 0·85. When the lamps were placed in rhombuses the value rose to a maximum of 0·9 when the acute angle of the rhombus diminished to 60°, and then decreased until when the angle of the rhombus was 45° the value of α was again 0·85. This, therefore, is the critical angle for the standard reflector when used at a spacing ratio of 1·5. The corresponding critical ratio is 2·414.

The rhombuses in Fig. 3 have an acute angle of 45°. Therefore the lay-outs of lighting units in Figs. 2 and 3 will give the same average illumination, and the same minimum illumination, if the standard reflector at a spacing ratio of 1·5 is used. If the angle of the rhombus is made intermediate between 45° and 90°, the illumination will be better, i.e. the value of α will be higher.

In making these calculations it was assumed that minimum illumination occurred at the corners of the dotted areas on the left of Figs. 1, 2 and 3.

There is no difficulty in showing that in this reflector the "critical ratio" varies with the spacing ratio. As the light is cut off at 20° below the horizontal, the minimum illumination is zero when the lamps are placed in squares at a spacing ratio of 3·89. Consideration shows that the critical angle for this spacing ratio is the apex angle of that isosceles triangle which, while not being a right-angled triangle, has the same radius of circumscribed circle as an isosceles right-angled triangle of equal area. The corresponding critical ratio is the real root of the equation $x^3 - 3x^2 - x - 1 = 0$, which is approximately 3·383. The critical angle is 32° 56′. That the critical ratio also varies with the shape of the polar distribution curve may be seen from the fact that if the light were cut off at an angle other than 20° below the horizontal, the value of spacing ratio at which the critical ratio is 3·383 would correspondingly vary.

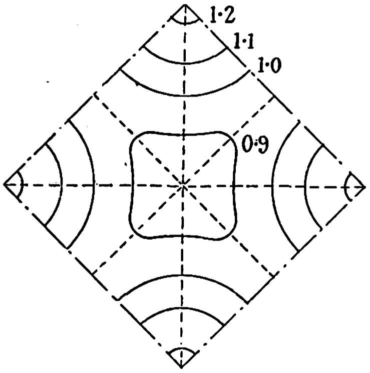


Maximum = 1·213
Minimum = 0·9

Fig. 6.

It would be of interest to have a curve giving the critical ratio for any spacing ratio for this reflector, but owing to the labour involved the author has omitted this. Until such a curve is drawn, however, it is considered that no great error would be made by taking the critical ratio as 2·414 for any value of spacing ratio likely to occur in practice.

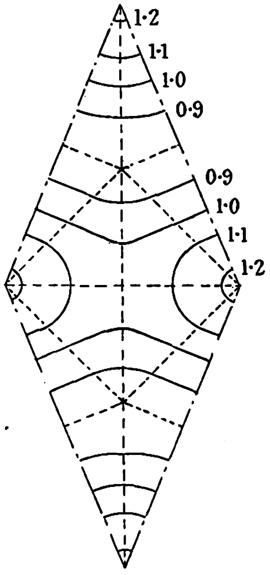
The isolux diagrams corresponding to Figs. 1, 2 and 3 are given in Figs. 6, 7, and 8 respectively. These latter figures represent rhombuses with a lamp (not shown) at each corner taken from the centre of a large number of lamps arranged as in Figs. 1, 2 and 3, respectively, and at a spacing ratio of 1·5. The difference in illumination between adjacent isolux lines is one-tenth of the value of average illumination. The line of average illumination is shown.



Maximum - 1·237
Minimum - 0·85

Fig. 7.

In the case of Fig. 7, the isolux diagram was drawn by plotting a contour illumination curve for half the diagonal, for half the side of the square, and for the line joining the centre of the side to the centre of the square. The points on these curves at which the illumination was equal to 0·9, 1·0, 1·1 and 1·2 times the average were then ascertained and marked on the squares. Suitable curves were then drawn between the points. Similar methods were adopted for Figs. 6 and 8.



Maximum - 1·23
Minimum - 0·85

Fig. 8.

These curves clearly show that there is a large area between lamps at which the illumination varies very little from the minimum value. This emphasizes the importance of knowing the minimum value of illumination as distinct from the average value.

The increase in illumination obtained by dividing the plane into rhombuses instead of squares is not so big as to justify going to great lengths to effect it; but in practice cases are not rare in which the obstructions in a ceiling would favour the use of rhombuses; in such cases it is of value to know that something is gained by not adhering to the use of squares.

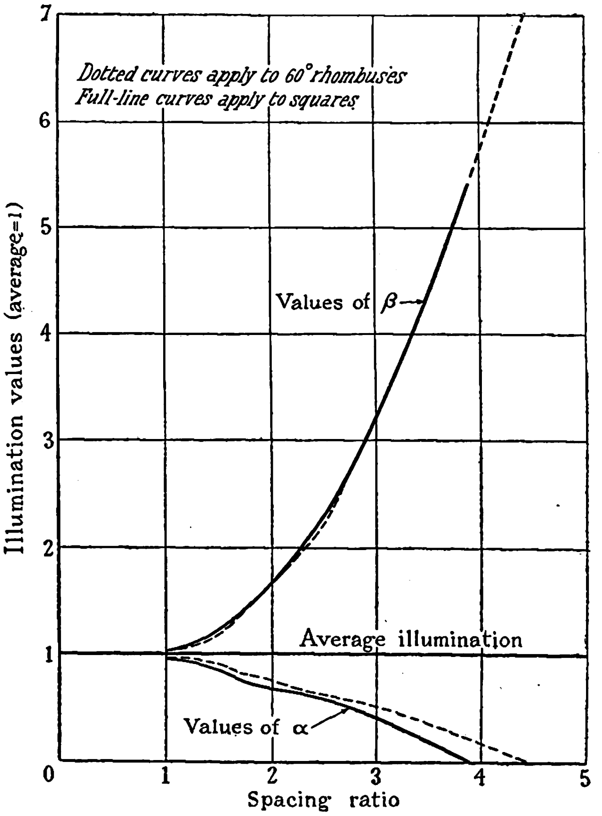


Fig. 9.

It is now necessary to consider how α and β vary with the spacing ratio. Lack of information on this point is one of the most constant sources of annoyance to the designer of lighting systems. A mere statement that a certain value of spacing ratio must not be exceeded is not sufficient in a case where, if it is exceeded by, say, 20 per cent, the number of lamps used can be halved. This would lead to an important economy if it could be safely done, and such cases frequently occur in practice, due to the fixed height of ceilings and disposition of beams, etc., in the ceiling. Hitherto, however, there has not, as far as the author is aware, been any means by which it was possible to ascertain how the values of α and β would be affected by exceeding the prescribed value of spacing ratio.

The curves in Fig. 9 are intended to supply this omission, as far as the standardized industrial reflector is concerned. Values of α and β are plotted as ordinates against values of spacing ratio as abscissæ. The abscissa at unity represents average illumination; the full-line curves apply to the case where the lamps are arranged in squares and the dotted curves apply to the case where they are arranged in 60° rhombuses. The curves below the abscissa at unity represent values of α, and those above it values of β.

It will be seen that for the values of β the dotted curve coincides with the full-line curve for most of its length; but for the values of α the dotted curve is always above the full-line curve.

These curves show that the smaller the spacing ratio the more uniform is the illumination, and they should be of great use to designers in estimating the *minimum* illumination of a proposed system, which, as pointed out above, is quite as important as the average illumination. The curves would be more complete if another curve were added, showing how the critical ratio varied with the spacing ratio. For the ordinates of this additional curve the same scale might be used as is already shown on the vertical axis of Fig. 9. Such a set of curves could be drawn for any direct reflector and would have a very well-defined meaning. They would be of more use than the polar distribution curve, and might be termed the "characteristic curves" of the reflector. It would be very useful if manufacturers would publish such curves relating to their reflectors.

The curves apply to the case in which the plane is divided into squares or rhombuses, but not to the case where it is divided into rectangles, which is frequently found convenient in practice. In such a case, of course, the term "spacing ratio" as defined above has a definite meaning, and the value of α would be less than that given by Fig. 9 for a square at the same spacing ratio. How much less is a matter that could in any particular case be calculated by using the distribution curve in Fig. 5 and the other information given above. This, however, would be somewhat laborious, and an experienced designer could make a guess that would be near enough for practical purposes.

It is necessary now to review the assumptions that have been made and consider how their validity affects the results.

It was assumed, in the first place, that the plane was very large and the portion along the edges, to which the results do not apply, was neglected. This portion, however, increases in area as the spacing ratio is diminished. It would be very laborious to take complete account of this effect, which might be called the "fringe effect." An idea of its magnitude may be gained by considering a very large area covered by lamps arranged in horizontal and vertical rows in squares. Numbering the vertical rows of lamps (starting from the end row) as 1, 2, 3, etc., the value of α between rows 1 and 2 would be equal to that given by Fig. 9, unless the spacing ratio were less than 1·74, in which case α would be less. Similarly the value of α between rows 2 and 3 would be equal to that given by Fig. 9, unless the spacing ratio were less than 1·08. This is about as low a spacing ratio as is likely to occur in practice, so that it will be seen that the effect is not very marked, especially if the end rows of lamps are placed close against the walls, and the latter are of a light colour and reflect the light well.

The whole of the numerical results obtained assumes that all the light on the plane comes direct from the units, none being reflected from the ceiling. This condition obtains with the standard reflector, provided the ceiling is of a dark colour. If it is white, light reflected from the plane may strike the ceiling and be reflected back on to the plane, causing a uniform increase in its illumination at all points. In workshops, however, this may usually be neglected, as such ceilings, if white at first, do not usually remain white after a short period.

The assumption that the polar curve of light distribution is the same in all planes containing the vertical axis of the unit is shown in Technical Paper No. 3 (mentioned above) to be approximately correct. Slight differences are introduced by the fact that the "ring filament" of a lamp has a gap in it, and slight errors in manufacture sometimes result in the axis of the lamp not being quite collinear with the axis of the reflector. Obviously no account can be taken of these factors, and they would not materially affect the result.

The assumption that every unit of the same wattage is identical as regards light output is not exactly true, owing to the tolerance allowed on the output of lamps of the same wattage, and to the fact that variation in efficiency may be shown between individual reflectors. The Standard Specification specifies only a lower limit (60 per cent) for the efficiency of reflectors; therefore if this value were to be used in calculations the results obtained would be slightly on the low side. This, however, should only be by a few per cent. The discrepancies due to these variations of the lamps, however, would be less as the spacing ratio decreased.

Another assumption that has been made is that the light from a unit is completely cut off at 20° below the horizontal. While the light from the filament is so cut off there would still be a very small amount of light emitted above this angle, owing to reflection from the inner surface of the bowl of the fitting. This would also have the effect of making the value of minimum illumination, calculated from the curves of Fig. 9, a trifle on the low side.

The remaining important assumption that has been made is that the unit is a point source of light, and that the inverse-square law holds for light emitted from it. This, of course, is not exactly true for points near the reflector. In an Appendix to the Standard Specification a point-to-point method of measuring the efficiency is described in which it is stated that the distance between the photometer head and the light centre of the lamp shall not be less than 8 times the diameter of the reflector. It is to be presumed, therefore, that at distances greater than this the inverse-square law is sensibly true. The diameter of the reflector varies from 10 in. for 40-watt lamps to 20 in. for 1 500-watt lamps. The general effect of this departure from the inverse-square law would be to make the values of β, obtained from Fig. 9, somewhat high, and the values of α somewhat low. In general, however, the effect would be extremely small, especially in those cases where no part of the plane was nearer to a reflector than 8 times the diameter of the reflector.

It is not contended that this paper deals with the subject exhaustively. It would be useful to have the curve of critical ratio plotted against spacing ratio added to Fig. 9, and it would be interesting to have curves similar to Fig. 9, but such as apply to a lighting unit in which the polar distribution curve is a circle (as is the case with diffusing globes).

There is also the possibility that some general theorems may be deduced regarding the value of the critical ratio, which will apply whatever the shape of the polar distribution curves.

However, it is thought that the results obtained are sufficient to be of use in the design of lighting systems, and they are embodied as briefly as possible under the following heading.

(2) Practical Rules for the Design of Electric Lighting Systems.

The following rules apply where a large number of direct lighting units are used to illuminate an area of great length and breadth. It is assumed that the standard industrial reflector (B.S.S. No. 232—1926) is used.

(*a*) Assuming that no light is reflected from the ceiling, the average illumination in foot-candles will be equal to 60 per cent of the number of lumens emitted by one lamp, divided by the area under it in square feet. This area is referred to as " A."

(*b*) If h is the mounting height of the lamp it is convenient to define the spacing ratio as $\sqrt{A}/h$, units being of course consistent. The ratio (Minimum illumination)/(Average illumination) is referred to as α, and (Maximum illumination)/(Average illumination) is referred to as β. α and β depend on the spacing ratio and the shape of the area " A." For a given spacing ratio α is a maximum when A is a rhombus, as in Fig. 1, having the ratio $p/q = 1 \cdot 732$, where $p =$ longer diagonal and $q =$ shorter diagonal of rhombus. The values of α and β corresponding to any spacing ratio under these conditions are given by the dotted curves in Fig. 9. When A is a square, as in Fig. 2, the values of α and β corresponding to any spacing ratio may be found from the full-line curves in Fig. 9. When A is a rhombus having a value for p/q less than $1 \cdot 732$ and greater than unity, the values of α and β for any spacing ratio will lie between the dotted and full-line curves in Fig. 9. The same will be the case when A is a rhombus having a ratio of p/q greater than $1 \cdot 732$ but less than a certain " critical " value, and the latter depends on the spacing ratio. When the spacing ratio is $1 \cdot 5$, the critical ratio is $2 \cdot 414$. For practical purposes no great error will be introduced by assuming that this value obtains for all spacing ratios.

When A is a rectangle the value of α will be less than that given in the full-line curve shown in Fig. 9. How much less is a matter that must be left to the judgment of the designer.

(*c*) The following example will make clear the application of the rules:—

A lighting system consists of 150-watt, 200-volt gas-filled lamps in the standardized industrial reflector arranged in rhombuses similar to those shown in Fig. 3, but the longer diagonal of the rhombus is 22 ft. and the shorter diagonal is 10 ft. The lamps are 9 ft. above the ground. Find the average and minimum illumination on a plane 3 ft. above the ground.

In solving this, the value of A is 110 sq. ft., the spacing ratio is 1·75, the lumens emitted by each unit are 1 014, and the average illumination is 9·22 foot-candles. As the value of p/q is 2·2 the value of α will be between the full-line curve and dotted curve in Fig. 9, where the spacing ratio is 1·75, i.e. between 0·81 and 0·73. Assume the value to be 0·75. This makes the minimum illumination 6·9 foot-candles.

For reasons indicated under the previous heading these results are probably a trifle on the low side and to give an arbitrary correction for this they might be increased by 5 per cent, giving 9·7 and 7·25 foot-candles respectively. These results would be correct when the reflectors were new and clean. To allow for their depreciation it is customary to divide by a " depreciation " factor which for fairly clean situations is usually taken as 1·3. This would reduce the results to 7·5 and 5·6 foot-candles, respectively.

HYSTERESIS MEASUREMENTS ON STRAIGHT BARS AND STRIPS.*

By C. E. WEBB, B.Sc., Associate Member, and L. H. FORD, B.Sc.

[From the National Physical Laboratory.]

(*Paper received* 11*th December*, 1929.)

SYNOPSIS.

The method of testing straight samples of high-permeability material, by using search-coils for the measurement of H and eliminating flux leakage from the length under test by means of compensating magnetizing windings, has been previously described in relation to permeability measurements. Its application to hysteresis measurements is found to involve more complicated switching operations, but a comparison of results obtained on bars and strips with those for rings of similar material shows good agreement when compensation is employed at each point on the loop. In the absence of compensation, large differences occur between the loops determined for straight and ring specimens.

In tests on magnet-steel bars compensation produces a negligible effect on the results and is unnecessary.

A drum controller to perform the switching operations required in carrying out a hysteresis loop under compensated conditions is described.

(1) INTRODUCTION.

In a recent paper † the authors described a method of making accurate permeability measurements on straight bars and strips of high-permeability material, such as is now commercially available for electrical machine construction. The method involved the use of search-coils for the measurement of the magnetizing force, H, and the elimination of flux leakage along the length of specimen spanned by the search-coils by the use of compensating magnetizing windings. It was shown that only by the application of such "compensation" could satisfactory results be obtained in the region of high permeability, and that in the absence of compensation the search-coil method was liable to very large errors (up to 35 per cent) in the value of H for a given value of B below about $H = 15$.

In determining hysteresis loops on straight samples of materials having high maximum permeability, and consequently low coercive force, similar errors are likely to occur. Tests were therefore made to see whether satisfactory results could be obtained by a method of compensation for flux leakage similar to that successfully employed in permeability measurements.

(2) DESCRIPTION OF TESTS AND RESULTS OBTAINED.

(a) *Apparatus Used.*

For a full description of the yoke tester and search-coils employed and of the methods of calibrating the instruments and measuring H and B, reference should be made to the previous paper. It may be briefly stated here, however, that both B and H are determined ballistically after equality of flux has been established between the middle and the mean of the two ends of the length of specimen under test. This equality is obtained by adjusting the current in two compensating coils, one at each end of the specimen, independently of the main magnetizing current, until on reversing both currents simultaneously there is no deflection on the ballistic galvanometer when connected to two opposing B search-coils of equal numbers of turns, one distributed over approximately 4 cm at the centre of the test-length, and the other in two halves each spread over approximately 1 cm at a mean distance of 3·5 cm from the centre.

The only change from the apparatus used in the previous investigation was in the magnetizing winding. As a result of tests to find the best arrangement of main and compensating coils, a bobbin was made up to carry a main winding of approximately 400 turns of No. 14 S.W.G. enamelled wire on the central 15 cm and a compensating winding in two sections, each of approximately 40 turns of 121/·0048-in. flexible cord on 1-cm lengths at the two ends. These windings were used throughout the hysteresis-loop tests.

(b) *Method of Testing at Low Values of* $H_{max.}$

The standard hysteresis test on high-permeability material is to determine the loop for $B_{max.} = 10\,000$. This corresponds to a maximum H equal to only two or three times the coercive force and allows all throws to be made to or from the tip-point. The first tests were therefore made at this value of $B_{max.}$, and loops having values of $H_{max.}$ equal to many times the coercive force, for which additional switching operations are required, were considered subsequently.

In permeability measurements by the method of reversals, the corresponding values of B and H are deduced from the galvanometer deflections when the material is taken from the positive to the negative tip of the hysteresis loop for the desired value of H, i.e. from P_1 to P_2 in Fig. 1. Since the magnetization has only to be reversed and not altered in magnitude, only one adjustment of the compensating current is required in determining each point on the permeability curve. To determine points on the hysteresis loop under compensated conditions, however, it is necessary to obtain zero leakage along the test-length at each point as well as at the tip-points, and more complicated adjustments of the magnetizing currents are required.

Starting from the positive tip-point, P_1 (Fig. 1), of the

* The Papers Committee invite written communications, with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† "Precision Permeability Measurements on Straight Bars and Strips in the Region of High Permeability," *Journal I.E.E.*, 1929, vol. 67, p. 1302.

loop for $B_{max.} = 10\,000$ with the compensating current adjusted, as in a permeability test, to give compensation for a complete reversal, it is found that, when the main current is switched off, a considerable fraction of the original compensating current must continue to flow if compensation is to be maintained. The exact value of the compensating current required is found by trial, and the galvanometer deflections are then read when the main current is switched off and the compensating current simultaneously reduced to this value. In this way a point A on the loop is determined. Points intermediate between P_1 and A, such as X_1, may be determined similarly by decreasing both currents from their values at P_1, the appropriate value of the compensating current being first found by trial for each point. For more negative values of H than that at A the main magnetizing current must be reversed as well as reduced in magnitude, the compensating current remaining in its original direction but becoming progressively smaller as the negative value of the main current increases, until at some point B no compensating current is required. Thus for points between A and B, such as X_2, the main and compensating magnetizations are in opposition. For points between B and P_2 both currents are in the negative direction, and a point such as X_3 may be determined by adjusting for compensation and then throwing to the tip-point, P_2, by increasing both currents simultaneously to their tip-point values.

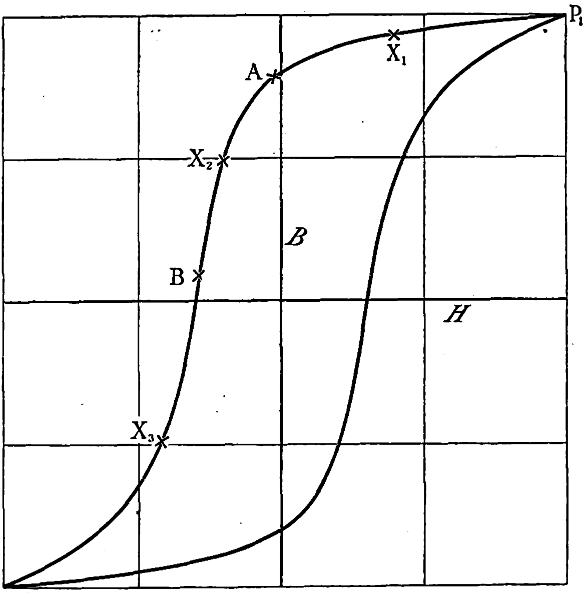

FIG. 1.—Typical hysteresis loop.

TABLE 1.

Point on loop to be reached	Resistances to be set	Switching operations to throw from P_1
X_1	R_3, R_4	Open S_3
A	$R_3 = \infty$, R_4	Open S_3
X_2	R_4, R_5	Open S_4, then open S_3 and reverse S_1
B	R_5	Open S_4, then open S_2 and reverse S_1
X_3	R_5, R_6	Open S_4 and S_5, then reverse S_1 and S_2

It will be seen that various combinations of simultaneous adjustments to the main and compensating currents have to be carried out, e.g. both currents altered in magnitude but not in direction, one current altered in magnitude but not in direction and the other both in magnitude and direction, etc. In the preliminary tests a number of mercury switches were used to perform the necessary operations, and a suitable circuit is shown in Fig. 2. Thus with switches S_1 and S_2 in position (1) and the remaining switches closed, the specimen may be brought to the positive tip-point, P_1, of the required loop by adjusting R_1 and R_2, while the resistance adjustments and switching operations for throwing from P_1 to each of the typical points on the loop, shown in Fig. 1, are given in Table 1.

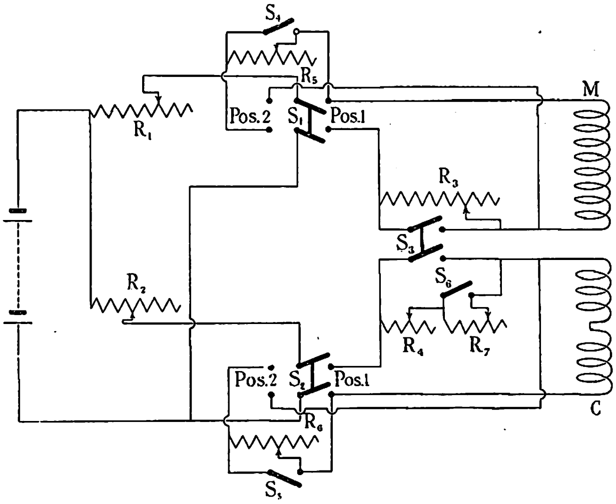

FIG. 2.—Circuit for performing switching operations required in a compensated hysteresis test.

Switch S_6 and resistance R_7 are not required when throwing only to or from the tip-point, but will be found to be needed when obtaining loops at high values of $H_{max.}$.

(c) Results Obtained at $B_{max.} = 10\,000$.

The hysteresis loop for $B_{max.} = 10\,000$ was determined, by the method described, on the sample of sheet material numbered 3B, which had been prepared for the previous investigation and had been found to have a maximum permeability of about 5 000. The loop is shown in Fig. 3 together with the loop obtained on the same sample without compensation. Without compensation the value of $H_{max.}$ is increased about 40 per cent (as would be expected from the results of permeability measurements recorded in the previous paper), while the remanence is decreased 12 per cent and the coercive force increased 10 per cent.

The individual points plotted in Fig. 3 show values obtained on the rings, numbered 3A, cut from the same sheets as strips 3B and very carefully annealed with them. These rings and strips possessed almost identical permeability, as shown in Table 4 of the previous paper, and the very close agreement between the points and the compensated curve in Fig. 3 affords a strong proof of the accuracy of the search-coil method of testing high-permeability strips for static hysteresis when compensation is applied.

A similar comparison of the hysteresis loops for $B_{max.} = 10\,000$ was made between the Armco iron bar 2D and ring 2A, which, as shown in Table 5 of the previous paper, also gave very close agreement for permeability. Some difficulty was experienced in these tests owing to the deflections depending to some extent on the rapidity of switching; this was a consequence of the high permeability of the material and the large cross-section of the specimens. Within the limits of error set by this tendency to variability, however, agreement was again obtained between the loops for the ring and for the bar (with compensation).

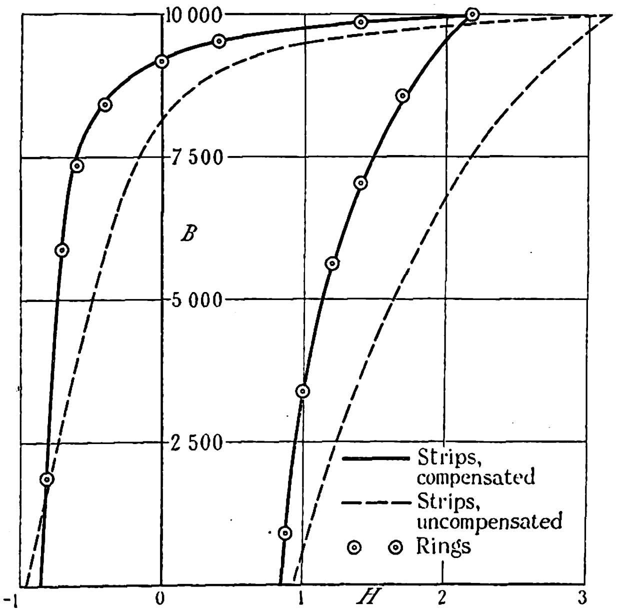

FIG. 3.—Hysteresis loops for $B_{max.} = 10\,000$ on sheet material strips and rings.

(d) Tests at High Values of $H_{max.}$

For hysteresis loops having a value of $H_{max.}$ equal to many times the coercive force the method of finding H and B by throwing from the tip-point of the loop is not sufficiently accurate, since the results depend ultimately on the determination of a small difference between two large galvanometer deflections. Points on the loop corresponding to low values of H were, therefore, found by throwing from the switch-off point of the main magnetizing current, A (Fig. 1). Much more sensitive calibrations of the galvanometer could then be used and the values of H and B relative to those at A could be found with high accuracy.

To determine with precision the value of H at A, an inductometer was connected with its primary in series with the main magnetizing winding and its secondary in opposition to the H search-coil. It was adjusted to give no deflection on the galvanometer when both currents were reversed, and the deflection on switching from the tip-point to the point A was then read, a sensitive calibration again being used. From this the value of H at A could be deduced with much increased accuracy.

The principal limitation to the accuracy obtainable lies in the uncertainty of the balance between the inductometer and the H search-coil, owing to the tendency for a double kick to occur. On this account there is some advantage in balancing the deflection due to the search-coil only partially instead of completely, and allowing for the amount of unbalance in computing the value of H at switch-off.

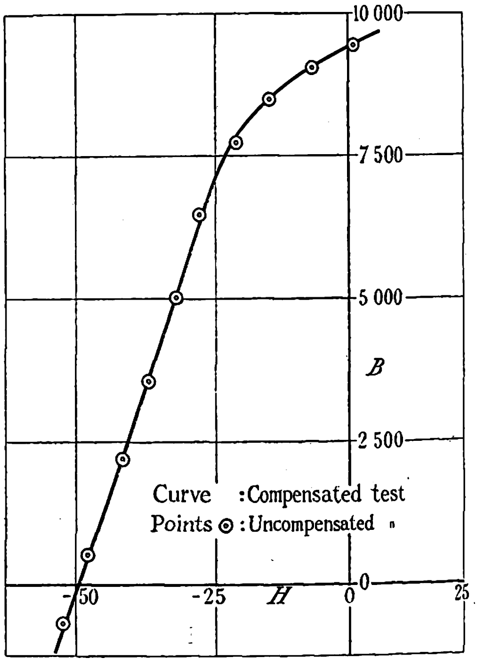

FIG. 4.—Portion of hysteresis loop for magnet-steel bar with and without compensation.

After A had been determined the inductometer was disconnected, its secondary being replaced by an equal resistance so as not to alter the galvanometer calibration, and further points on the loop, such as X_2 and B, were found by throwing from A as described above. The switching operations with the circuit of Fig. 2 were as before (see Table 1), except that after reaching A by opening switch S_3 further points such as X_2 were found by adjusting R_5 and R_7 to give compensation, and opening switch S_6 simultaneously with the reversal of S_1.

Comparative tests on rings and strips (with compensation) at high values of $H_{max.}$, similar to those at $B_{max.} = 10\,000$, showed good agreement, although there was greater uncertainty in the H readings at low values on the strips owing to the difficulty in balancing with the inductometer.

(e) Tests on Magnet-steel Bars.

The results plotted in Fig. 3 show clearly that considerable error results in hysteresis measurements on soft.

high-permeability material if compensation is not applied to eliminate leakage along the test-length. To find whether the effect of leakage is appreciable in tests on straight bars of hardened magnet steel by the yoke and search-coil method, a tungsten-steel bar, approximately $3 \times 1\cdot25$ cm^2 section, was subjected to a magnetization of $H_{max.} = 400$, and the portion of the hysteresis loop between the remanence and coercive force points was determined with and without compensation. The results are given in Fig. 4 and it will be seen that the points obtained without compensation lie almost exactly on the curve obtained with compensation. As this specimen had a coercive force of only about 50 it is a relatively soft magnet steel and thus represents the most favourable case for showing errors due to flux leakage. It may, therefore, be concluded that in all hysteresis tests on hardened magnet-steel specimens the effect of leakage is negligible.

(3) CONSTRUCTION OF DRUM CONTROLLER.

The switching operations in obtaining a complete hysteresis loop are complicated, and interlocking of the switches for main and compensating currents is needed to make operations in the two circuits satisfactorily simultaneous. To effect this and to allow the correct combinations of adjustments to be obtained automatically, a drum controller was designed and constructed. It is shown diagrammatically in Fig. 5.

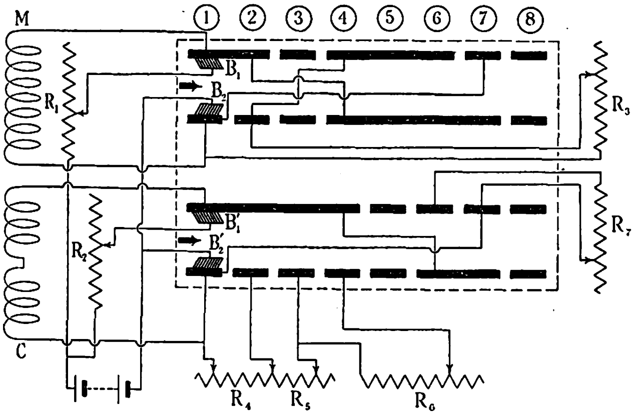

FIG. 5.—Circuit of drum controller for obtaining compensated hysteresis loops.

The central spindle of the controller carries two pairs of carbon brushes B_1, B_2 and B_1', B_2' connected to the source of supply through independent adjustable resistances, R_1 and R_2, and feeding the main magnetizing winding, M, and the compensating winding, C, respectively, through four banks of gunmetal contacts. The brushes, which are mounted on plungers sliding in cylindrical guide-arms, bear on the contacts with a considerable pressure applied by strong spiral springs, and are set in four perpendicular directions to balance the thrust on the spindle. Current is led to these brushes through four gunmetal slip-rings (not shown in the diagram) on the lower half of the spindle, the brushes for which are carried on keramot pillars mounted on the brass base of the controller. The gunmetal contacts are mounted inside four keramot rings supported on brass pillars. The whole controller is enclosed in a brass cylinder, approximately 12 in. high × 10 in. diameter, to exclude dust.

There are eight positions of the controller, numbered 1 to 8 in Fig. 5 (in which, it should be noted, the relative angular displacement of the brushes has been ignored and, for simplicity, they are shown as if they were in one vertical plane). The spindle is fitted with a cranked handle and by means of an adjustable stop, which can be made to operate on any of the eight positions, it is possible to throw rapidly from any one position to any other.

The operations performed in the various positions are given in Table 2, which also shows the points on the hysteresis loop to which each position corresponds (see Fig. 1).

TABLE 2.

Position on controller	Operation performed on		Point on loop
	(i) Main magnetizing current	(ii) Compensating current	
1	Set by R_1	Set by R_2	P_1
2	Reduced by inserting R_3	Reduced by inserting R_4	X_1
3	Reduced to zero	Further reduced by inserting R_5	A
4	Reversed and reduced by inserting R_3	Further reduced by inserting R_6	X_2
5	Reversed and reduced by inserting R_3	Reduced to zero	B
6	Reversed and reduced by inserting R_3	Reversed and reduced by inserting R_7	X_3
7	Reversed	Reversed	P_2
8	Zero	Zero	—

It will be seen that 8 is an off-position for both circuits and that the remaining positions, 1 to 7, correspond to the typical points on the loop of Fig. 1. Thus one complete revolution of the spindle carries the sample round a complete hysteresis loop, and by suitable adjustments of the associated variable resistances any desired point on the half of the loop from P_1 to P_2 can be attained.

By using positions 1 and 7 of the controller a simple reversal of current is obtainable, and the calibration of the galvanometer and demagnetization of the specimen may therefore be carried out on the controller, if desired. It is more convenient, however, to insert a mercury reversing switch in the main circuit for use in these operations.

A repetition of some of the previous measurements, using the controller, showed that it provides a quick and satisfactorily accurate means of obtaining hysteresis loops where compensation is necessary. By turning the spindle always in a clockwise direction a cyclic condition is automatically maintained, while by using the adjustable stop rapid throws can be made without difficulty either from the tip-point or from the switch-off point, A, to any desired point on the loop. Care must be taken, however, particularly when throwing from A, not to turn the spindle too rapidly through the positions corresponding to the tip-points when completing the loop after a throw in preparation for the next throw. Otherwise sufficient time may not be allowed for the flux to reach its proper maximum value. In practice, with a normal sample, no difficulty is experienced in this connection, provided the spindle is not turned very quickly.

(4) Conclusions.

(i) As would be expected from the results of permeability tests previously recorded, the yoke and search-coil method without compensation is found to be subject to large errors in hysteresis measurements on strips or bars of high-permeability material.

(ii) Accurate results are obtained by this method on such samples, however, when compensation is applied to eliminate flux leakage along the test-length at each point on the hysteresis loop. This is shown by the close agreement with tests on rings of similar material.

(iii) In determining hysteresis loops for values of $H_{max.}$ equal to many times the coercive force, increased accuracy may be obtained by balancing the H search-coil wholly or partially against an inductometer for a complete reversal, and deducing the value of H at switch-off from the deflection on switching off the main current. Points on the loop at low values of H are then found by throwing from the switch-off point instead of from the tip-point.

(iv) Magnet-steel bars may be tested without compensation with no appreciable error.

(v) The necessary switching operations for obtaining a hysteresis loop may be carried out satisfactorily with the drum controller described.

In conclusion, the authors desire to express their thanks to Dr. D. W. Dye, F.R.S., for helpful suggestions in the course of the work, and to Mr. A. Gridley for valuable assistance in the construction of the drum controller.

AN INVESTIGATION OF THE FREQUENCY VARIATIONS IN INDUCTION WATT-HOUR METERS.

By A. E. MOORE, M.Sc.Tech., Member, and W. T. SLATER, M.Sc.Tech., Student.

(*Paper first received 26th November,* 1929, *and in final form* 3*rd February,* 1930; *read before the* METER AND INSTRUMENT SECTION 7*th March,* 1930.)

SUMMARY.

The paper contains an account of experiments carried out by the authors to analyse some of the various factors concerned in the behaviour of induction watt-hour meters, with particular reference to the changes in accuracy produced by different frequencies.

The subject is dealt with under the following headings:—

Experimental determination of the changes in accuracy of induction watt-hour meters with changes in frequency.
The causes of the changes, namely braking effect of the voltage flux, and reactance of the disc.
Separation of the two effects, and determination of their relative magnitudes.
Determination of the time-constants of the discs.
Explanation of the torques produced in induction meters.
Determination of some of the other phase errors in the meters.
Conclusions.

LIST OF SYMBOLS.

V = voltage applied to the voltage coil.
I = current in the current coil.
ϕ = angle of phase difference between V and I.
Φ_V = active voltage flux.
Φ_I = active current flux.
e_V and e_I = e.m.f.'s induced in the disc by Φ_V and Φ_I respectively.
i_V and i_I = eddy currents produced by e_V and e_I in the disc, respectively.
θ_V = phase angle by which i_V lags behind e_V.
θ_I = phase angle by which i_I lags e_I.
δ = phase angle between V and Φ_V.
$\alpha = 90° - \delta$.
β = phase angle between I and Φ_I.
$\gamma = 90° - \phi_S$, where ϕ_S is the phase angle between V and I when the meter registers zero power factor.

EXPERIMENTAL DETERMINATION OF THE CHANGES IN ACCURACY OF INDUCTION WATT-HOUR METERS WITH CHANGES IN FREQUENCY.

In 1911 one of the authors gave an account of some tests on induction watt-hour meters with alternating currents of different wave-shapes,* and several possible causes of the variation in accuracy were set out as follows:—

(1) Alteration in the nature of the rotating or shifting magnetic fields.
(2) Effects on the fluxes in the cores by changes in the eddy currents and the hysteresis of the iron.
(3) Effects on the quadrature adjustments.
(4) Effects of frequency: it will be noted that as more of the harmonic wave is added the resultant wave approaches more nearly to the triple-frequency wave of the harmonic.

In the discussion on the paper referred to, Mr. J. T. Irwin stated that the indications of the meters were the sums of the indications for each separate frequency taken separately; that is, if $W_1 + W_3 + W_5$, etc., is the total load on the meter, the suffixes denoting the frequency with reference to the fundamental, and if K_1, K_3, K_5, etc., denote the constants for the meter at the corresponding frequency, power factor and load, the registration of the meter will be equal to $K_1W_1 + K_3W_3 + K_5W_5$, etc.

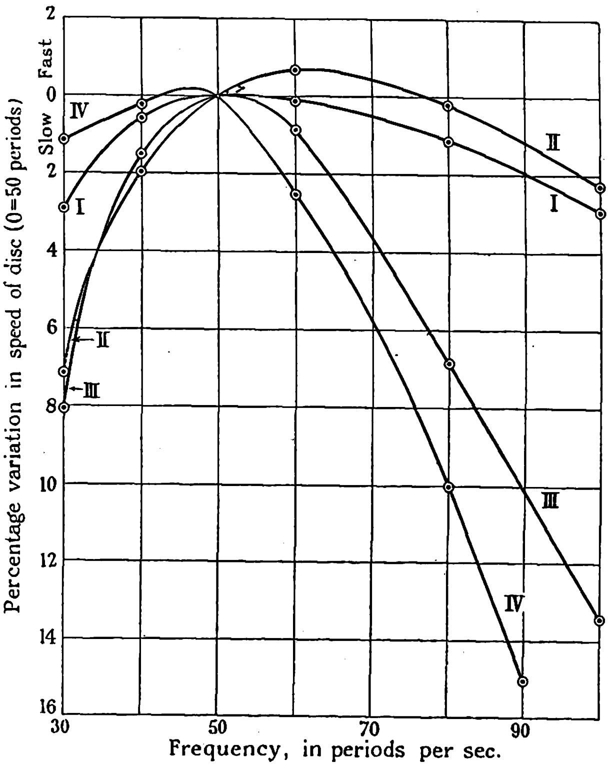

FIG. 1.—Curves showing the percentage variation in the speed of the disc with variation in frequency, for 4 induction watt-hour meters. The load is constant and the power factor unity.

Irwin analysed the curves of wave-shapes given and showed that the actual registrations of the meters agreed fairly well with the results calculated from this formula.

---

* H. A. RATCLIFF and A. E. MOORE: "Electricity Meters, with Notes on Meter Testing," *Journal I.E.E.*, 1911, vol. 47, p. 3.

In the authors' reply to the discussion on the earlier paper two curves were given showing the variation in accuracy with changes in frequency of two of the meters previously tested. These two meters were those which gave the least and the greatest variations respectively with changes in wave-shape, and the two curves I and IV, Fig. 1, are here reproduced, together with curves for two other meters. All the meters ran slower on the distorted waves than on the sinusoidal waves, and as they all appear to run slower as the frequency is increased there were good reasons for believing that their inaccuracy on distorted waves was mainly a question of their accuracy at different frequencies.

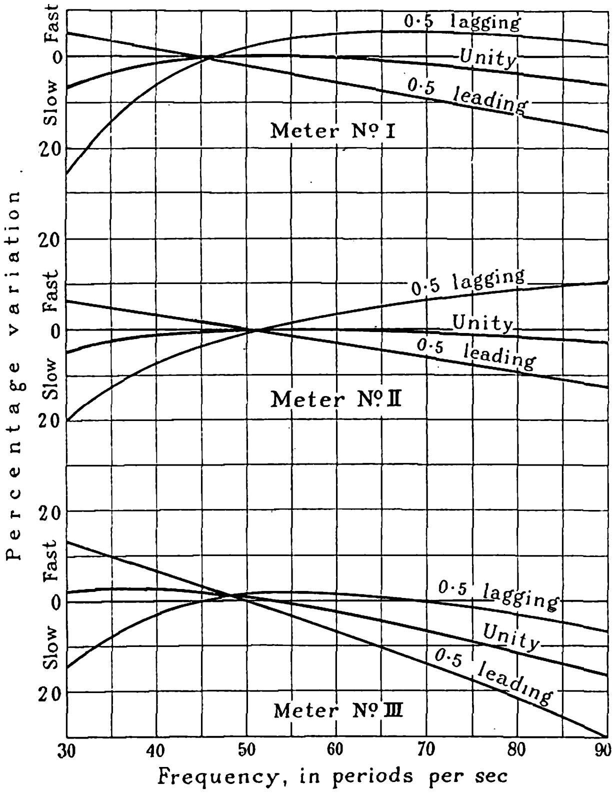

FIG. 2.—Curves showing the percentage variation in accuracy of 3 induction watt-hour meters with change in frequency, from the accuracy at unity power factor at a frequency of 50. The meters were adjusted to register approximately correctly on low power factors at a frequency of 50.

Causes of the Changes.—The changes in accuracy with changes in frequency are least when the power factor of the load is unity, the reason being that the power-factor adjustment in the meter depends on the frequency of the supply. Fig. 2 illustrates this point. Curves of accuracy are shown for three meters for which the adjustment for power factor was made at a frequency of approximately 50 periods per sec. The meters were tested at 80 per cent of full-load volt-amperes at unity power factor and at a power factor of 0·5 with both leading and lagging currents, and at frequencies varying from 30 to 90. The meters are, as may be expected, very inaccurate at 0·5 power factor at other than normal frequency, but they also show varying degrees of inaccuracy with changes in frequency even at unity power factor, and it was in search of the explanation of these unity power-factor errors that the investigation described below was undertaken.

The meter represented by curve I, Fig. 1, is a Metropolitan-Vickers type "N" meter. These meters employ a thin disc and it was thought that possibly their good characteristics were due in some measure to this. An induction meter may, for the moment, be considered as a small induction motor with short-circuited rotor, and the conditions obtaining—even when the disc is rotating at full-load speed—are somewhat similar to the starting condition in the induction motor. If the time-constant of the rotor is high the starting torque is small and the torque may be increased by increasing the resistance of the rotor. Applying this reasoning to the meter, it might be expected that the same conditions would obtain. A thin disc would have a lower time-constant than a thick one of the same material, and if discs of different thicknesses of the same material, or of the same thickness of different materials, were tried in the meter, it might be expected that the thinner discs and the discs of higher specific resistance would be less affected by changes in the frequency of the rotor currents than would the thicker or more highly conducting discs.

For the purpose of carrying out tests the Metropolitan-Vickers Co. supplied three interchangeable discs for a type "N" meter, (I) a standard disc of corrugated aluminium 0·022 in. thick, (II) a copper disc, 0·034 in. thick, and (III) an aluminium disc, 0·063 in. thick.

The meter was rated at 5 amperes, 100 volts, 50 cycles, and was tested at 100 volts, 4 amperes, unity power factor, at frequencies varying from 30 to 100, with each of the discs in turn. The results obtained for the discs I, II and III are represented in Fig. 3 by curves I, II and III respectively.

The curves are similar to those in Fig. 1, and they were considered sufficiently good to justify further investigation on the same lines. Four more discs were obtained as follows: (IV) a thinner plain aluminium disc, 0·018 in. thick, (V) a plain Eureka disc, 0·034 in. thick, (VI) a corrugated copper disc 0·022 in. thick, and (VII) a corrugated Eureka disc 0·022 in. thick.

The meter was tested again with discs Nos. IV and V in the same manner as already described and the results are shown by curves IV and V in Fig. 3. The curves appear to indicate that the thickness and conductivity of the disc play an important part in the behaviour of the meters under certain conditions. With the thick discs of high conductivity the speed and, therefore, the driving torque, rapidly diminish when the frequency is increased above a certain value, but this diminution in speed is less marked with the thinner discs and is changed to an increase of speed in the cases of the very thin aluminium and the thick Eureka discs. It is not suggested that Eureka alloy would be suitable for the discs of these meters—on the contrary the driving torque when it is used is so very small that probably they would be useless—but it was desirable to make experiments with high-resistance discs in order to strengthen or disprove the assumptions made.

After obtaining the curves in Fig. 3 it was necessary to explain why the speed at 30 was lower than at 50 periods per sec.; and also why, in the cases of the thinner aluminium and the Eureka discs, the speed of the meter increased throughout the range of frequencies 30 to 100.

At first the diminution in speed below 50 periods per sec. was thought to be due to the ohmic resistance of the pressure coils, and in some meters it may be so to a certain extent. The effect of the ohmic resistance would be to limit the magnetizing current as the frequency is diminished and hence, therefore, to limit the voltage flux. If such were the case the permeability of the iron would also affect the result. From measurements of the resistance and impedance of the voltage coils, however, it was concluded that the effect—in this meter at any rate—must be relatively small and unimportant.

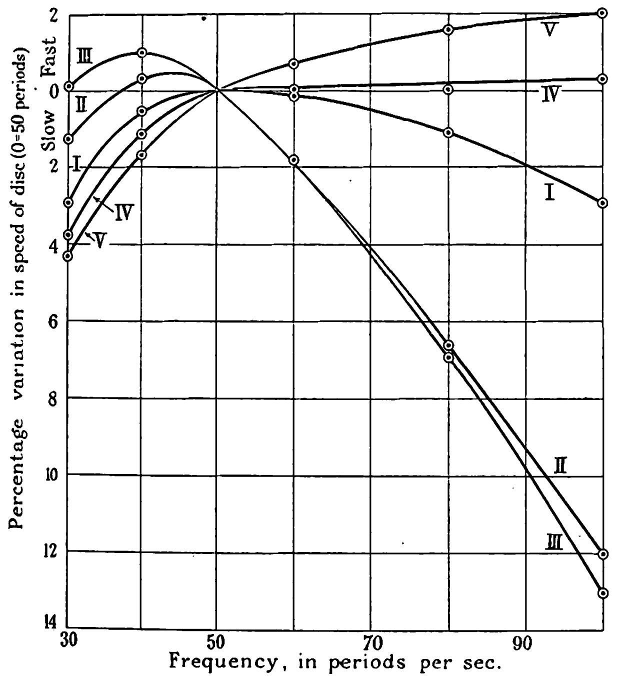

FIG. 3.—Curves showing the percentage variation in the speed of the disc with variation in frequency, for 5 different discs in one meter. Load constant at unity power factor.

The next cause which suggested itself was the change in the brake torque due to changes in the strength of the voltage flux with changes in the frequency. If we consider the driving torque to be due to the eddy currents induced by, say, the voltage pole acting on the flux of the current pole, then the driving fluxes also act as brake fluxes, and the voltage-coil flux acts in this manner to a very considerable extent. The eddy currents are proportional to the frequency and the flux, but the voltage flux is inversely proportional to the frequency. Hence the eddy currents due to the voltage flux are independent of frequency. The current flux is substantially independent of frequency, and therefore the driving torque produced by the current flux and voltage flux eddy-currents is also independent of frequency. The brake torque produced by the voltage flux is, however, proportional to the square of the voltage flux.

When the frequency is doubled the voltage flux is halved; so that if the voltage flux is at all comparable in magnitude with the flux of the permanent brake magnet there is a considerable diminution in total brake torque as the frequency is increased and, of course, a considerable increase in the brake torque as the frequency is diminished. It may be noted how rapidly the curves in Figs. 1 and 3 bend down as the frequency is diminished below 50.

In order to verify this assumption, tests were made on two different makes of polyphase meter (two single-phase elements combined) in the following manner. Only one of the elements in each meter was loaded with current and voltage at the normal frequency of 50 (100 volts, 4 amperes, 400 watts). The voltage coils only of the second element were excited from an entirely separate a.c. supply, with normal voltage but with successively different frequencies. The two curves shown in Fig. 4 were obtained in this manner, and they obviously indicate that the speed of the meter approaches a maximum as the frequency of the supply to the free voltage-coil circuit is increased. The maximum speeds were obtained by disconnecting the supply from the free voltage-coil circuits, and they are given in Fig. 4. It will be noted that they are little in excess of the speeds obtained at a frequency of 100.

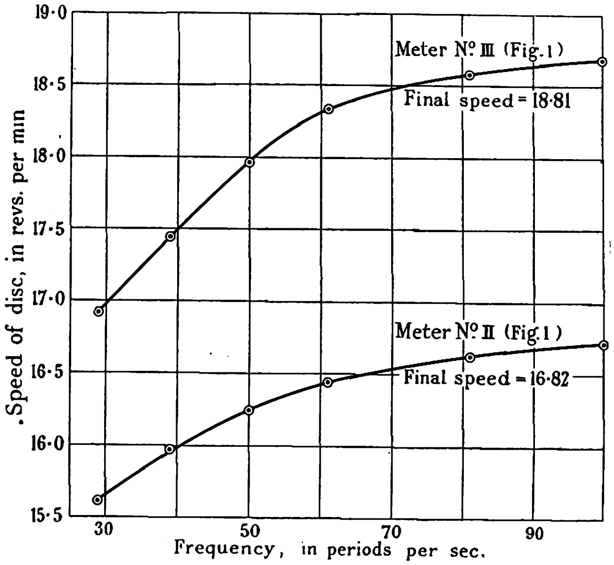

FIG. 4.—Curves showing how the braking action of the voltage flux slows the meter down with decrease of frequency, due to increase in voltage flux.

From the foregoing results it may be inferred that the changes in the reactance of the disc, and the changes in the magnitude of the voltage flux, due to changes in frequency, act in opposite senses, the one slowing the meter down and the other speeding it up with increase in frequency.

Separation of the Two Effects, and Determination of their Relative Magnitudes.—The next set of tests was made for the purpose of separating the two effects in order to ascertain, if possible, their relative magnitudes. The polyphase meters were used again, but in this case the isolated voltage-coil was energized from the same supply and therefore at the same frequency as the working element of the meter. Observations were made over a range of frequency from 30 to 100, and the revolutions of the disc were timed (*a*) with the isolated voltage-coil energized, and (*b*) with it not energized. If the voltage coils of the two meter elements are alike—and presumably they are very nearly so—then, if the difference in the times be subtracted from time (*b*) the result is the time which would be taken if the voltage fluxes acted only as driving fluxes and not as brake fluxes also (assuming always that there is no very great interference between the two elements of the meters). The results of these tests on two meters are shown in Fig. 5. Curves II and III represent the variation in speed with both voltage fluxes acting as brake fluxes, curves II_a and III_a with only one voltage flux acting as brake flux, and curves II_b and III_b are deduced, as stated above, to represent the variation in speed if neither voltage flux acted as a brake flux. Curves II_b and III_b therefore represent changes in speed with changes of frequency due to the reactance of the disc. The effect of the reactance of the disc is thus shown to slow the meter down with increase of frequency of the supply.

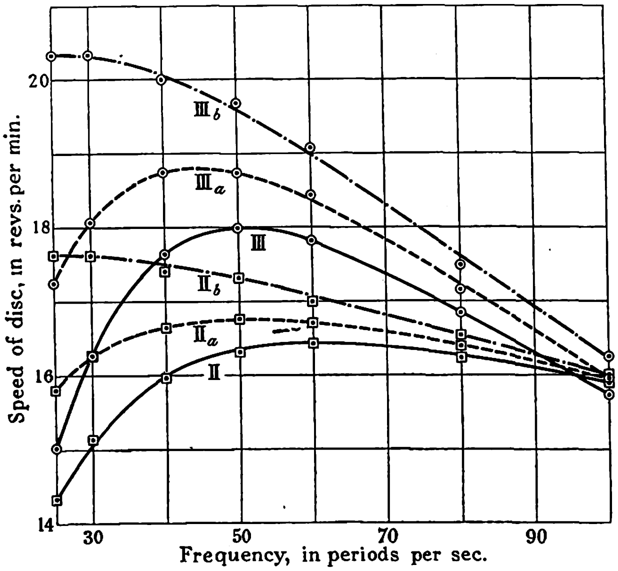

FIG. 5.—Curves showing how the reactance of the disc slows the meter down with increase in frequency.

Curves II_b and III_b should be the curves connecting the driving torque of the meters with the frequency. To test this, the driving torques of the meters were measured with the discs stationary in order to eliminate the effects of the driving fluxes acting as brake fluxes. A curve for one disc is shown in Fig. 6, and it is very similar in shape to curves II_b and III_b in Fig. 5. The torque/frequency curves for stationary discs all obey the rule that the more conductive the disc the steeper is the curve.

The next procedure was the deduction of theoretical curves for a meter having particular data. Values for the time-constant of the disc and also for the ratio of voltage flux to brake-magnet flux were assumed, and, after several values had been tried, calculations were made for two meters as follows:—

(1) Voltage flux at 50 periods per sec. to have a value equivalent to 20 per cent of that of the permanent brake magnet.
Time-constant of the disc to be 0·0005.
(2) Voltage flux as in (1).
Time-constant of the disc to be 0·001.

The figures from which the curves in Fig. 7 are plotted were obtained in the following manner.

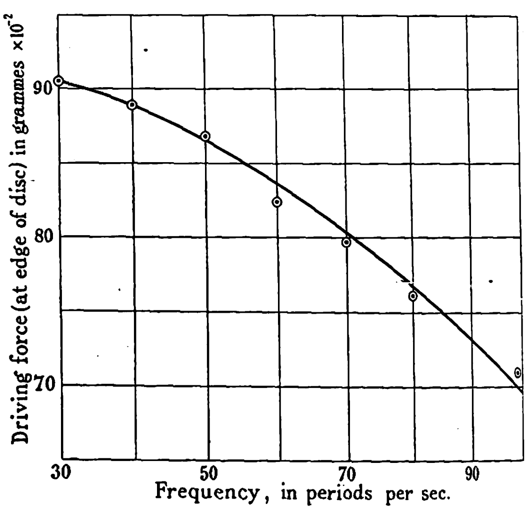

FIG. 6.—Curve showing the variation in driving torque at different frequencies. Disc stationary.

Braking Effect (*Curve A in Fig.* 7).

The brake torque at 50 periods per sec. is proportional to (Brake-magnet flux)^2

+ (Voltage flux at 50 periods per sec.)^2

This is proportional to $1^2 + \left(\frac{20}{100}\right)^2$

The voltage flux is inversely proportional to the frequency, so that the brake torque at *f* periods is proportional to

$$1^2 + \left(\frac{20}{100} \times \frac{50}{f}\right)^2$$

The percentage deviation of the brake torque at different frequencies from the brake torque at 50 periods was then calculated and plotted as curve A in Fig. 7.

Disc Effect (*Curves* C *and* E *in Fig.* 7).

Next the values for the effect of the reactance of the disc on the speed were calculated thus:—

If *L* and *R* are the inductance and resistance respectively of the eddy-current path in the disc, the angle of lag of the eddy current will be θ, where $\tan\theta = \omega L/R$. It is shown on page 1028 that the torque is proportional to $\cos^2\theta$. Then

For case (1), at *f* periods $\tan\theta = 2\pi \times f \times 0{\cdot}0005$, and
For case (2), at *f* periods $\tan\theta = 2\pi \times f \times 0{\cdot}001$

The percentage deviation of the driving torque at different frequencies from that at 50 periods per sec. is shown by the dotted curves C and E in Fig. 7.

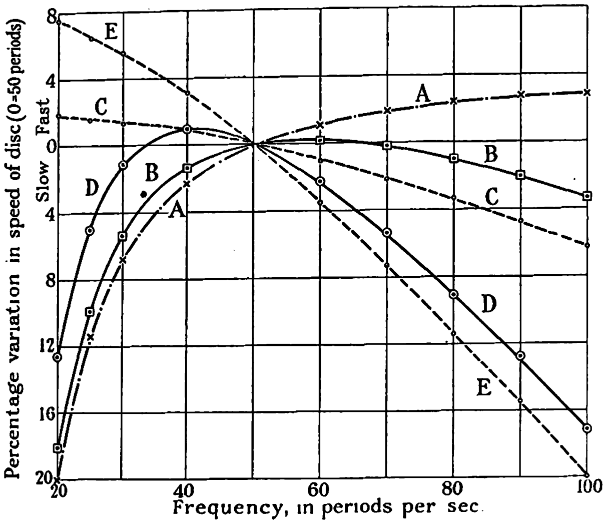

FIG. 7.—Curves plotted from assumed values of brake-magnet flux, voltage flux and disc reactance, showing how the speed should vary with frequency. (Compare curves B and D with those given in Figs. 1 and 3.)

The remaining curves B and D represent the percentage deviation due to the combined effects of the voltage flux and disc reactance for the two cases chosen. These curves appear to justify the assumptions previously made, for

Curve A is of the same general shape as the curves in Fig 4.

Curves C and E are of the same general shape as curves II_b and III_b in Fig. 5.

Curves B and D are of the same general shape as the curves in Fig. 3.

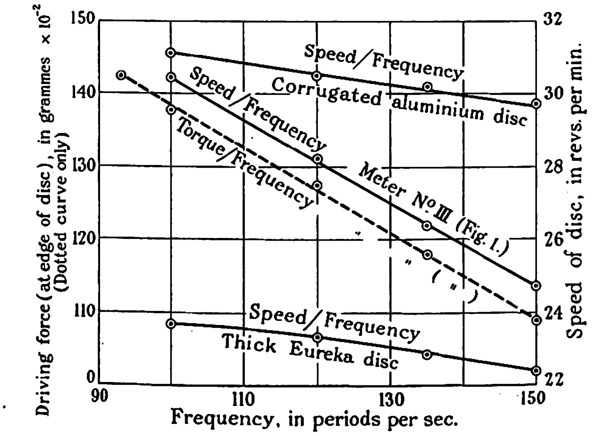

FIG. 8A.—Curve showing the diminution of speed of the thick Eureka disc with frequencies above 100. Also Speed/frequency and Torque/frequency curves for meter No. III (Fig. 1).

From these theoretical curves it was inferred that although the curves for the thin aluminium disc and the Eureka disc in Fig. 3 continue to rise as the frequency increases to 100, they would probably fall at higher frequencies. That this was actually the case is shown by the curves in Fig. 8A. Tests were carried out at frequencies varying from 100 to 150 on (1) the standard corrugated disc, (2) the thick Eureka disc, and (3) meter No. III, Fig. 1. Fig. 8B shows the curves for 100 to 150 periods per sec.—dotted lines—plotted as continuation curves to the corresponding curves I and V in Fig. 3. It must be pointed out, however, that two different machines were used for the supply, and, while the wave-shape of the machine used for all the tests up to 100 periods per sec. was approximately sinusoidal,

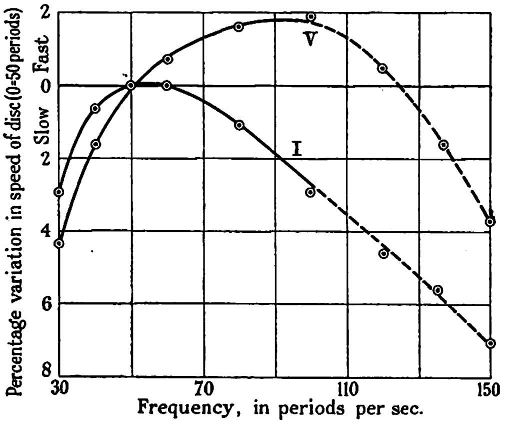

FIG. 8B.—Speed/frequency curves for
I. Standard aluminium disc.
V. Thick Eureka disc.

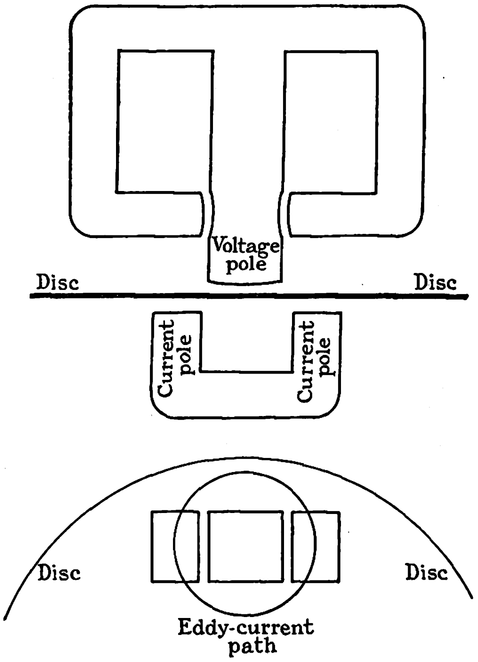

FIG. 9.

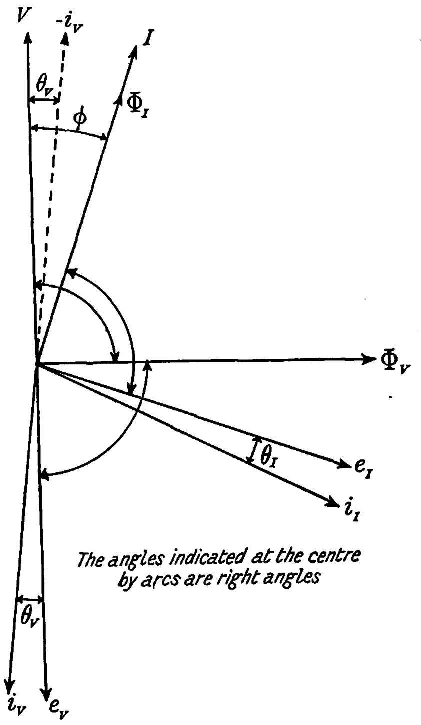
that for frequencies above 100 was very far from being sinusoidal. Also, the adjustments of the type "N" meter had been disturbed between the two sets of tests. In drawing the curves as continuation curves, therefore, it has been assumed that the speeds of the discs would be the same at 100 periods per sec. in both sets of tests. The dotted torque curve in Fig. 8A is an almost exact continuation of the torque curve in Fig. 6, the difference in the torque scale being that both elements of the meter were used in the tests for Fig. 8A, whilst only one element was used for the curve in Fig. 6.

The driving torque has been assumed to be proportional to $\cos^2 \theta$, where θ is the angle of lag of the eddy current due to the reactance of the disc. This is arrived at as follows. Fig. 9 is a diagrammatic representation of the meter element, and Fig. 10 shows the vector diagram assumed. In considering the theory so far, only the torque between the current flux and the eddy current produced by the voltage flux has been considered; the second part of the torque is dealt with later and will be shown to follow the same laws. The voltage flux Φ_V is assumed to be in quadrature with the voltage V at all frequencies, and also to be strictly inversely proportional to the frequency in magnitude. The current flux Φ_I is assumed always to be in phase with the current and to be strictly proportional to the current, whatever the frequency. In modern meters operating at unity power factor these assumptions are justifiable, at least as a first approximation.



The angles indicated at the centre by arcs are right angles

FIG. 10.

The torque is produced by the eddy current i_V acting on the current flux Φ_I and is proportional to

$$\Phi_I i_V \cos(\phi - \theta_V)$$

Now $$i_V = \frac{e_V}{R} \cos \theta_V$$

where R is the resistance of the eddy-current paths, and e_V is the voltage induced in the disc by the flux Φ_V. Substituting these values the torque is proportional to

$$\Phi_I \frac{e_V}{R} \cos \theta_V \cos(\phi - \theta_V)$$

But $$e_V \propto \Phi_V \times f$$
$$\propto \frac{V}{f} \times f$$
$$\propto V$$

where f is the frequency, and $\Phi_I \propto I$.

The torque is therefore proportional to

$$IV \cos \theta_V \cos(\phi - \theta_V)$$

At unity power factor $\phi = 0$ and the torque is then proportional to

$$VI \cos^2 \theta_V$$

DETERMINATION OF THE TIME-CONSTANTS OF THE DISCS, AND THE RATIO OF THE VOLTAGE FLUX TO THE BRAKE-MAGNET FLUX.

The formula Torque $\propto VI \cos^2 \theta$ was used to calculate the time-constants of several discs from the standstill torque/frequency curves already obtained.*

We have $$\cos^2 \theta = \frac{1}{1 + T^2\omega^2}$$

where T is the time-constant of the disc, and $\omega = 2\pi f$.

Let the standstill torques for two frequencies f_1 and f_2 be $\mathbf{T}_1$ and $\mathbf{T}_2$ respectively. Then

$$\frac{\mathbf{T}_1}{\mathbf{T}_2} = \frac{1 + (2\pi f_2 T)^2}{1 + (2\pi f_1 T)^2}$$

$$\therefore \quad \mathbf{T}_1 - \mathbf{T}_2 = (2\pi T)^2 (\mathbf{T}_2 f_2^2 - \mathbf{T}_1 f_1^2)$$

from which T can be calculated directly. The following time-constants were calculated in this way.

Disc	Time-constant
Thick copper	0·0008
Thin copper	0·0005$_5$
Standard aluminium	0·0004$_5$
Very thin aluminium ..	0·0002

The last value is very approximate, since the small torque rendered the measurement of the small variations rather uncertain.

---

* It may be of interest to explain that the experimental work already described was carried out by one of the authors in 1914–15, but the work was then discontinued. The values for the time-constants previously used for Fig. 7 were found by trial only; the values by calculation were not determined until the work was resumed some six or seven years later. It is interesting to note that the values determined for the time-constants of the thick copper and the standard aluminium discs agree very closely with the values assumed for them in respect of Fig. 7. The value assumed on page 1026 for the ratio of the voltage flux to the brake-magnet flux also appears to be very nearly the same as that found by determination at the later date, page 1029.

Experiments were also carried out to determine the value of the ratio Φ_V/Φ_B for the meter on which most of the tests were carried out, Φ_B being the brake-magnet flux.

A 2-element meter was driven by a constant load on the top element. In the first case (A) the bottom element was not in circuit, and the brake torque was therefore due to two brake magnets and one voltage pole. In the second case (B), the voltage pole of the bottom element was energized and the brake torque was then due to two brake magnets and two voltage poles. The figures for case (B) are the average of two readings obtained when the connections to the bottom voltage pole were reversed, the two readings being taken to eliminate any error due to magnetic interaction between the elements.

For case (A) the disc made 15 revolutions in 95·8 seconds, and for case (B) the average time for 15 revolutions was 97·45 seconds.

Let x denote the ratio Φ_V/Φ_B.

The brake torque in case (A) is proportional to

$$2\Phi_B^2 + \Phi_V^2$$
$$= \Phi_B^2(2 + x^2)$$

The brake torque in case (B) is proportional to

$$2\Phi_B^2 + 2\Phi_V^2$$
$$= \Phi_B^2(2 + 2x^2)$$

Since the speed is inversely proportional to the brake torque we have

$$\frac{2 + x^2}{2 + 2x^2} = \frac{95\cdot 8}{97\cdot 45}$$

from which $x = 0\cdot 187$.

The tests just described were carried out at a frequency of 50. A second similar set of tests was now made at a frequency of 30 and gave the result

$$x = 0\cdot 318.$$

If the theory be correct the ratio

$$\frac{x \text{ at 30 periods per sec.}}{x \text{ at 50 periods per sec.}} = \frac{0\cdot 318}{0\cdot 187} = 1\cdot 7$$

should be the same as the ratio $50/30 = 1\cdot 67$, since the voltage flux is inversely proportional to the frequency. The result is in good agreement. Another point of interest is that the ratio Φ_V/Φ_B is very nearly the same as that arbitrarily chosen in the earlier experiments, viz. 0·2 at 50 periods per sec.

EXPLANATION OF THE TORQUES PRODUCED IN INDUCTION METERS.

So far no account has been taken of the torque resulting from the eddy currents induced by the current flux reacting on the voltage flux. Several writers contend that the two torques are in opposite directions. The authors do not agree with this contention, and would say that if it were true the meters would not work. In the case of the hypothetical induction meter the mean values of the two torques are exactly equal, and there would obviously be no resultant torque to turn the rotor.

It is easy to show in many ways that the two torques are in the same direction, but perhaps the following method will suffice. Take a magnet system such as that indicated in Fig. 11 and suppose that V and I are in phase. Then Φ_V and Φ_I will be in quadrature. The poles 1, 2 and 3 will come up as, say, N poles in rotation, pole 3 becoming N 180° later than pole 1, and pole 2 90° later than pole 1. Let the fluxes be denoted by Φ_1, Φ_2, and Φ_3, and the eddy currents produced by them by i_1, i_2, and i_3 respectively. In considering the reactions of the eddy currents on the fluxes to produce torque the vector diagram should be drawn as shown in Fig. 11, and it will be clear that the torques are represented by $\Phi_1 \times i_2$ (dotted), $\Phi_2 \times i_1$, $\Phi_2 \times i_3$ (dotted), and $\Phi_3 \times i_2$. These products are all positive, indicating that the torques are all in one direction.

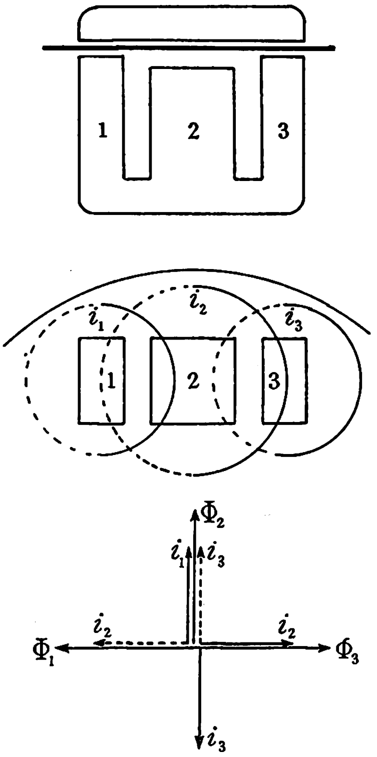


FIG. 11.

Fig. 12 and the corresponding vector diagram indicate that this conception of the direction of the torques is also true where there are only 2 poles instead of 3.

DETERMINATION OF SOME OF THE OTHER PHASE ERRORS IN THE METERS.

When developing the formula to cover both sources of driving torque, it was considered that the results so far obtained were sufficiently good to warrant a rather fuller treatment of the torque formula, taking into consideration as fully as possible the numerous sources of error which arise in an actual meter.

Fig. 13 is the vector diagram assumed for the meter. The combined effect of the iron losses and eddy currents in the iron of the current pole causes the flux to lag behind the current by an angle β.

In a hypothetical meter the voltage flux would be in exact quadrature with the voltage. In an actual meter the resistance of the windings and the losses in the iron core cause the flux to lead exact quadrature, often by an angle of several degrees, and several methods for correcting this lead are in use.

In the Metropolitan-Vickers type " N " meter used in the tests the corrector or quadrature loop is a metal strip or band embracing that part of the voltage pole which is active on the disc. The currents induced in this loop cause an increase in the lag of the voltage flux, and the amount of increase can be adjusted by moving the loop over the voltage pole so as to embrace more or less flux as required.

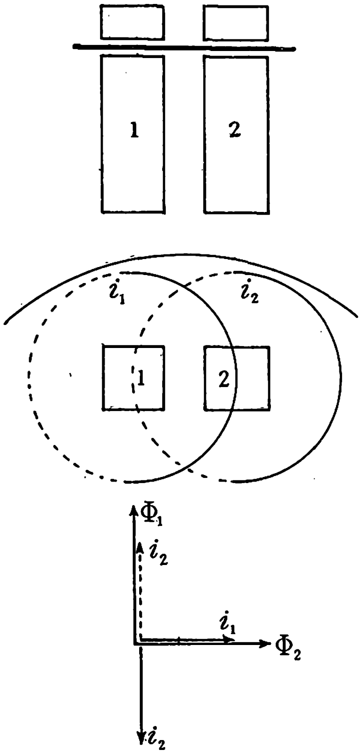

FIG. 12.

In the vector diagram, Fig. 13, it is assumed that the combined effect of the resistance, iron losses and the quadrature loop is to cause the voltage flux to lead exact quadrature by an angle denoted by α. This angle varies and the value to which it is adjusted depends on a number of conditions. The meter is suitable for measuring correctly on low power factors when the position of the quadrature loop is so adjusted that the disc is stationary with the load on the meter adjusted to zero power factor. It is then usually assumed that the voltage flux is in exact quadrature with the voltage. This assumption would be correct, however, only if the disc reactance were zero or negligible, and it has been demonstrated in what has gone before that the reactance is not negligible but may have a very considerable effect on the behaviour of the meter under certain conditions.

One conclusion which was drawn from the frequency tests was that the adjustment of the quadrature loop for standstill at zero power factor would depend on the time-constant of the disc. Tests were made to verify this, and it was found that if the loop was correctly adjusted for the standard aluminium disc, and then the thick copper disc substituted without any other alteration, the copper disc rotated forward. When the loop was correctly adjusted for the copper disc, and the aluminium disc substituted, the disc rotated backward. It therefore appeared that the actual phase of the voltage flux required depended on the time-constant of the disc used, and on the frequency. With the loop removed altogether it was found that at zero power factor at a frequency of 50 the standard aluminium disc rotated backwards, and the thick aluminium disc rotated forwards. It is shown later that the phase of the active voltage flux is not affected by changing the disc, and this suggests that the time-constant of the eddy-current path between the voltage poles is not the same as that between the current poles. That is, θ_V is not of the same value as θ_I. If θ_V were equal to θ_I the position of the power-factor corrector would be the same for all discs.

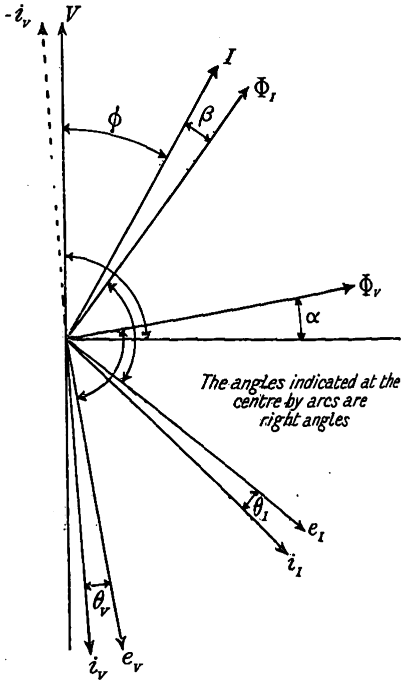

FIG. 13.

Reverting to the vector diagram, the eddy-current paths have time-constants T_V and T_I, not necessarily equal, causing the eddy currents to lag behind the induced e.m.f.'s by angles θ_V and θ_I respectively.

The torque is proportional to

$$\Phi_I i_V \cos(\phi+\alpha+\beta-\theta_V)+\Phi_V i_I \cos(\phi+\alpha+\beta+\theta_I)$$

$$=\Phi_I\frac{e_V}{R_V}\cos\theta_V\cos(\phi+\alpha+\beta-\theta_V)$$

$$+\Phi_V\frac{e_I}{R_I}\cos\theta_I\cos(\phi+\alpha+\beta+\theta_I)$$

and since e_V and e_I are $\propto \Phi_V$ and Φ_I respectively, the torque is

$$\propto \Phi_V\Phi_I\left[\frac{1}{R_V}\cos\theta_V\cos(\phi+\alpha+\beta-\theta_V)\right.$$

$$\left.+\frac{1}{R_I}\cos\theta_I\cos(\phi+\alpha+\beta+\theta_I)\right]$$

Now R_V and R_I are not necessarily equal, but they do not differ by more than a few per cent, and since the curves obtained are not curves of absolute value, but rather curves of change of absolute value, the error in assuming R_V equal to R_I will not be great. This can be seen more clearly, perhaps, from the following:—

The torque is proportional to

$$\Phi_V\Phi_I\left[\frac{1}{R_V}\cos\theta_V\cos(\phi+\alpha+\beta-\theta_V)\right.$$

$$\left.+\frac{1}{R_I}\cos\theta_I\cos(\phi+\alpha+\beta+\theta_I)\right]$$

Assuming that $R_V = R_I$, this becomes

$$\frac{\Phi_V\Phi_I}{R_V}[\cos\theta_V\cos(\phi+\alpha+\beta-\theta_V)$$

$$+\cos\theta_I\cos(\phi+\alpha+\beta+\theta_I)]$$

and the difference in the value of the two equations, due to the change in the value of the cosine terms, will not differ by more than a few per cent—not a serious error, since the changes themselves are small.

Experiments were next carried out to determine the values of the various phase angles assumed. It is obviously best to carry out such tests at or about zero power factor, for here the angles have their greatest effect.

The first experiments were made at zero power factor, as indicated on a Duddell-Mather wattmeter, and the speed of the disc was determined. This method did not prove successful on account of the friction with the heavy discs being comparable with the driving torque. The procedure was therefore altered and the power factor adjusted until the torque on the induction meter was as near zero as could be determined, after which the watts were read on the standard wattmeter. It was found that the removal of the brake magnets greatly increased the ease of working and the accuracy of the determinations and, so far as could be ascertained, did not affect the results.

Let ϕ_S be the phase angle between V and I when the induction meter indicates zero power factor; also let $\phi_S = 90° - \gamma$.

The torque on the disc is zero, and therefore

$$0=\cos\theta_V\cos(\phi+\alpha+\beta-\theta_V)$$

$$+\cos\theta_I\cos(\phi+\alpha+\beta+\theta_I)$$

and $$\phi=\phi_S=90°-\gamma$$

Substituting, we get

$$0=\cos\theta_V\cos(90°-\gamma+\alpha+\beta-\theta_V)$$

$$+\cos\theta_I\cos(90°-\gamma+\alpha+\beta+\theta_I)$$

$$=\cos\theta_V\sin(\theta_V+\gamma-\alpha-\beta)$$

$$+\cos\theta_I\sin(\gamma-\alpha-\beta-\theta_I)$$

If θ_V and θ_I are assumed to be small angles, and their cosines very nearly unity, the equation can be reduced to

$$0=\sin(\theta_V+\gamma-\alpha-\beta)+\sin(\gamma-\alpha-\beta-\theta_I)$$

without incurring any serious error. The solution of this equation is

$$\gamma=\alpha+\beta-\tfrac{1}{2}(\theta_V-\theta_I)$$

This equation and procedure were then used to deduce separately the values of the various phase angles assumed and to determine the effect of frequency on the angles.

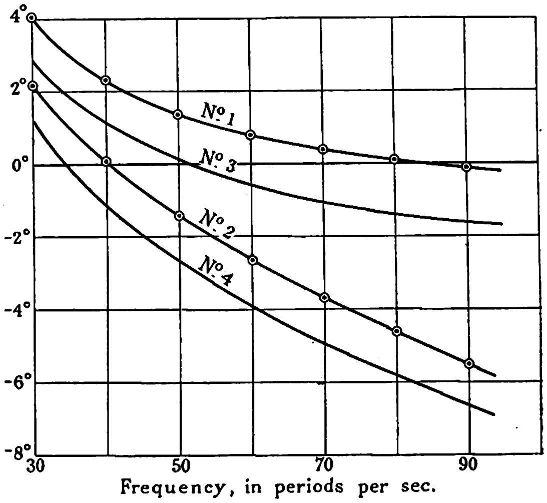

FIG. 14.—Curves of γ/frequency:—

(1) for standard corrugated aluminium disc with power-factor loop removed.
(2) for standard aluminium disc with power-factor loop in position.
(3) for thick copper disc with power-factor loop removed.
(4) for thick copper disc with power-factor loop in position.

Effect of Power-factor Adjustment.—With the power-factor adjustment removed, a curve connecting γ and the frequency was obtained experimentally for the standard corrugated aluminium disc. The power-factor adjuster was then replaced, and a second γ/frequency curve obtained. These curves are shown in Fig. 14, curves 1 and 2.

At any particular frequency the value of β is the same for both curves, and, since the same disc was used in both tests, the values of θ_V and θ_I are the same for both curves. The only change therefore is in the value of α, due to the addition of the power-factor adjuster. Therefore the difference between the two γ/frequency curves gives the effect of the power-factor adjuster on the phase of the voltage flux. This is shown in Fig. 15.

Without altering the position of the power-factor adjuster, this disc was removed and the thick copper disc put in its place. With the power-factor adjuster still in the same position, a γ/frequency curve was obtained. A second γ/frequency curve was obtained after the power-factor adjuster had been removed.

The curves obtained are shown in Fig. 14, curves 3 and 4. Points showing the difference between these two curves are plotted in Fig. 15, and they are coincident with the curve already deduced from the experiments on the standard disc.

The conclusion to be drawn from this is that the effect of the power-factor adjuster on the phase of the voltage flux, for any given position of the adjuster, is not affected by the nature of the disc used in the meter. For any other position of the adjuster the slope of the curve will be different, but it was found that all the curves are practically straight lines passing through the point (O, O).

Effect of Resistance of Voltage Coil.—The inductance and resistance of the voltage coil were determined to be 2·4 henrys and 48 ohms, respectively.

The theoretical effect of the resistance of the winding on the phase of the voltage flux can easily be calculated for any frequency.

The voltage pole shown in Fig. 9 does not carry the total flux produced by the voltage coil, but only a leakage flux. The main flux passes in a good iron circuit, thereby increasing the inductance of the coil without increasing its resistance. In order to determine the effect of the resistance of the coil on the phase of the leakage flux, it was decided to determine the effect of artificially increasing the resistance.

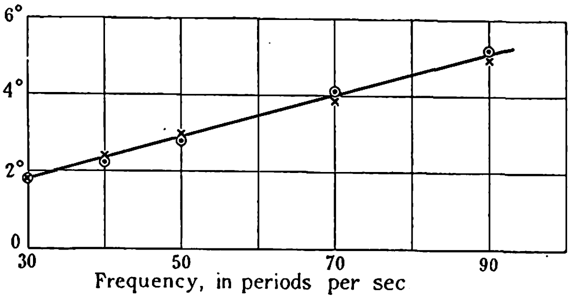

Fig. 15.—Curve connecting the variation in lag of the voltage flux due to the power-factor loop, with frequency. Points marked × are deduced from curves 3 and 4, and points marked ⊙ from curves 1 and 2 in Fig. 14.

The tests were made on a meter from which the power-factor adjuster had been removed. The reason for removing the adjuster was that it is very difficult to replace it in exactly the same position every time.

Curves of γ/frequency for two discs, in the normal meter, have been given already in Fig. 14. Tests for these curves were repeated, but with a resistance of 50 ohms connected in series with the voltage coil. The original curves, 3 and 4, and the new curves, 1 and 2, are shown in Fig. 16. The difference between the two curves for the same disc gives the decrease in lag of the flux due to the increased resistance (Fig. 17).

The resistance of the voltage coil is 48 ohms, and the added resistance 50 ohms. Remembering that at these small angles the sine of the angle is very nearly proportional to the angle, the effect of the added 50 ohms may be considered to be equal to that of the 50 ohms (approx.) of the voltage coil itself.

In Fig. 17 there is given also a curve calculated from the resistance and inductance of the coil. Although the experimental curve is not coincident with the calculated curve, the difference does not appear to be greater than the expected errors of observation.

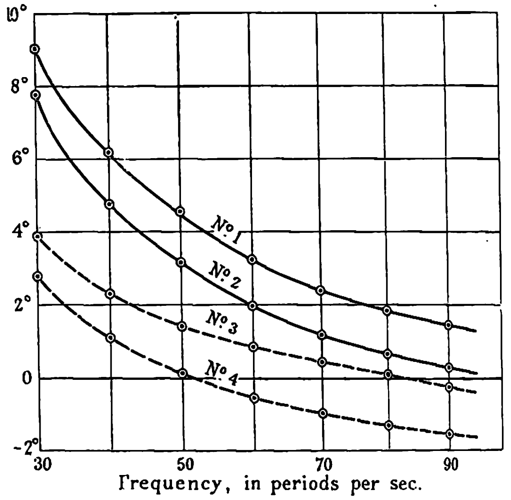

Fig. 16.—Curves of γ/frequency for meter, showing effect of added resistance in voltage circuit:—

(3) standard aluminium disc, no added resistance.
(1) standard aluminium disc, 50 ohms added resistance.
(4) thick copper disc, no added resistance.
(2) thick copper disc, 50 ohms added resistance.

Effect of Iron Losses in Voltage Pole.—This was estimated and found to be negligible.

Effect of Iron Losses in Current Pole.—This makes the flux lag behind the current by an angle which has been denoted by β. To determine this angle, the value of γ was obtained at three loads for each of a number of frequencies. These values of γ were plotted against the load and the curves were extended back to the point at which the load was zero. At this point β is also zero, and therefore any increase in γ is due to the angle β.

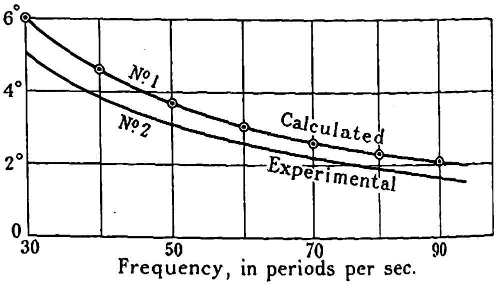

Fig. 17.—Curves showing phase alteration of voltage flux due to resistance of voltage coil.

β appears to be about 0·5° at 30, and 1° at 100 periods per sec. These figures are small and, having regard to the manner in which they are obtained, must be considered as approximate only.

CONCLUSIONS.

From the behaviour of the meters on varying frequency the authors conclude that induction meters may be expected to register slower on distorted than on sinusoidal wave-shapes. The results given in the paper previously referred to * show that all the induction meters tested register slower on distorted waves. In the discussion on the paper, Mr. L. Wild attributed the uniform slow running of the meters on distorted waves to the fact that all the waves used were not smooth waves but had what he termed "architectural features" on them. He himself had found that induction meters registered sometimes faster and sometimes slower on distorted, but smooth, waves than they did on sinusoidal waves. The variations in accuracy obtained by Wild were comparatively small, as were also those obtained by Rosa, Lloyd and Reid at Washington;† and the authors are inclined to attribute them to inconsistencies in the meters themselves, or to changes in the iron losses, or to both.

It would appear from the results and deductions that, in order to reduce the frequency errors in the meters, certain points must be kept in mind in the design. First, the ratio of the active voltage flux to the permanent brake-magnet flux should be kept as low as expediency will permit. Secondly, the time-constant of the eddy-current paths should be as low as possible, consistent with a reasonably high torque. Since a reduction in the active voltage flux would result in a reduced torque, it would appear that the point first mentioned should be effected by means of stronger brake magnets. This would result in lower speeds—a desirable feature in some types of meters.

The authors have not attacked the problem of the additional errors shown by induction meters when working at other than unity power factor at various frequencies. It would appear that the present method of power-factor correction leaves something to be desired. The meters are adjusted at one particular frequency, and it is possible that at higher frequencies the errors introduced by the correctors may be equal to, if not greater than, those which they are intended to eliminate.

The usual theory of induction watt-hour meters assumes that certain factors, such as the phase of the voltage flux and the time-constant of the eddy-current paths, are practically those that would hold in an ideal meter. The authors have shown that these assumptions are not justified even in modern, well-designed meters. In the case of the thick copper disc and the thick aluminium disc the time-constant is about 0·0008, and at a frequency of 50 the current would lag by an angle of about 14°. At a frequency of 100 the angle would be about 27°, and these angles are comparatively large.

The authors wish to express their indebtedness to the Principal and Governing Body of the Manchester College of Technology for facilities for carrying out the experiments described in the paper.

DISCUSSION BEFORE THE METER AND INSTRUMENT SECTION, 7TH MARCH, 1930.

Mr. E. Fawssett: The figures given on page 1029 are remarkably accurate. Two very small differences between large quantities, which in one case are less than 2 per cent apart, are divided one into the other. The result obtained is found to be within 2 per cent of the theoretical value. On page 1030 the effect of altering the compensation is considered, and it follows from the tests described that where a meter has good shunt-coil and magnetic characteristics it is possible to choose a disc requiring no other compensation at all. This has actually been done and a meter with good inherent characteristics, requiring no extra compensation whatever, was the result. The curves of Fig. 14 show very clearly that the best meter is the one with the smallest initial inherent errors for which compensation has to be made. Similarly, Fig. 16 indicates that a meter with a shunt coil of the minimum resistance gives the best performance, and, incidentally, why the high-class British meter has an advantage over the Continental meter, which is usually equipped with a shunt coil of much higher resistance. At the end of the paper angles of 14° and 27° are given for the lag of the eddy currents in the thick discs at 50 and 100 cycles; as these values seemed to be large, I tried to think of a way of checking them experimentally. Mr. Richardson, one of my technical assistants in meter development work, suggested a method which employed a Metropolitan-Vickers meter of the type used by the authors, with its disc and compensator in place. The latter was adjusted for correct quadrature at zero power factor, the disc was removed, and a wound rotor consisting of two coils wound in opposite directions and held in place by two thin mica discs was substituted. A current (which represented the eddy currents and occupied the same position in space) was led in from outside by flexible ligaments, the substituted rotor being sufficiently free to move to a position of balance. The power factor was varied until the zero-torque point was reached with the coils at the maximum position, at which stage the phase of the disc eddies should have been 91° behind that of the series current, or 1° behind that of the voltage which induced them. For the disc mentioned by the authors the corresponding figure was 14°, and in case the discrepancy was due to the absence of the disc one of these was inserted as well. A change of less than 1° was the result, so that the angle obtained seemed to be very much less than that given in the paper. I should be glad if the authors could point out the cause of the divergence. On the general question of the effect of frequency change at unity power factor, the performance of the meters available on the British market is exceedingly variable. On the North-East Coast some 100 000 existing meters will have to be changed over from 40 to 50 cycles per sec. before long, and it has been necessary to choose types that can be left in circuit until the individual periodic change of each is due to take place. On 11 types of meters, British and foreign, selected from those which are available in this country, it was found that when the power factor adjustment had been set correctly for 40 cycles per second the error at the higher frequency varied from 2·1 per cent fast to 2·3 per cent slow; thus the various meters fall on different parts of the authors' characteristic curves. I agree with them that the torques in an induction meter are both positive and not opposing. To explain this, consider a meter circuit in which the main current I and the main voltage V are in phase (see Fig. A). The flux due to I is substantially in phase with it, but that part which cuts the disc lags slightly behind and induces an e.m.f. in the disc which lags by 90°. The eddy currents (b) due to the latter lag slightly more and these, which we may call "disc series eddies," are acted upon by the disc shunt flux (a) so as to produce a torque proportional to the vector product of (a) and (b). These vectors are substantially, but not in all cases necessarily, exactly in phase. The disc shunt flux (a) also induces an e.m.f. in the disc which lags by 90°, and the resultant eddy currents (d) have a further slight lag. These, which we may call "disc shunt eddies," react with the disc series flux (c), and it is because the two vectors are in opposition that the idea of the negative torque has grown up. It has, however, been overlooked that these eddy currents are displaced 180 electrical degrees in position on the disc; thus a flux having a given direction at any moment is in this case reacting with the opposite side of the eddy ring, so that this torque is proportional to $cd \cos (180 - \phi)$ or $c'd \cos \phi$, where ϕ is a small angle such that θ and ϕ together exercise the minimum effect at unity power factor in the circuit. Both torques are positive at unity power factor (see Fig. B): they are portions of sine curves, 90° apart, and their resultant has a peak of twice the frequency. I have endeavoured to give an alternative way of regarding this problem, which has apparently puzzled electrical engineers for some time, and I hope that my presentation confirms the authors' argument. I have always believed their solution to be the true one, and that the theory championed in books by well-known authorities, to the effect that the torques were opposing, was really founded upon a misconception.

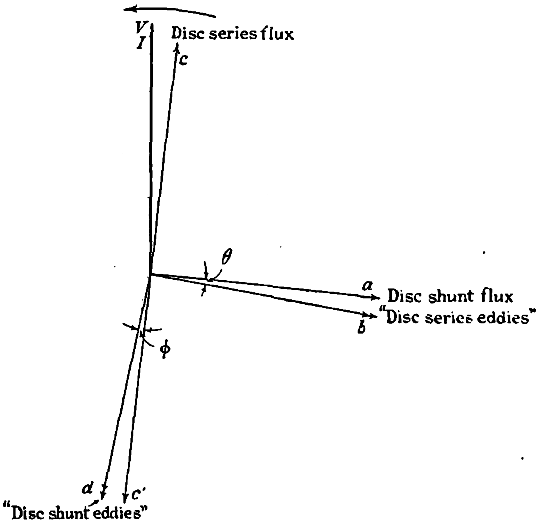

FIG. A.

Mr. W. Lawson: I have been familiar for many years with this phenomenon of variation in induction meters with changes of frequency, and some time before the War carried out experiments in connection with it. I selected two meters designed for 25 cycles per sec. (one was manufactured by Metropolitan-Vickers, Ltd., while the other was of foreign origin), and tried the effect of increasing the frequency to 27 cycles per sec. With the Metropolitan-Vickers meter the change was + 0·8 per cent at unity power factor and + 5·5 per cent at 0·25 power factor. Under the same conditions the other meter registered changes of + 1·4 per cent and + 13·7 per cent respectively. The results afforded striking evidence as to the effect of changes of frequency. Recently I had to deal with the unusual case of a supply system which was temporarily on 25 cycles per sec. and after about two months was to be changed over to 50 cycles. The district had only recently been opened up and a considerable number of meters had to be fixed immediately. Only 50-cycle meters were available and it was decided to adjust these temporarily for 25 cycles. The shunt coils became rather hot but fortunately they were able to stand the conditions, and of course the meters ran very slow. The braking system of these meters consisted of a pair of brake magnets with their poles opposed, and in order to reduce the flux across the gaps a wedge-shaped piece of strip iron was used to bridge across the poles of the magnets situated above the disc. All the tester had to do was to move the strip until the correct position had been reached. When the supply was changed from 25 to 50 cycles per sec. it was only necessary to remove the piece of iron and the meter was then adapted to suit the new conditions. The method was rather rough-and-ready and might be open to criticism on account of the change in the brake flux. No undue risk was, in fact, taken as the meters themselves were ultimately all removed, but it is interesting to note that on appreciable permanent alteration in the meters had taken place. The question of wave-form is undoubtedly connected with this subject. At the time of the paper by Messrs. Ratcliff and Moore [*] it was thought, and

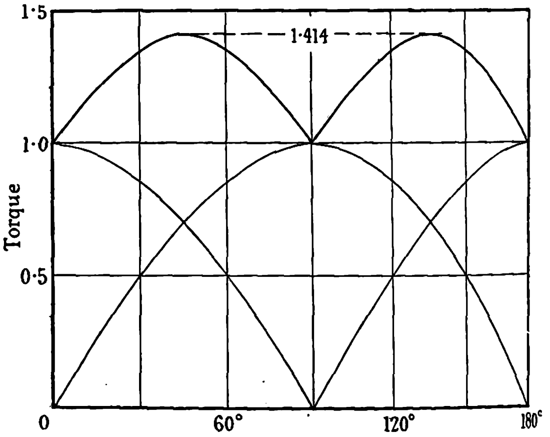

FIG. B.

---

[*] *Loc. cit.*

rightly so, that meters susceptible to change of frequency would turn out also to be susceptible to changes of wave-form. At that time I had contemplated the purchase of a 3-phase double generator set for a.c. meter testing, but as the oscillograph proved the wave-form to be very irregular I was rather dubious about acquiring such a machine. In order to come to a definite conclusion, I decided to carry out tests with this machine on some meters that were much affected by changes of frequency and compare the results with similar tests on the same meters carried out with the machine at the National Physical Laboratory, the wave-form of which was beyond question. The greatest difference in an average of about 6 readings in each series was of the order of 0·18 per cent. I consider the test to be proof that the wave-form of the machine was satisfactory. The method formed a practical way of dealing with testing apparatus the wave-form of which was in doubt, and the machine in question, judged by the standard of the N.P.L. and most of the manufacturers, is undoubtedly quite suitable for its purpose. Before carrying out the test it was necessary to test the meters for constancy, and this took about 4 months. I first found that the frequency of the supply on which they were being tested was subject to variation, then that there were very small variations in the indication of the wattmeter, and finally that the stop-watch which I was using was not at all times reliable. Having eliminated all the sources of error, a very large number of readings was taken before I could be satisfied as to the constancy of the meters. The effects of variations of frequency, as shown by the curves given in the paper, are interesting and it is clear that the better performance of the thin discs is due to the fact that the higher resistance tends to swamp the reactance of the disc. The reactance produces the drooping curve and the employment of a thin disc delays this effect until the higher frequencies are reached, as shown in Fig. 8B, which gives the curves for an aluminium standard disc and a thick Eureka disc. With regard to the theory of the induction meter, it appears to me that the meter follows essentially the same law as the induction motor. The chief difficulty is in visualizing a rotating magnetic field, and it would appear that this expression is misleading, for what we have, in effect, is an oscillating field. Taking the case of the permanent-magnet brake system, we have here a reverse torque produced by a disc passing through a gradually increasing and then gradually diminishing magnetic field. If the permanent magnet were rotated it would drag the disc along with it and produce rotation. The actions of the voltage and current fluxes would appear to produce a field which sweeps along the disc in waves of varying intensity, and so creates a condition which will generate the eddy currents necessary to produce driving torque.

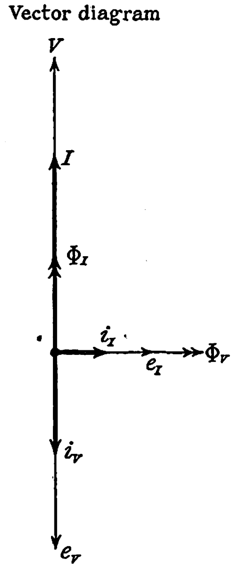

FIG. C.

LIST OF SYMBOLS.

V = applied voltage.
I = current in series coils.
Φ_V = flux due to applied voltage (V).
Φ_I = flux due to current (I).
e_V = induced voltage in disc due to Φ_V.
e_I = induced voltage in disc due to Φ_I.
i_V = induced current in disc due to Φ_V.
i_I = induced current in disc due to Φ_I.

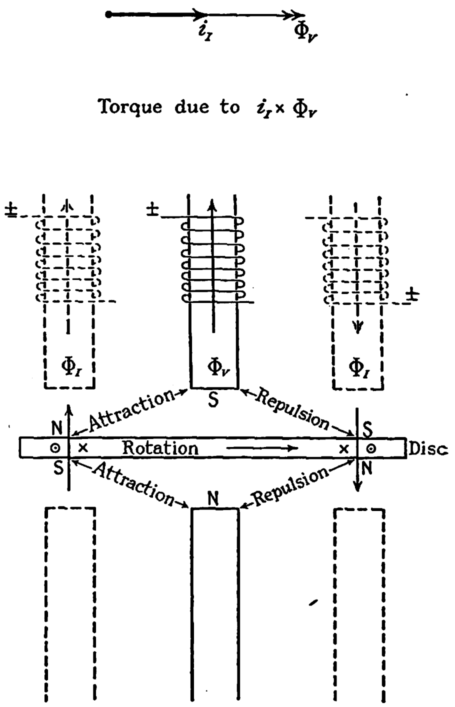

FIG. D.

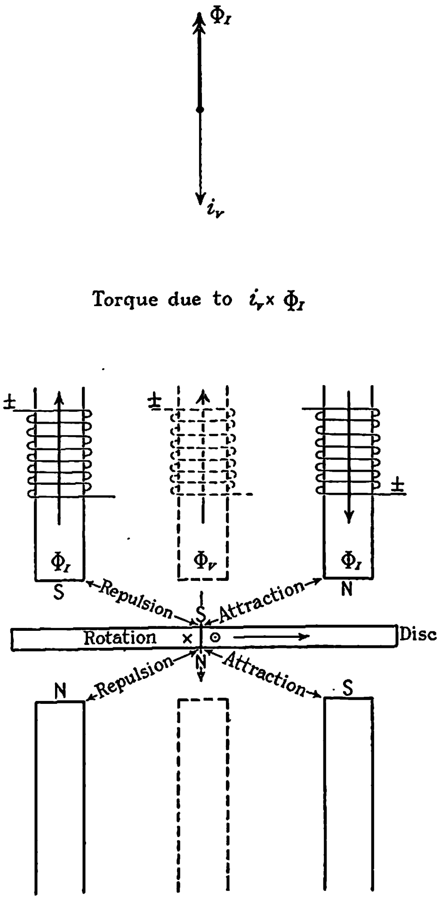
Mr. G. F. Shotter: According to the authors, several writers contend that the two torques, produced by the action of the shunt flux on the flux due to the series eddy-currents and the series flux on the flux due to the shunt eddy-currents, respectively, are in opposition. I endorse the authors' contention that this is not so and that the torques are in the same direction. I should like to put forward an explanation of my own theory of the induction watt-hour meter. In Fig. C is given the general vector diagram of the voltages, currents and fluxes of a perfect meter under unity power-factor conditions. It will be understood, however, that the imperfections of a commercial meter do not in any way interfere with the reasoning on which I base my theory. To simplify matters, Figs. D and E show the fundamental magnetic elements of an induction watt-hour meter consisting of one main shunt-magnet excited from the source of potential and two magnets excited from the current, which is in phase with the source of potential.



Torque due to $i_V \times \Phi_I$

Fig. E.

A little consideration will show that the potential and current elements could be interchanged without any alteration to the theory. It will be seen from the vector diagram that the flux from the shunt element is in quadrature with the applied e.m.f. Before proceeding with the explanation of the diagrams it will be as well to consider the following points: (1) A continuous torque can only exist between two in-phase fluxes. (2) Although an instantaneous torque does exist between two fluxes 90° apart, the resultant torque over one complete cycle is zero. (3) Any two fluxes can be split up into in-phase and out-of-phase components, but only the in-phase components can be considered. It is, of course, assumed that these fluxes are not coincident in space. (4) Alternating fluxes in phase can be replaced, for simplification, by magnets excited by direct current or by permanent magnets. (5) It should be noted that a continuous torque-producing flux can be either in phase or 180° out of phase, the effect being produced by attraction instead of repulsion, or vice-versa. The relationship between the torque-producing fluxes will be observed from the vector diagrams of Figs. D and E. These figures are self-explanatory and give the correct polarity not only of the windings but also of the fluxes concerned. Figs. D and E further show that the two continuous torques produced by $i_I\ \Phi_V$ and $i_V\ \Phi_I$ are in the same direction and, in the case of a disc of dimensions sufficient to cause no restriction to the eddy lines, the two torques should be practically equal. Since putting forward this theory I have carried out an experiment in an attempt to prove its correctness. This is illustrated in Figs. F and G. The experiment was carried out on a commercial meter in which the metal disc was replaced by a mica one. Upon this were placed three copper rings in such a position that two of these came under the series iron and the other—at the opposite side of the disc—could be brought separately under the shunt iron. It was found that in both cases the rotation was always in the same direction, and also that the torques produced by the two causes were approximately the same. It will be seen from the expression of the torque values that the equality of the torques is independent of the relative values of the shunt and series fluxes. It is interesting to point out that the torque impulses on the disc are of four times the frequency. In connection with the effect of wave-form the authors will, I think, agree that it is generally accepted that the errors are due to (*a*) the pure frequency effects, and (*b*) saturation. This explanation, however, seems difficult to apply to the results which I obtained a few years ago on one particular type of meter having variations as large as 2 per cent at 1/20th full load, the variation being approximately inversely proportional to the load. The wave-form of the supply was not abnormal, but it probably contained a third harmonic, as it was from a delta/star power transformer. It appeared to be produced entirely by the shunt system and to be due to the use of solid return paths. I should be glad to know whether the authors have noticed any phenomena of this nature.

Mr. Wilfred Holmes: All supply stations in this country will shortly be operating at 50 cycles per sec. It would therefore appear, on first consideration, that the frequency error in meters is not now very important. The author rightly points out that the study of frequency variation is a key to the solution of the problem of wave-form error in meters. He does not deal in detail with the effect of the quadrature loop (the lagging coil or copper stamping which usually goes round the shunt pole) upon frequency errors. For some time a meter manufacturer in this country made meters without quadrature loops. In one design the pole pieces were of cast iron and the quadrature adjustment was made by adding resistance in series with the potential circuit. This meter had a curve similar to curve II, Fig. 1, except that the fastest point was at 83 cycles. I refer to this fastest point as the " frequency-curve peak." In another design of meter the fastest point was at 33 cycles.

This meter had laminated poles and no quadrature loop, the quadrature adjustment being made by means of a specially shaped tongue-piece placed between the two series poles and carrying part of the shunt flux. This latter meter was designed for use in cases where accuracy on both 25 cycles and 50 cycles was required, and although it was fast on 33 cycles it was particularly useful for supply stations which were to change over from 25 cycles to 50 cycles. In meters generally, in order to comply with B.E.S.A. requirements regarding change of frequency, it was found necessary to vary the thickness of the discs, and thus 20-mil discs for 100 cycles, 40-mil discs for 50 cycles and 60-mil discs for 25 cycles had to be supplied. The authors have explained why this was necessary and have shown the theory to be in line with practice. It is well known that an induction meter should be accurate on change of frequency, because, as has been pointed out, the potential coil acts like an iron-cored impedance coil and with a fixed voltage the flux decreases with increased frequency; as the eddy currents in the disc are proportional to flux × frequency, the torque should not alter with frequency. This is clearly explained on page 1025 of the paper, and it is shown that the speed variation produced by a change of frequency is due to the voltage flux acting as a brake on the disc. The braking can only occur if the disc rotates, so that from this point of view it would be more accurate if the meter could register with the disc stationary. The obvious solution is to reduce the speed, and that is why the modern meters run at 12 instead of at 40 r.p.m. This is confirmed on page 1033 of the paper.

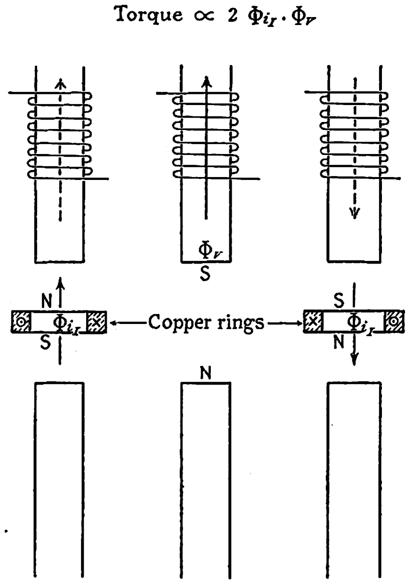


Fig. F.

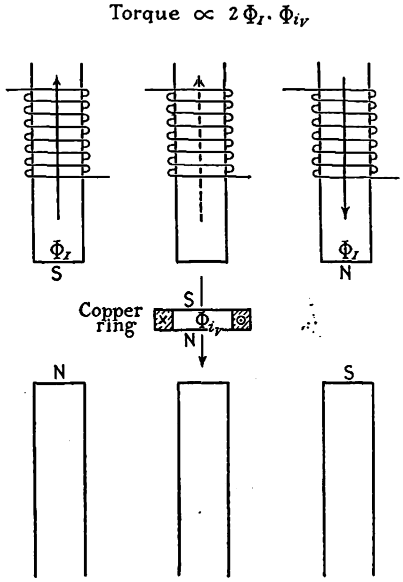

Fig. G.

Let $\Phi_V = \Phi_{i_V} = 100$ units, and $\Phi_I = \Phi_{i_I} = 10$ units.
Then $2\,\Phi_{i_I}\,.\,\Phi_V = 2\,000$ units, and $2\,\Phi_I\,.\,\Phi_{i_V} = 2\,000$ units.

Mr. S. Garbutt (*communicated*): The authors refer to tests carried out in 1911 on induction watt-hour meters with alternating currents of different wave-shapes. The meaning of this does not become clear until actual reference is made to the paper quoted, which points out that the wave-forms of both voltage and current of the supply used in the tests were distorted. This is a different problem from the distortion of only one of the wave-forms, and it has been shown by Mr. R. G. Isaacs * that in a circuit where the voltage wave-form is sinusoidal, but the current wave-form is badly distorted, the registrations of induction watt-hour meters are within the usual limits of accuracy. The initial examination of the curves in Figs. 1 and 2 leads to the opinion that, although the induction watt-hour meters may conform to the usual limits of accuracy when tested at their rated frequency, they are appreciably inaccurate if the wave-forms of pressure and current of the supply are distorted. Further comparison of the curves for meters I and II respectively shows that under certain conditions the errors may balance each other to some extent, but that meter No. III would under-register in any circumstance of distorted wave-form. If meters register in the consumers' favour, due to distorted voltage and current wave-forms, in the near future the majority of supply undertakings will be purchasing their electrical energy in bulk supply through meters. A suggestion of practical value was put forward by Mr. J. T. Irwin (who is referred to on page 1023)—to the effect that "each type of meter should be tested at frequencies much higher than those at which it is to be used, and rejected if not up to a definite standard." I should like to ask the authors whether they know what is the wave-form of the current in the pressure coil of an induction watt-hour meter when the voltage applied to the coil has a sinusoidal wave-form.

---

* *Proceedings of the Meter Engineers' Technical Association*, 1928, vol. 2, p. 80.

Messrs. A. E. Moore and **W. T. Slater** (*in reply*): The discussion shows that there is general agreement with our contention that the theory of the induction meter, when treated from the point of view of alternating fluxes stationary in space, shows that the two resultant torque components are in the same direction. It would appear that the fallacy of the theory of opposing torques is due to vector diagrams which show only the time phase of the fluxes and currents, whereas to obtain the directions of the resultant torques it is necessary to consider not only the time phase but also the space phase of the fluxes and currents. The theory of the meter responds equally to the moving-field conception and the same conclusions obtain, as, of course, they should do.

Mr. Fawssett supports our conclusions that the best performance is obtained on meters requiring least compensation. It may be noted that the theory of the perfect induction meter shows that the behaviour of the instrument is quite independent of frequency and wave-shape. Mr. Fawssett questions the probability of the angle of lag of the eddy currents in the thick copper disc being of the order of 14° at 50, and 27° at 100 periods. The angles are calculated in the usual way from the value determined for the time-constant of the disc, and the frequency, and it may be noted that the values have been used in the calculations for the curves given in Fig. 7. The conditions obtaining in the wound rotor and in the disc may be quite different, since in the wound rotor the eddy-current path is defined whereas in the disc it is not. Presumably, the torque will depend upon the position of the currents in the disc, and it may be that, with higher frequencies, the eddies spread out into paths of greater radius. Such a change in position could not take place in a wound rotor; but what effect this consideration would have on the theory which we have set forth has not yet been investigated. That some makes of meters run faster and some slower when the frequency is increased above the normal for the meters can be deduced from the curves given in Figs. 1, 2 and 3.

The figures given by Mr. Lawson for the variation in accuracy of meters when the frequency is changed from 25 to 27 periods per sec. may be expected, and may be deduced from the theory of the meters. The variations are usually greater in those meters normally designed for 25 periods than in meters for, say, 50 periods. A first-class induction watt-hour meter, correctly adjusted, gives excellent results when used at the frequency for which it has been adjusted, but it may have large errors if used at other frequencies, particularly if the power factor is not unity. One of the authors has occasionally had to test induction meters which have been used in tests on loads at frequencies considerably different from that for which the meters have been adjusted. In some cases, small changes in the frequency or in the power factor have resulted in such large changes in accuracy that it has been impossible even to approximate to the correct results. Mr. Lawson's account of his procedure with reference to the change-over meters indicates some of the problems presented to the meter engineer and his ingenuity and resource in meeting them.

Mr. Holmes refers to what he terms the "frequency-curve peak" and cites cases where this occurs at frequencies of 83 and 33 respectively. A study of the theoretical curves given in Fig. 7 explains why the peak occurs at different frequencies with different shunt magnets and discs. The use of different discs for different frequencies is interesting and, as Mr. Fawssett points out, our experiments show that it would be possible to select a self-compensating disc for a particular meter.

With reference to the point raised by Mr. Garbutt in connection with the wave-form errors in induction meters, we would point out that the conclusions attributed to R. G. Isaacs were indicated by J. T. Irwin in the 1911 paper.* We do not quite understand the object of Mr. Garbutt's question relative to the wave-shape of the current in the shunt coils. The wave-shape may easily be determined by means of an oscillograph, but it is the wave-shape of the shunt flux which is of importance. Provided that the iron and copper losses in the shunt system are small, then with a sinusoidal wave of voltage there will be a sinusoidal wave of flux. If the winding were highly resistive there would be a tendency for the shunt-current wave to be sinusoidal with a sinusoidal voltage and, since the permeability of the iron is not constant, the resultant flux wave would not be sinusoidal. It may be that the bad effect of distorted waves on some meters is due in some measure to the distortion of the shunt-flux wave brought about by a highly resistive shunt coil.

Mr. Shotter gives another interesting method of explaining the theory of the induction meter. We do not quite understand what is meant in the last part of his remarks by a certain meter "having variations of 2 per cent at 1/20th full load," since he does not state whether the meter was tested on more than one source of supply.

* *Loc. cit.*

SOME DEVELOPMENTS OF THE THERMIONIC VOLTMETER.*

By E. B. Moullin, M.A., Associate Member.

(*Paper first received* 28*th January, and in final form* 22*nd April,* 1930.)

Summary.

In this paper the various ways are considered in which a 3-electrode valve should be used in a thermionic voltmeter, and the accumulated experience is described of several years' work by the author in making valve voltmeters for various purposes. No one arrangement can possess every desirable property, and it is shown how to produce a voltmeter to fulfil specified requirements. The effective input resistance of the various arrangements, and the harmonic currents produced by grid current, are considered analytically and experimentally. The effect on range and sensitivity of providing additional batteries is also discussed, extra batteries being found to be an advantage only in very low-range instruments.

The effect on the calibration of a change in the valve and in temperature is found to depend on the form of the rectifier used. In general, a thermionic voltmeter cannot read R.M.S. values. The wave-form error of various systems is investigated; with one arrangement the reading is proportional to the peak voltage and in another to the mean. The possibility of a frequency error is discussed; tests show that the error is negligible for frequencies up to 1 000 kilocycles per sec., whilst from indirect tests it would appear that the error is probably negligible for frequencies up to 30 times this value.

(1) Introduction.

A rectifier, such as a crystal or thermionic valve, may be used to make an alternating voltage perceptible to a polarized galvanometer, and in recent years these have been combined to produce a satisfactory voltmeter. The thermionic valve, with either two, three or four electrodes, possesses great potentialities for voltmeter use, and this paper explores some of the most desirable.

The ideal a.c. thermionic voltmeter should possess the following properties. It should be as portable as a d.c. ammeter and be permanently calibrated; it should possess great sensitivity and wide range and be unaffected by a steady voltage between its terminals; its input resistance should be infinite, and its readings should be proportional to the R.M.S. value of any wave-form and unaffected by frequency.

By a suitable choice of valve, batteries and galvanometer, most of these desirable attributes can be secured, but they cannot all be secured simultaneously. Simplicity and portability are two of the most desirable attributes: the fixed location inevitable with a table full of semi-portable apparatus imposes severe limitations on the use of a thermionic voltmeter, and therefore it must be worth while to design portable instruments, even though they may possess limitations which are well understood. The same consideration underlies much of the art and skill of instrument design; for example, the silver voltameter and current balance may be the most perfect ammeters known, yet their sphere of application is vastly more limited than that of a direct-reading pivoted instrument.

We shall now consider how to make portable thermionic voltmeters having the least number of features which will in general be undesirable.

(2) Elimination of Unessential Batteries and Method of Reproducing Calibration Conditions.

A thermionic voltmeter must have a battery to heat the filament and to this extent cannot be as portable as a moving-coil voltmeter. But this battery need not supply more than, say, $0 \cdot 1$ amp. at 3 or 4 volts; it can therefore be a small dry battery and the inconvenience of this is not overwhelming. Additional batteries are not essential to the working of the voltmeter. We shall therefore postulate a problem as follows: Given a galvanometer, thermionic valve and filament battery, to produce a voltmeter which shall possess the greatest possible number of desirable qualities.

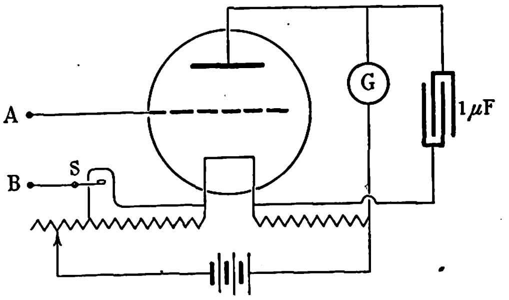

Fig. 1.

The instrument is to be permanently calibrated and provision must therefore be made to reproduce the conditions, in respect of filament current, anode and grid potential, which obtained at the time of calibration. If connections basically like those depicted in Fig. 1 are used we may reproduce the exact calibration conditions by adjusting the filament rheostat until the galvanometer in the anode circuit deflects to a marked point on the scale. It is convenient to provide a testing switch (marked S in Fig. 1) which temporarily removes the grid bias and so enhances the test-point deflection. The sensitivity of the galvanometer must at least be sufficient to produce an adequate deflection for the test point. With ordinary valves, this usually entails that the galvanometer shall be as sensitive as it is possible to make a portable unipivot instrument.

---

* The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

(3) LIMITATIONS OF RANGE.

Consider the system of Fig. 1. An alternating voltage applied between A and B produces an increase of mean anode current which is proportional to the square of the applied voltage when this voltage is very small. The lower limit of range depends, therefore, on the sensitivity of the galvanometer; in a portable voltmeter equipped with a unipivot instrument the smallest detectable current is of the order of 0·25 μA, and this will be produced by an applied p.d. of about 0·1 volt (R.M.S.) Provision of additional anode potential will not alter this sensitivity appreciably but will extend the square-law portion of the scale. Greater sensitivity can be obtained only by using several valves in parallel or by adding an amplifier. The upper limit of range is imposed by the available anode potential, and in Fig. 1 this is supposed to be 4·5 volts positive to the negative end of the filament. When the grid becomes appreciably more positive than the anode the grid current will exceed the anode current, which tends to a limiting or maximum value. This is illustrated by the curve of Fig. 2 (which relates to a P.M.4 valve connected as in Fig. 1 but with zero grid bias). Fig. 2 shows that if the applied voltage exceeds about 12 volts maximum (8·4 volts R.M.S.) the anode current increases very slowly, and it becomes necessary to move the galvanometer to the grid circuit and use the valve as a diode. Such an arrangement would be undesirable because the voltmeter would take considerable power from the source and so have a low effective resistance. Therefore the negative grid-bias must be increased, but if extra batteries are precluded this must be done by some automatic process. Two such methods are shown in Figs. 3 and 4, and of these Fig. 3 has the great advantage of isolating the voltmeter from steady voltages and so confers one of the desirable attributes postulated in the Introduction. In Fig. 3 the spurts of rectified grid current divide between the parallel paths provided by the condenser and the grid leak. The capacity of the condenser is so large that sensibly all the alternating components flow through it, leaving a substantially steady p.d. between its terminals. The combination of large capacity and high resistance is therefore precisely equivalent to a battery giving a negative bias to the grid and, moreover, a bias which increases in proportion to the applied a.c. voltage. The saturation effect of Fig. 2 will now be delayed and anode current will flow during a portion only of the positive half-cycle of voltage.

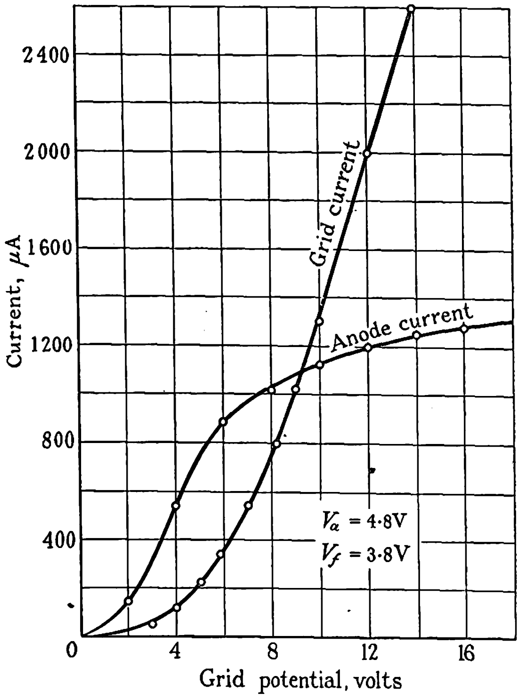

FIG. 2.

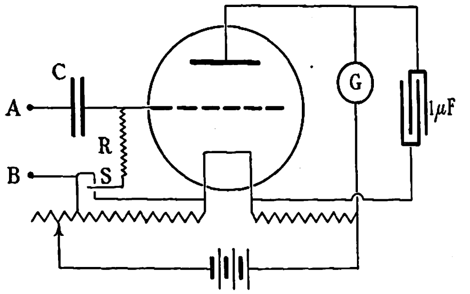

FIG. 3.

In the system of Fig. 4 the positive voltage applied to the grid is but a small fraction of the voltage applied between A and B, and this fraction depends on the ratio of the effective resistance of the grid-filament path compared with that of the grid leak in series with it. Here anode current will flow during the whole of the positive half-cycle of voltage, but in effect the voltmeter is fed from a potential divider. Since no current flows during the negative half-cycle, the resistance is infinite for that period and so the system is preferable to a potential divider; moreover, the variable conductivity of the grid provides a potential divider in which the tapping point is lowered automatically as the applied voltage is increased. The systems shown in Figs. 1, 3, and 4 take power from the source; we shall now consider the effective input resistance of voltmeters which use any one of these three systems.

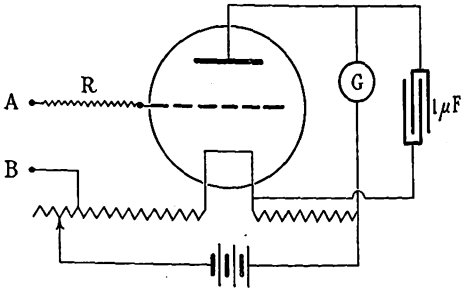

FIG. 4.

(4) EFFECTIVE INPUT RESISTANCE.

The effective input resistance may become finite from any or all of four independent causes; namely, energy transferred from the grid to the anode circuit, dielectric losses in the valve cap and instrument generally, losses in the grid leak, and losses due to grid current flowing during a part or the whole of the positive half-cycle of applied voltage. The energy is transferred from grid to anode by means of the grid-to-anode capacity and is wasted in the resistance of the anode circuit impedance (galvanometer, etc.). The anode circuit impedance should be shunted by a large capacity, say 1 μF, and then the anode is in effect short-circuited to the filament and the anode potential does not fluctuate. The grid-anode capacity is then in parallel with the grid-filament capacity and contributes only to the input capacity without contributing anything to the input resistance. We shall presume that the anode is so connected to the filament and that then the first-mentioned cause of loss is removed.

The dielectric losses are reduced by removing the valve cap and intelligently disposing the valve and terminals in the instrument case; dielectric loss cannot be eliminated, and is troublesome to measure. The results obtained on a voltmeter constructed as in Fig. 1, but without the calibrating switch, may be quoted as an example. A circuit having an inductance of 1·14 mH was tuned to a frequency of 212 kilocycles per sec. ($\lambda = 1\,420$ m), and by plotting the resonance curve the inherent decrement was found to be 1·80 per cent. The complete voltmeter (of the type depicted in Fig. 1) was then connected across the whole of the inductance, but, to prevent grid damping, the filament was not switched on. The circuit decrement was determined again with the voltmeter connected to the circuit and was now found to be 1·85 per cent, so that the presence of the voltmeter had increased the apparent resistance of the coil by 3 per cent. But some of this 3 per cent increase is due to the capacity of the voltmeter increasing the apparent resistance of the coil in a manner analogous to self-capacity.

The two resonance curves showed the apparent input capacity of the voltmeter to be 5·5 $\mu\mu$F and it may be calculated, from the value of L and the frequency, that the tuning capacity was 485 $\mu\mu$F. Now if a condenser of capacity C_1 shunts a coil L, which is in series with a condenser of capacity C_2, and the system is tuned to resonance, it is well known that C_1 increases the apparent resistance of the coil in the ratio $[(C_1 + C_2)/C_2]^2$: in this case the ratio is $(485/479\cdot 5)^2 = 1\cdot 023$. Thus practically all the observed increase of decrement could be accounted for if the power factor of the voltmeter were zero. In this instrument the valve cap had been removed and the grid was connected to the input terminal by a bare lead only about 3 cm long, otherwise so small a capacity as 5·5 $\mu\mu$F would not have been achieved. As a contrast, a similar voltmeter containing a similar valve, but in which the valve cap was intact and placed in a moulded ebonite valve-holder and the grid lead was long and heavy, may be quoted. This instrument had a capacity of 19 $\mu\mu$F, and increased the apparent resistance of the same circuit by 20 per cent. It may be calculated that the shunting effect of 19 $\mu\mu$F would increase the apparent resistance of the coil by 8·2 per cent, so the residue of 11·8 per cent must be attributed to bad power factor. From the stated values of L, C, f and δ, it may be calculated that an increase of 11·8 per cent would be produced by a resistance of 2 MΩ shunting the coil. It will also be found that the impedance of 19 $\mu\mu$F at the relevant frequency is 1/25·3 MΩ, so that the power factor of the voltmeter was 0·02. If the same process is applied to the rather inadequate difference observed for the capless valve, a power factor of 0·005 will be deduced: on the other hand, if the effect of the capacity had been ignored the voltmeter would have been held to have a power factor of 0·017. So it is clear that if the cap is removed and all due precautions are taken the power factor need not exceed 0·01, and if the cap is not removed it will be about 0·02.

Concerning the power factor of valve capacities, a paper* by G. W. Sutton should be consulted. Sutton finds, for valves without their caps, power factors which range from 0·003 to 0·02, and concludes that "it should be sufficient merely to remove the cap from an ordinary receiving valve for use as a valve voltmeter."†

When the system of Fig. 3 is used, conditions are made worse both because of the conductance of the grid leak and also because of the poor power factor inevitably associated with the grid leak and condenser. As an example, a carefully constructed voltmeter arranged as in Fig. 3, but with some switching arrangements on the filament side of the leak (of resistance 1 MΩ) had an apparent capacity of 31 $\mu\mu$F and raised the decrement of the test circuit from 1·8 per cent to 3 per cent. The enhanced capacity is due partly to some switching arrangements, but is partly inevitable from the earth capacity of the rather bulky grid condenser and leak connections. It may be found that the capacity of 31 $\mu\mu$F increases the apparent resistance of the coil by 13·8 per cent and so leaves a residue of 52 per cent to attribute to the grid leak and to power factor. It may be found that this increase would be produced by a shunt resistance of 0·5 MΩ, but this is due partly to the real resistance of the 1-MΩ leak, and so the power factor is equivalent to a shunt resistance of 1 MΩ. Combining this with the impedance of 31 $\mu\mu$F at 212 kilocycles per sec., the power factor of the voltmeter is 0·024. A voltmeter arranged as in Fig. 4 and having an unshunted grid leak of 1 MΩ had an apparent capacity of 25 $\mu\mu$F, and increased the resistance of the same test circuit by 25 per cent.

In general, therefore, a voltmeter will have a power factor between, say, 0·01 and 0·03, and the capacity will approach that of the electrodes only with the arrangement of Fig. 1. Probably the power factor is substantially constant at all frequencies, so to obtain a high value for the effective resistance at radio frequencies it is important to keep the capacity small. Viewed in this way it is more important to keep the capacity small than would appear from considering the ratio of this capacity to the other capacities of the system. In default of an actual measurement of resistance, we may estimate its value by arbitrarily assigning a power factor of, say, 0·02 to the measured value of the input capacity.

Grid current must flow in the arrangement of Figs.

---

* "The Power Factor and Capacity of the Electrodes and Base of Triode Valves, with special reference to their use in Thermionic Voltmeters," *Proceedings of the Physical Society of London*, 1927, vol. 40, p. 14.

† See also Bibliography, (8), p. 592, Table 2.

3 and 4 in order that their purpose may be fulfilled, and it will flow in the arrangement of Fig. 1 when the peak value of the applied voltage exceeds the grid bias of about 1·2 V.

We may deduce the wave-form of grid current for the system of Fig. 1 from a static characteristic connecting the steady voltage between the terminals of the voltmeter and the resultant grid current. Such a static curve taken from a complete voltmeter of a well-known pattern,* typified by Fig. 1, is shown in Fig. 5. From this curve we may readily obtain the wave-form of grid current which results from a sinusoidal applied voltage. Four such wave-forms are exhibited in Fig. 6, and correspond respectively to an applied p.d. of 0·71, 1, 1·42 and 2 volts (all R.M.S.). The other half of the positive half-cycle is, of course, an exact replica of that shown by Fig. 6, and the current is zero throughout the negative half-cycle. If the ordinates of the curves of Fig. 6 are multiplied by the corresponding ordinates of their appropriate voltage wave, a curve of input power may be plotted: the effective resistance can then be deduced from the mean height of this curve taken over a whole cycle of applied p.d. This has been done for the four curves of Fig. 6, and Fig. 7 exhibits the effective resistance plotted as a function of the R.M.S. value of the applied p.d. The full-scale deflection for this pattern of voltmeter is usually fixed at 1·5 volts (R.M.S.), and hence the effective resistance for grid damping does not fall below 0·4 MΩ.

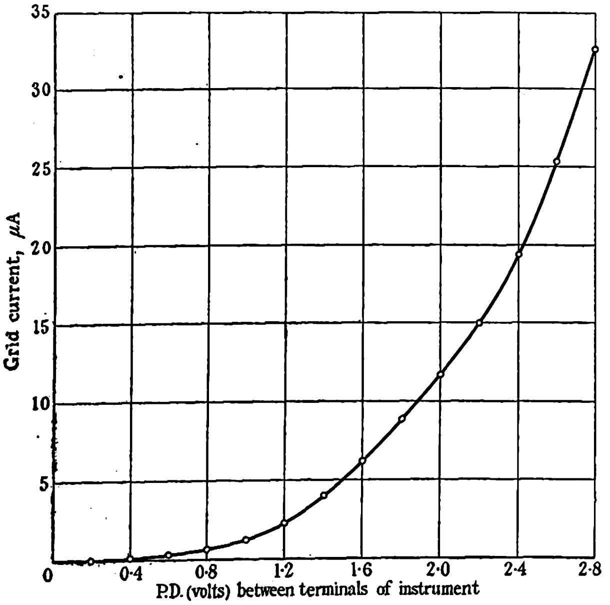

FIG. 5.

Though it is preferable to deduce the effective resistance from curves such as Fig. 5, the resistance can be measured by observing the decrement which the voltmeter adds to a tuned circuit. As an example of such a measurement may be quoted an experience from the same measuring circuit described previously. This had an inherent decrement of 1·8 per cent at 212 kilocycles per sec. With the voltmeter across the whole of the 1·14-mH coil the decrement was increased to 3·4 per cent, and from this it follows that the effective resistance of the voltmeter was about 0·31 MΩ. This figure is in fair agreement with the deduced figure of 0·4 MΩ; and also the measurement was not made on the same instrument from which Fig. 5 was obtained. Since the resistance is a function of the applied voltage, the voltmeter will distort slightly the top of the resonance curve of the circuit to which it is attached.

The effective resistance due to power factor will vary roughly as the reciprocal of the frequency, whereas the resistance due to grid current is independent of frequency. Assuming that the resistance at full scale is 0·4 MΩ for grid current and 14 MΩ for dielectric loss at 212 kilocycles per sec. (i.e. power factor of 0·01 with capacity of 5·54 $\mu\mu$F), we obtain the resistance-frequency values collected in Table 1.

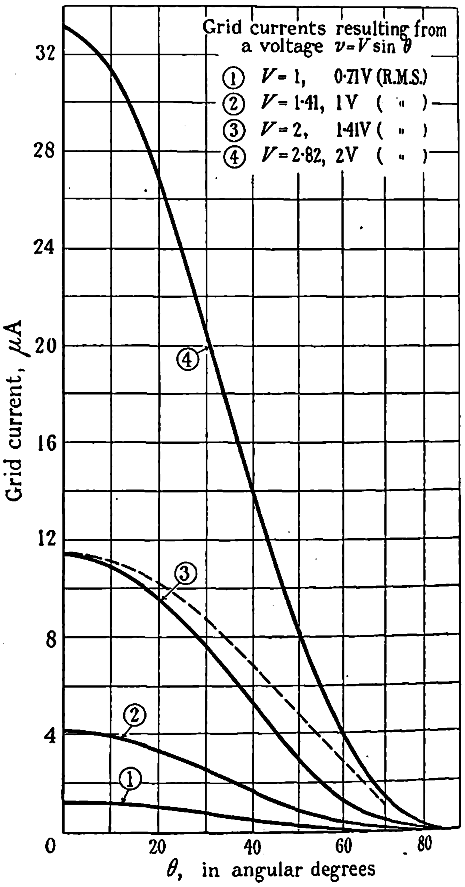

FIG. 6.

In addition to adding effective resistance the voltmeter also creates harmonic currents and it is of some interest to estimate their value. The fundamental amplitude can be obtained at once from the deduced values of effective resistance. Thus for the four curves of Fig. 6 the maxima of the fundamental components are respectively 11·3, 4·4, 1·23, and 0·435 μA when the positive peak values were respectively 33, 11·5, 4·2 and 1·2 μA, and the ratio of positive peak to fundamental amplitude does not differ much from 3. It is scarcely worth while to make a Fourier analysis of the curves of Fig. 6, but they approximate roughly to the form $y = (1 - \cos 2x)$ from $x = 0$ to $x = \pi$ and $y = 0$ from $x = \pi$ to $x = 2\pi$, and this is the equation of the dotted curve near (3) of Fig. 6. The Fourier series representing this curve is

---

* Moullin Voltmeter, Pattern A, No. L22474.

$$y = \frac{1}{4} + \frac{4}{3\pi}\left(\sin x - \frac{3\pi}{16}\cos 2x - \frac{1}{5}\sin 3x - \frac{1}{35}\sin 5x \ldots\right)$$

According to this the second harmonic is 59 per cent and the third harmonic 20 per cent of the fundamental. If we had supposed the curves of Fig. 6 to be sine curves during the positive half-cycle and zero during the negative half-cycle, it may be shown that the second harmonic would have been 48 per cent and the third harmonic 8 per cent. Evidently the size of the second harmonic is not very sensitive to the exact shape of the curve, and we may assume roughly that the second-harmonic current through the voltmeter is about 50 per cent of the fundamental: from this we may estimate roughly the second-harmonic current in the remainder of the circuit.

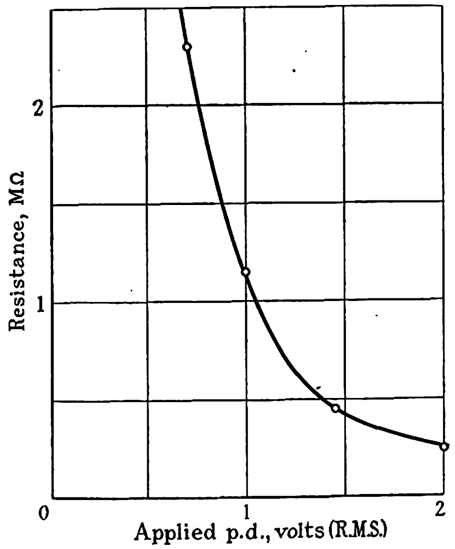

FIG. 7.

TABLE 1.

Frequency	λ	Resistance
kilocycles per sec.	m	MΩ
1	300 000	0·4
100	3 000	0·395
1 000	300	0·376
10 000	30	0·17
30 000	10	0·08

We now consider the effective resistance due to grid current in the arrangement of Fig. 3. A 6-volt filament battery will permit a negative bias of at least 1·4 volts. We shall assume that this has been provided and then there will be no grid current until the applied voltage exceeds 1·0 volt (R.M.S.). The current flowing in this condition has been studied closely by S. E. A. Landale,* who shows there that if the equation of the grid current curve is taken to be a parabola, then the mean grid current may be predicted accurately from 0·10 volt (R.M.S.) up to any value. Reference to this paper will show how to determine the effective resistance accurately, but we shall do this roughly for the voltmeter having the static characteristic represented by Fig. 8. Over the range covered in this figure we shall assume the grid-current curve to be straight, starting at 1·4 V and having a slope of 15 μA/V. Let us take a grid leak of 2 MΩ and a permanent bias of − 1·4 V. Consider Fig. 9, which shows a positive half-cycle of voltage of maximum value V. Grid current flows during that portion of the cycle only which is shown shaded. Let the mean grid current be I, then grid current will begin to flow at

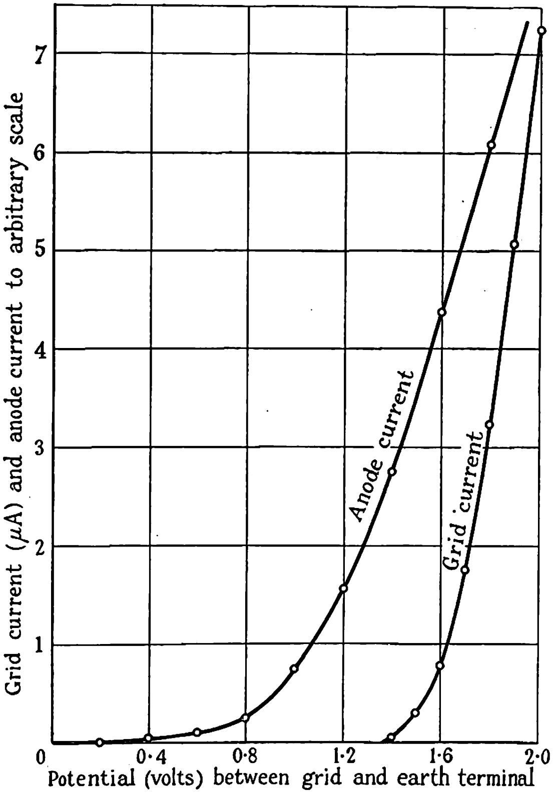

FIG. 8.

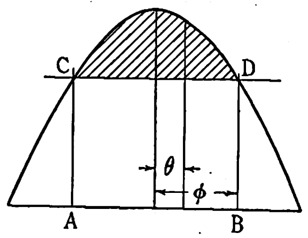

FIG. 9.

---

* See Bibliography, (15).

the moment of the cycle when the voltage rises to a value AC given by the equation $RI + 1{\cdot}4 = V \cos \phi$. Now $I = Ab/2\pi$, where b is the slope conductance of the grid characteristic and A is the area of the shaded cap. From this we have

$$\frac{bRV}{\pi}(\sin \phi - \phi \cos \phi) + 1{\cdot}4 = V \cos \phi$$

Taking $b = 15\,\mu\text{A/V}$ and $R = 2\,\text{M}\Omega$, we have

$$\frac{30V}{\pi}(\sin \phi - \phi \cos \phi) + 1{\cdot}4 = V \cos \phi$$

On substituting in this $\phi = \pi/10$, $\pi/8$ and $\pi/6$, we find that $V = 1{\cdot}64\,\text{V}$, $1{\cdot}92$ V and $3{\cdot}3$ V respectively. The instantaneous grid current is $i = V(\cos \theta - \cos \phi)b$ and the instantaneous rate of working is

$$\begin{aligned} W &= iV \cos \theta \\ &= bV^2 (\cos^2 \theta - \cos \theta \cos \phi) \end{aligned}$$

$$\therefore \quad \frac{\int_0^\phi iV \cos \theta \,.\, d\theta}{\pi} = \frac{bV^2}{2\pi}\left(\phi - \frac{\sin 2\phi}{2}\right) = \frac{V^2}{2R}$$

where R is the effective resistance

$$\therefore \quad R = \frac{\pi}{b(\phi - \frac{1}{2}\sin 2\phi)}$$

Giving ϕ the values $\pi/10$, $\pi/8$ and $\pi/6$ we find that R has the values 10, 5 and $2{\cdot}3$ MΩ respectively. This effective resistance is in parallel with a grid leak of 2 MΩ, and so the net effective values are $1{\cdot}68$, $1{\cdot}43$ and $1{\cdot}07$ MΩ respectively.

In accordance with our previous working we shall take the effective resistance due to imperfect power factor as equivalent to $1{\cdot}25$ MΩ at 212 kilocycles per sec. (i.e. power factor of $0{\cdot}02$ with a capacity of 30 $\mu\mu$F) and so obtain the resistance/frequency values collected in Table 2.

TABLE 2.

Frequency	λ	Resistance (MΩ)		
		$V = 1{\cdot}64$	$V = 1{\cdot}92$	$V = 3{\cdot}3$
kilocycles per sec.	m			
1	300 000	1·68	1·43	1·07
100	3 000	0·1	0·93	0·73
1 000	300	0·22	0·22	0·20
10 000	30	0·026	0·026	0·026

Comparing this with Table 1 we see that the grid-leak system of Fig. 3 is better than the arrangement of Fig. 1, except for frequencies which make the effect of imperfect power factor all-important. This is a point worth careful notice and is of general application in radio work. Since we find ϕ is a small angle, we can approach the matter more simply and in a way which leads to a simple experimental method of determining the effective resistance. Since grid current does not start to flow until the voltage has reached the value $V \cos \phi$, and since $\cos \phi$ is very nearly unity, we can write

$$\frac{\int_0^\phi iV \cos \theta \,.\, d\theta}{\pi} \doteqdot \frac{V\int_0^\phi i \,.\, d\theta}{\pi} = VI$$

where I is the mean grid current.

$$\therefore \quad VI = V^2/2R$$

whence $$R = \frac{V}{2I} = \frac{V_{R.M.S.}}{\sqrt{2}I}$$

If, therefore, a curve connecting rectified grid current and R.M.S. voltage be plotted from experiment the effective input resistance is found by dividing the voltage by $\sqrt{2}$ times the corresponding mean grid current. For large applied voltages, say $V > 14$, the curve of grid current and voltage becomes a straight line which just does not pass through the origin, and then I approaches very closely to the value $I = V/R$, where R is the grid-leak resistance. This is very nearly true for all valves and all reasonable values of R.*

Then we have $$\begin{aligned} R &\doteqdot V/(2I) \\ &\doteqdot \tfrac{1}{2}R \end{aligned}$$

and so the effective resistance tends to a limiting value equal to half that of the grid leak. This simple formula must always under-estimate the effective resistance, because I is always a little less than V/R and not all the grid current flows at quite the full voltage V. Hence the effective resistance must be more than half that of the grid leak. Since this effective resistance is in parallel with the grid leak the net effective resistance must always be greater than $\frac{1}{3}R$. If, therefore, the voltmeter has a 3-MΩ grid leak the effective resistance cannot fall below 1 MΩ and must always be less than 3 MΩ. In parallel with this there is the effective resistance due to imperfect power factor, and this is a function of frequency, probably varying inversely as the frequency. S. E. A. Landale calculates (*loc. cit.*, Table 3) the effective resistance due to grid current for a certain D.E.L. 410 valve combined with a 1-MΩ grid leak and finds the values shown collected in Table 3.

TABLE 3.

Applied p.d.	Effective resistance
volts (R.M.S.)	MΩ
63·1	0·57
20·6	0·58
7·74	0·62
1·77	0·72
0·24	1·75

Table 3 shows that the limiting value of $\frac{1}{2}R$ is approached very slowly and that it is more appropriate to take a figure of about $0{\cdot}65$ than one of $0{\cdot}5$.

---

* Bibliography, (11), p. 887; also Bibliography, (15).

The oscillograms shown in Figs. 10 (*a*) and 10 (*b*) are instructive in illustrating the foregoing analysis. Fig. 10 (*a*) shows the current flowing through the grid leak for an applied voltage of 12 volts (R.M.S.) and with a permanent bias of $-1\cdot 0$ V. The top edge of the thick black line is the zero of the record and the oscillograph spot would lie on this when no voltage was applied. It will be seen that the current flowing is sensibly a sine curve superposed on a steady current. A thin line has been drawn half-way between the tops and bottoms of the sine curve, and the distance between this line and the top of the black zero line represents the mean rectified current which we have called I. Measurement on the oscillograms shows that I is 86 per cent of the maximum superposed alternating current, and this illustrates the truth of our approximate equation $I = V/R$. Grid current would flow during those portions of the sine curve which lie above the zero line. Fig. 10 (*b*) is an oscillogram of the current entering the condenser from the source, that is, the input current to the voltmeter, and the mean value of this current is zero. If the grid current were zero this would be a sine curve equably disposed above and below the zero line, and if a grid-bias battery of voltage RI had been placed between the grid leak and the filament the curve would still have been a sine curve disposed equably above and below a zero line depressed an amount proportional to RI. In reality, spurts of grid current flow and are shown in Fig. 10 (*b*) by the high peaks above the zero line; the duration of these peaks corresponds to the duration of the shaded cap in Fig. 9. To obtain the requisite sensitivity (the currents being but a few microamperes) it was necessary to use an Einthoven galvanometer of relatively low natural frequency; consequently the wave-form of the peaks is not faithful and is distorted by the oscillograph.* Rough measurements from Fig. 10 (*b*) show that the grid current lasted for about one-sixth of the whole cycle, and this corresponds to $\phi = 30°$ in Fig. 9.

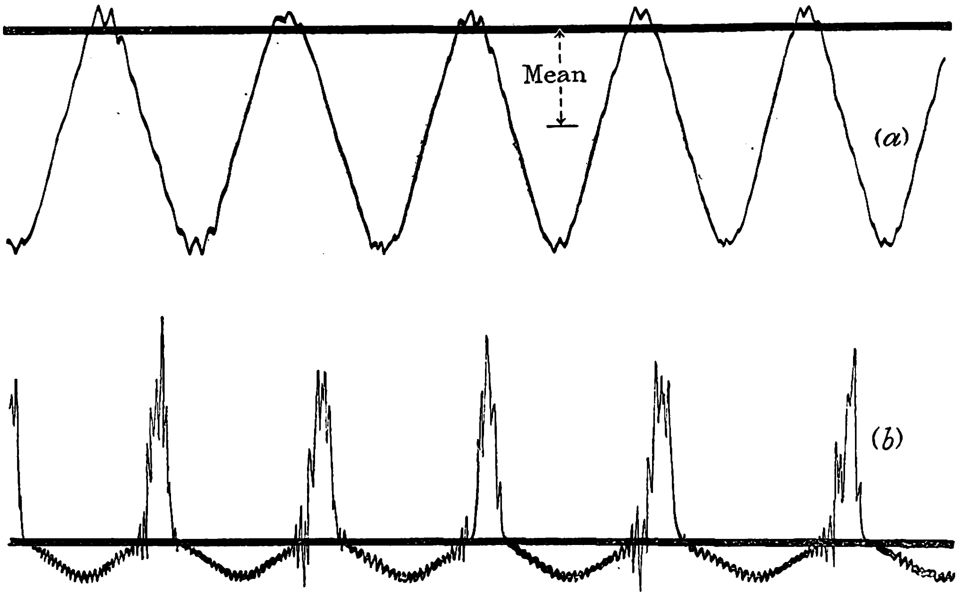

FIG. 10.

To make a rough estimate of the harmonic currents produced by the voltmeter, we shall assume the wave-form of the current passing from the grid into the filament to be that shown in Fig. 11. The Fourier series which represents this is

$$y = \frac{a\pi}{144}\Big\{1 + 3\cdot 25 \sin x + 13 \cos 2x - 13\cdot 3 \sin 3x + 6\cdot 5 \cos 4x - 3 \sin 5x \ldots\Big\}$$

where, of course, $a\pi/144 = I \doteqdot V/R$.

According to this, at the moment of maximum voltage there is a fundamental component of current equal to $3\cdot 25\ V/R$ entering the grid and passing to the filament, and a fundamental component of current equal to V/R entering the grid leak and passing to the filament. The fundamental component entering the condenser is therefore equal to $4\cdot 25\ V/R$ and this leads to an effective resistance of $0\cdot 236\ R$. This value is less than our lower limit of $\frac{1}{3}R$, partly because, in reality, ϕ is much less than 30°. According to the assumed wave-form the second harmonic will be $13/4\cdot 25 = 3$ times the fundamental, the third harmonic will have about the same value and the fourth harmonic will be about $1\frac{1}{2}$ times the fundamental. We may therefore regard the voltmeter as being roughly equivalent to a resistance $\frac{1}{4}R$ and taking a second- and third-harmonic current of value about $9\ V/R$.

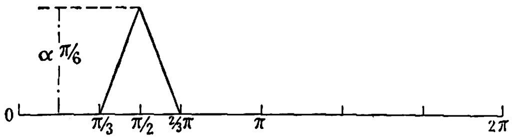

FIG. 11.

---

* The author is indebted for these oscillograms to the courtesy of the research department of Messrs. Cambridge Instrument Co., Ltd., London and Cambridge.

We shall now consider the grid current taken by the arrangement of Fig. 4, and this system presents much less difficulty than either of the other two. If the voltage is applied to the grid in Fig. 4 through a resistance of the order of 1 megohm, the valve itself adds to this resistance a negligible amount when the grid is positive and an infinite amount when the grid is negative. This is capable of very definite experimental proof as follows: Let a curve be plotted connecting the grid current with the steady voltage applied between the terminals A B. The result is a straight line which misses the origin by only a small fraction of a volt.* The slope of this line will differ inappreciably from the resistance of the grid leak. (In the example quoted above, the voltage-drop across the valve was in general less than 2 per cent of the applied p.d. when the grid leak had a resistance of 1·65 MΩ.) Consequently the grid current will be $i = (V/R)\sin pt$ during the positive half-cycle and zero during the negative half-cycle. The static curve is, of course, sufficient to substantiate this, but a further check can be obtained from an a.c. measurement as follows. The maximum grid current will have the value V/R and the mean during a half-cycle will be $2/\pi$ of this, and so the mean during a whole cycle will be $I = V/(\pi R)$. An example of such a test, in which R was 1·65 MΩ, is shown by the figures given in Table 4.

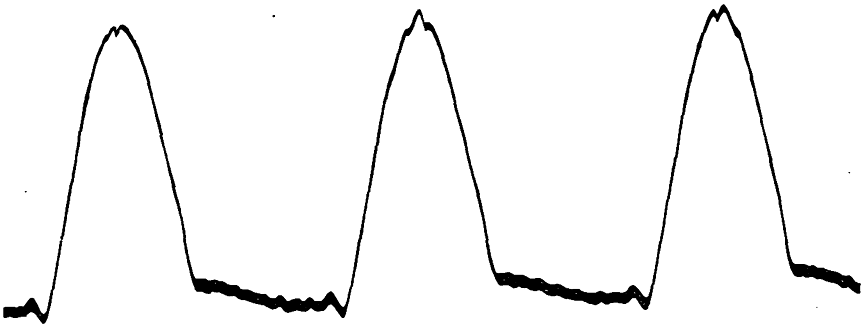

FIG. 12.

The oscillogram of Fig. 12 shows the wave-form of grid current for 100 volts (R.M.S.), and the half-sine curves followed by blank spaces are apparent. The dark line which falls below the zero is due to the overshoot of the underdamped Einthoven fibre.

We obtain the effective resistance $R_{eff.}$ as follows.

$$\text{Mean power} = \frac{\int_0^\pi (V^2/R)\sin^2 x\,dx}{2\pi}$$

$$= \frac{V^2}{4R} = \frac{V^2_{\text{R.M.S.}}}{2R}$$

$$\therefore\quad R_{eff.} = 2R$$

The harmonic analysis of the grid current is here very definite and is

$$i = \frac{V}{\pi R}\left[1 + \frac{\pi}{2}\sin pt + \frac{1}{8}\sin 3pt + \frac{1}{24}\sin 5pt + \frac{\sqrt{5}}{3}\sin(2pt + \lambda_2) + \frac{\sqrt{5}}{15}\sin(4pt + \lambda_4)\right]$$

The voltmeter therefore behaves as a constant resistance of value $2R$ and passes a second-harmonic current of amplitude $0{\cdot}235\ V/R$ and higher harmonics of negligible amplitude.

(5) USE OF THE ANODE CURRENT AND CONSIDERATIONS WHEN TO USE EXTRA BATTERIES.

Grid current flows in each of the three systems considered, and in that of Figs. 3 and 4 it is essential for the purpose of extending the range beyond that suitable for Fig. 1. If, therefore, there is a rectified grid current, should it not be used to actuate the indicating galvanometer? This turns very largely on the sensitivity of the galvanometer to be used as the indicator, and also partly on the desired scale shape. The most sensitive portable galvanometers require about 20 μA for full-scale deflection, and the a.c. voltage required to give this rectified current will dictate the range of the most sensitive voltmeter we can make. Referring to Fig. 5, we may estimate that 2 volts (R.M.S.) would produce a mean grid current of about 8 μA, and 1·4 volts (R.M.S.) a mean grid current of about 2·5 μA. This system is unsuitable for voltages above 1·5 volts (R.M.S.) because the input resistance then becomes inconveniently small, so that if the grid current is indicated we could not get more than about 15 per cent of the available deflection. The rectified anode current is, however, much larger than the rectified grid current, and for the bright-filament valve to which Fig. 4 refers full-scale deflection may be obtained for 1·5 volts (R.M.S.). In this case, therefore, it is essential to use the anode current. Conditions would not be much improved by using an anode battery of considerable voltage. If this were provided, the anode current with no applied a.c. voltage would be considerable and a balanced

TABLE 4.

Applied p.d.	Measured value of I	Deduced value of R
volts (R.M.S.)	μA	ohms
240	65	1·66
200	55	1·64
180	48	1·68
80	21	1·70
46	12	1·71

---

* For an example of such a curve see Bibliography, (11), Fig. 8.

system would have to be used. The rectified anode current (μA) would be given approximately by the equation $I = 16\ V^2$* and so there would be about 35 μA for 1·5 volts (R.M.S.) applied. We could then obtain full-scale deflection for 1·1 volts instead of 1·5 volts, but the scale would be of the square-law type, which in general is inconvenient. There would be but a trifling increase of sensitivity and considerable loss of portability and convenience.

Let us turn now to the arrangement of Fig. 3. Since the negative bias automatically increases with the applied voltage, it will be still more necessary to use the anode current with Fig. 3 than with Fig. 1. Since the bias grows progressively with the applied voltage, ultimately there will result an anode current which flows during only a portion of the positive half-cycle, this portion being slightly wider than the shaded cap of Fig. 9. This is illustrated by the oscillogram of Fig. 13, which shows the spurts of anode current with an applied p.d. of 12 volts. The combination of this effect with the effect illustrated by Fig. 2 causes the rectified anode current to reach a limiting value for an applied voltage of about 70 volts (R.M.S.). But for voltages of the order of 70, the rectified grid current will be ample to indicate directly since it is sensibly equal to the maximum of the applied voltage divided by the grid-leak resistance. Thus with a 3-MΩ grid leak (giving the voltmeter an effective resistance of about 1 MΩ) full-scale deflection of 20 μA will result from an applied p.d. of 42 volts. The scale will be accurately linear and will be useful for voltages above about 5. If we are content with a leak of 1 MΩ (effective resistance $\frac{1}{3}$ MΩ) we can obtain a full-scale deflection for 14 volts and the scale will be useful for voltages greater than about 1·5. The system of Fig. 3, but with the galvanometer in series with the grid leak, therefore becomes naturally the next step of the range to that of Fig. 1. The decision of when to use grid current in preference to the anode current is associated with the desired input resistance, but it is probably correct to say that the grid current should be used when measuring voltages greater than about 5. Using dull-filament valves in the arrangement of Fig. 3, it is convenient to make a two-range voltmeter having a range of 0–5 volts with the galvanometer in the anode circuit, and a range of about 0–30 with the galvanometer in the grid circuit.

Is it any advantage to provide additional batteries for the system of Fig. 3? If the voltmeter is to be unaffected by steady voltages—and this was one of the desirable attributes postulated—the input system of Fig. 3 must be used. To obtain the greatest possible input resistance, grid current must be prevented by adding a grid bias battery of voltage exceeding the peak value of that applied. This battery will increase the input resistance from $\frac{1}{3}$ R to R for acoustic frequencies, but for very high frequencies the effect of imperfect power factor will swamp the advantage gained. We shall, therefore, surely decide to abandon a separate grid-bias battery. If grid current is permitted, the decrease of mean grid potential is roughly equal to the peak value of the applied voltage, and this is substantially true even down to 0·3 volt (R.M.S.).* With an anode battery of adequate voltage there need be no rectification of anode current and the decrease of mean anode current will be g times the decrease of grid potential, where g is the mutual conductance of the valve. Taking g as 2 mA/V it should be possible to get a decrease of anode current of about 2·8 mA for an applied voltage of 1 volt (R.M.S.) and the scale will be approximately linear. This is in striking contrast with the previous best figure of 16 μA for 1 volt (R.M.S.) with a square-law scale. The initial anode current will, however, now be several milliamperes and a balanced system is imperative. Also this arrangement is not capable of an extensive range, for the linear portion of the anode-current characteristic will soon be exceeded and the mean grid potential will correspond to zero anode current. Rectification of anode current will counteract the decrease of mean grid potential and there will be some applied voltage for which the indicator readings will commence to reverse. This condition can be delayed by an increase of anode battery, but it cannot thereby be postponed indefinitely.

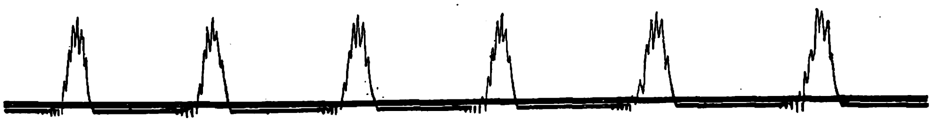

FIG. 13.

So it seems that additional batteries are advantageous and worth while only for voltmeters in which full-scale deflection is to be produced by a small fraction of a volt. If a full-scale deflection for 1·5 volts (R.M.S.) is sufficient sensitivity, then it is both unnecessary and very inconvenient to use any batteries other than the 6-volt accumulator for the filament. Coming now to the arrangement of Fig. 4, the effective resistance of which is 2 R and in which $I = (\sqrt{2})V/(\pi R)$, it will be sufficient if R is 1 MΩ and then we shall have $I = 20\ \mu$A for $V = 45$ volts, and the grid current should be indicated for voltages greater than about 5. There are some advantages, in respect of scale shape, in indicating the anode rather than the grid current; these are discussed in the appropriate section. If a high-voltage anode battery is used with this system, there would result sinusoidal decreases of anode current and a relatively small increase having a complex wave-form. The mean decrease of anode current would be given approximately by $I = (\sqrt{2})Vg$. This relation would hold over a limited range only. For very small applied voltages the decrease would not vastly dominate the increase of anode current, and for values of V of 1 or 2 volts the anode current would be decreased to zero before V had reached its negative maximum. The scale would there fore be linear over a limited range, and in this range its slope could be about 1 mA per volt applied. The arrangement would require a balanced system but might be useful in very special circumstances. As a general purpose voltmeter there is nothing to be gained by using an anode battery with the system of Fig. 4.

---

* See Bibliography, (15).

(6) FREQUENCY ERROR, PERMANENCE OF CALIBRATION AND EFFECT OF TEMPERATURE.

The indications of the system of Fig. 1 are independent of frequency up to a very high value, because the time of flight of an electron from the filament to the grid or anode is short compared with a micro-second. The lower limit of frequency is imposed by the periodic time of the galvanometer movement. If, therefore, the voltmeter is calibrated at, say, 50 cycles per sec. the calibration probably remains unaltered up to many millions of cycles per second. It is not easy to make a direct test of the validity of this statement, both because electrometers of like sensitivity are not readily arranged and because their readings are not necessarily correct at the upper end of the present spectrum of frequency. A direct comparison has been made with an electrometer for frequencies up to 1 megacycle per sec.* The accuracy of comparison was such that a disagreement of 1·5 per cent could have been detected and this was not observable at any frequency up to 10^6 cycles per sec. Fig. 14 shows a resonance curve taken at a frequency of $30 \cdot 5 \times 10^6$ cycles per sec. ($\lambda = 9 \cdot 83$ m). The ordinates are the readings of a voltmeter coupled loosely to the measuring circuit, and the abscissæ are the values of the total circuit capacity. Inspection of the shape of the resonance curve shows that relative calibration has remained correct up to frequencies of over 30 megacycles per sec. Since the absolute value of the calibration has remained correct over a change of frequency from 50 to 10^6 cycles per sec., it has probably remained absolutely correct in the change from 10^6 to 30×10^6 cycles per sec., since we have experimental proof that the relative calibration has remained unchanged. We may regard such a voltmeter as the standard at such frequencies, for the capacity of an electrometer would often prohibit its use and the inductance of its suspension would probably vitiate its readings.

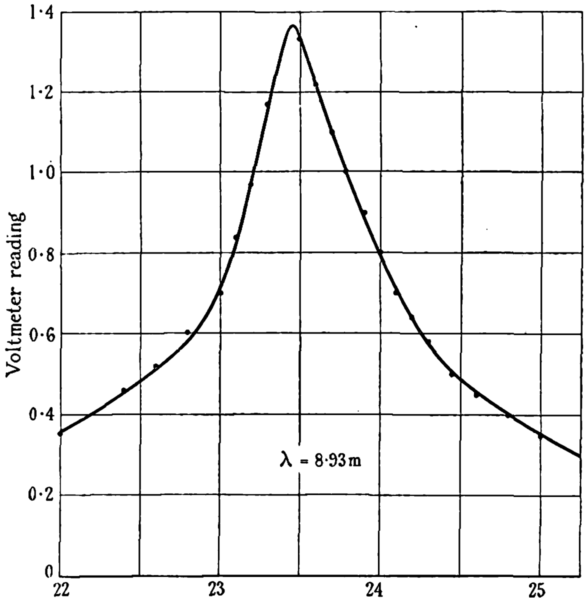

FIG. 14.

If these voltmeters are used at frequencies of the order of 30 megacycles per sec. a deflection may be found when the terminals are short-circuited. Apparently this is due to a voltage induced in the grid-bias coils, and the deflection is removed by shunting them by a suitable capacity. Voltmeters so provided may be used with as little care at 30 megacycles per sec. as at 100 kilocycles per sec.

The calibration of the system of Fig. 3 is also independent of frequency: so far as the response of grid or anode current to change of grid potential is concerned this follows from the tests of the system of Fig. 1. We have then to consider only whether the a.c. voltage applied to the grid remains the same fraction of that applied between A and B at all frequencies. This condition is fulfilled by making the impedance of the grid condenser sufficiently small at the lowest frequency to be used: as the voltmeter and grid leak in parallel have an effective resistance $\frac{1}{3}$ R we must so arrange C that $\frac{1}{3} R >> 1/(pC)$. If we make $\frac{1}{3} R = 5/(pC)$ at, say, 50 cycles per sec., then the calibration made at 50 cycles will be 2 per cent low at an infinite frequency. If $R = 3$ MΩ this condition is fulfilled when $C = 0 \cdot 016\ \mu$F. A voltmeter of the pattern typified by Fig. 1 was connected in parallel with one typified by Fig. 3 and the readings of the two instruments were compared for different frequencies up to 6×10^6 cycles per sec. No difference was detectable at a deflection of 1·5 volts. In comparing two voltmeters connected in parallel at frequencies of the order of 6 megacycles per sec., due attention must be paid to the inductance of the lead to the grid-leak instrument, for this may easily cause the p.d. applied to the grid to differ from that applied to the other instrument, even though the two are separated by but a few inches.

The distributed capacity of the resistance R makes the calibration of instruments of the pattern typified by Fig. 4 dependent on frequency. At very high frequencies this distributed capacity will be sufficient to convert Fig. 4 effectively into Fig. 3 and thus increase the mean grid current from $I = (\sqrt{2}) V/(\pi R)$ to $I = (\sqrt{2}) V/R$, and a direct test shows that the factor π has sensibly been reached at a frequency of 2 megacycles per sec. There will be an intermediate range of frequency where the correction factor may behave in a complicated manner; however, this pattern of voltmeter is not intended for use at frequencies above a few kilocycles per second.

The permanence of calibration depends on the permanence of the valve characteristic and also on that of the grid leak (when there is one). The patterns of voltmeter typified by Figs. 3 and 4 are almost independent of the valve if this is used as a diode: this follows because $I = (\sqrt{2}) V/R$ and $I = (\sqrt{2}) V/(\pi R)$ respectively. Also it is capable of simple experimental proof, for it will be found that the calibration is independent of filament current over an enormous range: the range is so great that it is superfluous to provide a test-point condition and it is sufficient to use an accumulator of the correct nominal voltage. For these patterns, ageing of the valves need not be considered, but the permanence of calibration is directly proportional to the permanence of the resistance of the grid leak. Modern grid leaks are very permanent in value but have an appreciable temperature coefficient, and for this reason it is difficult to guarantee an absolute accuracy of closer than ± 2 per cent. It should, however, be noticed that even large changes of grid-leak resistance will not alter the relative calibration of the scale.

---

* See E. B. MOULLIN: "Radio-Frequency Measurements," chap. 2, p. 38, Table 3.

The permanence of calibration of the pattern typified by Fig. 1 does depend on the permanence of the valve characteristic, but experience shows that the calibration remains permanent for many years, provided the valves are aged for a few hours before calibration and are run with less than the rated filament current. A certain voltmeter tested by the author seven years after calibration was found to be unchanged between 1·5 V and 0·4 V, but below this the calibration had changed slightly. Possibly the satisfactory permanence of calibration is due partly to the method of adjusting the instrument zero by bringing the anode current to a predecided initial value: perhaps the filament current necessary to produce this increases by a very small amount as the valve gets older, but if this be so there is evidently no appreciable change of shape of the characteristic. When the anode current is indicated in the systems of Figs. 3 and 4, then calibration will depend on the permanence of the valve.

The effect of temperature has been studied by enclosing the voltmeter in a large case in which the air could be raised to various temperatures between + 8° C, and + 40° C. A given air temperature was maintained for a considerable period of time and it was then assumed that the whole voltmeter had reached the air temperature. An instrument typified by Fig. 3 and used as a diode was found to have a mean temperature coefficient, between 14·5° C. and 40° C., of 0·23 per cent per deg. C. An instrument typified by Fig. 4 and used as a triode was found to have a mean temperature coefficient, between 8° C. and 40° C., of 0·15 per cent per deg. C. A temperature coefficient of about + 0·2 per cent per deg. C. is probably about an average value for grid-leak voltmeters, and therefore their absolute accuracy should be reliable to ± 2 per cent if they are not exposed to a temperature range of more than ± 10 deg. C. from 15° C. Voltmeters typified by Fig. 1 have no measurable temperature coefficient.

(7) Dependence of Calibration on Wave-Form.

It is usual for an a.c. voltmeter to read the R.M.S. value of a wave of any shape, but a thermionic voltmeter does not generally do this. If the equation relating the instantaneous current i through the valve with the instantaneous value v of the applied voltage is $i = bv + cv^2$, then the mean current $I = cV^2$, where V is the R.M.S. value of the applied voltage. Valve characteristics approximate to a parabola over a very limited range, and so at best the voltmeter reading will be only roughly proportional to the R.M.S. applied voltage. If the system of Fig. 1 is provided with a suitable anode battery the indicator readings will be proportional to the R.M.S. voltage if the peak value does not exceed 2 or 3 volts,* but with ordinary valves it is difficult to extend this range very much. It must be recognized that ordinary thermionic voltmeters do not measure the R.M.S. value and it is merely fortuitous good fortune if their readings are approximately proportional thereto. It so happens that the indications of the system of Fig. 1, when employed with bright-filament valves, are not very sensitive to wave-form so long as the wave-form is not extraordinarily non-sinusoidal, for example, not more so than that ordinarily obtained from dynamos or from the magnetizing current of saturated iron. A test of this is recorded† on a wave having an in-phase third harmonic of about 30 per cent, and then the true R.M.S. value was about 1 per cent greater than that recorded by the voltmeter. A test of the curve connecting anode current and applied d.c. voltage shows that the equation is sensibly parabolic over the range ± 1 V, and so the convenient property of this pattern is explained. If the applied wave contains even harmonics the positive and negative peaks are likely to have different values, and then a reversal of connections to the voltmeter will generally yield different readings and little useful information can be deduced from either. As an example, a voltmeter of the type of Fig. 1 was connected across a resistance to measure the input current to a voltmeter of the type of Fig. 3. With the valve in type 3 switched off, the voltmeter reading was 0·52 V, from which it was deduced that the grid-leak resistance was 1·64 MΩ (the value measured by a bridge was 1·63 MΩ). With the valve switched on, this reading became 1·4 V or 1·62 V, according to the sense of connection. Reference to the oscillogram, Fig. 10 (*b*), will at once explain the difference of readings but does not suggest how to interpret them.

If the anode current is indicated in the system of Fig. 3, the reading must be very sensitive to wave-form and quite uninterpretable in terms of R.M.S. value. The anode current flows only during portions of a cycle (see oscillogram, Fig. 13), and the indications will be some function of the shape of the crest of the wave and quite independent of the shape of its main portion.

The mean anode current in the arrangement of Fig. 4 will also be dependent on wave-form, but is not nearly so dependent as in Fig. 3 because it will flow during the whole of the positive half-cycle of applied voltage. Experiment shows that the calibration is roughly independent of wave-form for such wave-forms as are ordinarily produced by dynamos. Thus a wave-form having an 8 per cent fifth harmonic‡ produced a deflection 1·8 per cent less than was produced by a sinusoidal voltage of the same R.M.S. value. But a wave-form having an anti-phase third harmonic of 34 per cent and an anti-phase fifth harmonic of 8 per cent § produced a deflection too small by 5 per cent. The shape of the scale makes the fractional change of voltage indicated greater than the fractional change of deflection. Experiment shows that the relative values of the calibration are unaffected by wave-form.

---

‡ See Moullin: *Journal I.E.E.*, 1928, vol. 66, p. 891, Fig. 11b.

§ See Moullin: *loc. cit.*, Fig. 11a.

When, however, the systems of Figs. 3 and 4 are used as diodes, such voltmeters measure specified properties of the wave-form and yield more information than if they measured the R.M.S. value. The relation $I = \sqrt{2}V/R$ for Fig. 3 shows that the mean grid current is proportional to the peak value of a sine curve, and it is evident from a consideration of Fig. 8 that it will be roughly proportional to the peak value of any wave-form. This has been examined experimentally in a paper by the author,* where it is shown that the readings of several very complex wave-forms are proportional to the peak value to an accuracy of better than ± 3 per cent. These experiments are supported by a rough analysis, but a more exact analysis† shows that the voltmeter must measure the peak value with an accuracy even greater than that deduced by experimental methods.

The system of Fig. 4 necessarily measures the mean value of a half wave, and this follows from the linear relation between grid current and applied d.c. voltage. The only cause of error would be from a higher harmonic of frequency sufficient to convert Fig. 4 effectively into Fig. 3, but as a given harmonic contributes to the mean in the inverse ratio of its order number the magnitude of this possible error is very small.

Sometimes the inability to read R.M.S. values with a thermionic voltmeter is annoying, and sometimes it is helpful. The times when it is annoying are very few. Low-range voltmeters are required mostly at radio frequencies where the available power and permissible capacity are small; at radio frequencies most measurements are made in resonant circuits having a low decrement and these necessarily filter away harmonics to very minute values. If a high-range voltmeter (say for more than 40 V) is being used at acoustic frequencies, presumably it is preferred to an electrometer because it has the power of indicating distortion of wave-form. To sum up, therefore, we may say that "wave-form error" is very seldom troublesome or deceptive so long as thermionic voltmeters are operated by those who understand their properties and characteristics.

(8) The Scale Shape and Multi-Ranging.

The most desirable shape of scale depends on the purpose for which the voltmeter is required. If it is used mainly as an indicator of a maximum, then a square law is convenient, but the useful range is very limited. To obtain a wide range on one scale it is preferable for the scale to be open at the start and to close up towards the top. The information contained in this paper should suffice to show how to deduce from the static characteristic the scale shape for any type of thermionic voltmeter. The scale shape for voltmeters of the type of Fig. 1 is roughly parabolic, but the openness of the upper part of the scale can be curbed by inserting a high resistance in the anode circuit; by this means about 50 per cent of the scale can be made linear. The same result can be achieved more elegantly and usefully by the reflex system of Medlam and Oschwald,* illustrated diagrammatically in Fig. 15. Here the anode-circuit resistance R not only lowers the anode potential but also provides an increasing negative bias to the grid. It should be noticed that this system cannot be used without a separate anode battery, and it will be subject to wave-form errors roughly corresponding to Fig. 3 used as a triode. When the systems of Figs. 3 and 4 are used as triodes the scale closes towards the top. The range 0–60 V is readily covered on two scales: the low range is useful from 1 to 4 V, and the second scale has an overlap on the first of 15 per cent of the maximum deflection. This arrangement is undesirable if wave-form error is important, and then it is best to achieve the second scale by using the valve as a diode. The first scale then remains 1–4 V and the second scale is linear from 0 to 16 V, with an overlap of the first of about 10 per cent of full deflection.

The system of Fig. 4, when used as a triode, is very convenient for obtaining an enormous range by simply shunting the galvanometer. The range 0–200 V may be covered in three stages, viz. 0–4–20–200 V; the overlap between the first and second range is 35 per cent of full deflection and between the second and third is 25 per cent. Width of range in three stages is the only reason for using the arrangement of Fig. 4 as a triode. When the arrangements of Figs. 3 and 4 are used as diodes the calibration is linear.

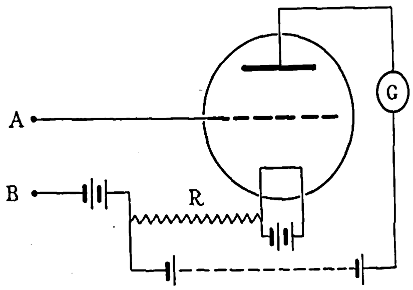

Fig. 15.

The convenience of a voltmeter is enhanced enormously if the scale is engraved directly and so obviates an appeal to a calibration chart. It is undesirable to have more than two scales on one dial, and it is desirable that a change of range can be charted by a constant multiplying factor over the whole of at least one scale. It can be shown that this condition is fulfilled only if the equation connecting deflection θ with applied voltage V is of the form $\theta = AV^n$, where the index n has any real value. It is therefore possible to test whether one scale can be used for two ranges by making a logarithmic plot of θ and V and choosing that portion, if any, which becomes a straight line. It happens that the arrangement of Fig. 4 used as a triode does conform very closely to this condition over the range from about 5 to 200 V. Of course the scale does not conform precisely to the equation $\theta = AV^n$, and it is impossible to use one scale for two ranges in a voltmeter which has to meet an overall accuracy guarantee. However, the correspondence is quite close enough for many practical purposes, and the possibility of obtaining an enormous range, at the sacrifice of some accuracy, is worth remembering. We are confronted by the same difficulty when using the systems of Figs. 3 and 4 as diodes, for though the calibration is linear, it is a line which does not pass through the origin. By experiment with either instrument we have $\theta = a(-5 + V)$ from 10 volts upwards.* Suppose that θ is full scale for 100 volts and the galvanometer is shunted so that it is again full scale for 200 volts. If we now apply 100 volts we shall obtain a deflection corresponding to 51·2 V, so the two scales disagree at that point by 2·4 per cent. Alternatively, if we make 100 volts applied to the upper range produce the deflection marked 50 on the dial, then 200 volts will produce the deflection marked 97·5 V; the instrument will then be 2·5 per cent low at full scale. If the two ranges are made to agree at about $\frac{3}{4}$ scale and if the high range is never used unnecessarily, then we could use only one scale and never have an error of more than ± 1·2 per cent. Such a makeshift would be intolerable in a voltmeter which had to meet a general guarantee of accuracy, but it would be no serious disadvantage to an intelligent operator.

RECENT DEVELOPMENTS IN DIRECTION-FINDING APPARATUS.

By R. H. Barfield, M.Sc.(Eng.), Associate Member.

(*Paper first received 8th December,* 1929, *and in final form* 3*rd March,* 1930; *read before the* Wireless Section *2nd April,* 1930.)

Summary.

Part (1) describes a four-aerial direction-finding system erected at a site near the Radio Research Station, Slough, and gives details of the tests carried out on this apparatus at wavelengths of 300 to 600 m. The system is based on the Adcock principle, but a modification has been introduced to correct for the asymmetry of the aerial system with respect to its upper and lower portions which is unavoidable if the operating hut is at ground-level.

In the first test the performance of the new direction-finding system was compared with that of a rotating-loop direction-finder over a prolonged period which included conditions of most severe "night effect." In the second test a calibration of the system was made by means of a transmitter attached to a kite which provided a source of downcoming waves of known angle of incidence and polarization.

The results of the tests show the new system to be considerably superior to the closed-loop system for conditions of "night effect." They indicate, however, a residual instrumental error of the system in the presence of downcoming waves. Finally, a further modification of the system by which it is hoped this will be eliminated is described.

Part (2) describes two distinct types of portable short-wave direction-finding apparatus and gives details of the methods by which they were tested and compared under working conditions at wavelengths of 12 to 60 m.

The first instrument is of the totally-screened closed-loop type.

The second instrument is of the rotating Adcock type consisting of a single pair of spaced vertical aerials pivoted about a vertical axis.

The tests described are divided into four sections:—

(*a*) Tests for instrumental error with a local transmitter situated first on the ground and then elevated 40 ft. above the ground with its aerial at various angles to the vertical to give waves of varying polarization.

(*b*) Tests on the effects of the immediate surroundings of the receiver.

(*c*) Direction-finding observations on the "ground ray" of a transmitter up to the maximum distance at which the ray is detectable.

(*d*) Long-range tests at which only downcoming waves were being received.

Test (*a*) showed the Adcock to be much superior to the loop in the presence of downcoming horizontally polarized waves, while (*b*), (*c*) and (*d*) show that for observations on the ground ray both instruments are equally satisfactory and that with due precaution in the choice of a site their performance is much the same as that of longer-wave apparatus. For observations just outside the range of the ground ray both systems are equally useless, while at greater ranges (beyond the "skip distance") the results again demonstrate the superiority of the Adcock to the loop.

It is shown that the results generally confirm the conclusions with respect to the nature of the propagation of the waves arrived at by Eckersley [*] from somewhat similar experiments.

Table of Contents.

Part 1. Medium waves (300 to 600 m).
- (1) Introduction.
- (2) Description of balanced Adcock system.
- (3) Tests:
  - (*a*) Ground ray.
  - (*b*) Comparison with loop direction-finder during "night effect."
  - (*c*) With kite transmitter.
- (4) Conclusions and future work.

Part 2. Short waves (12 to 60 m).
- (1) Description of closed-loop direction-finder.
- (2) Description of rotating Adcock direction-finder.
- (3) Description of tests:
  - (*a*) With local transmitter elevated and on ground.
  - (*b*) Effect of immediate surroundings.
  - (*c*) Ground-ray tests.
  - (*d*) Long-range tests.
- (4) Conclusions.

Part 1. MEDIUM WAVES (300 TO 600 M).

(1) Introduction.

It is well known that direction-finding apparatus based on the closed-loop principle such as the Bellini-Tosi single- or double-coil systems—in fact all existing systems which are employed in a practical capacity as an aid to marine or aerial navigation—are subject to a very serious inherent limitation or defect. They determine not the direction of travel of the waves but only that of the resultant horizontal magnetic field of the waves. When it is a question of taking measurements on the ground ray of a wave alone these two directions are at right angles, but when, on the other hand, it is a question of receiving waves which have travelled via the Heaviside layer, some of which arrive from the upper atmosphere with horizontally polarized components, there is no necessary relationship between them. In fact these systems are entirely unreliable as direction-finders under such conditions.

The first attempt to produce an instrument not subject to this limitation was made in 1916 by Adcock,[*] who pointed out that a directional receiving system consisting of spaced vertical aerials should theoretically determine the true direction of travel under all circumstances. Adcock actually constructed such an apparatus and demonstrated the improved nature of the results to be obtained with such a system, though this work was not actually published until after the lapse of several years.

Barfield: "The Cause and Elimination of Night Errors in Radio Direction-Finding," *Journal I.E.E.*, 1926, vol. 64, p. 831.

During this time attempts were being made at Slough to produce a direction-finder free from the defect described above, which might be conveniently designated " horizontal effect "—a direction-of-travel-finder as distinct from a direction-of-field-finder.

A system based on Adcock's principle was in due course produced which gave almost complete freedom from " horizontal effect." The system, however, relied for its success on the suspension of the hut containing the operator and apparatus at a height of some 20 ft. above the ground. An account of this work is given in an earlier publication by Dr. Smith-Rose and the author.

The subsequent work described in this paper has been devoted to the development of the Adcock principle as a practical system for medium waves by removing the drawback of an elevated hut, and to the construction of portable apparatus (described in Part 2). A considerable amount of attention has been devoted to testing and calibrating.

(2) Description of Balanced Adcock System.

The system differs from that described in the earlier paper[*] in three respects:—(1) The hut containing the apparatus is on the ground, (2) balancing condensers are inserted in the earth leads to compensate for the lowering of the hut, and (3) the aerial system is supported by a single central mast instead of four separate masts (see Fig. 1).

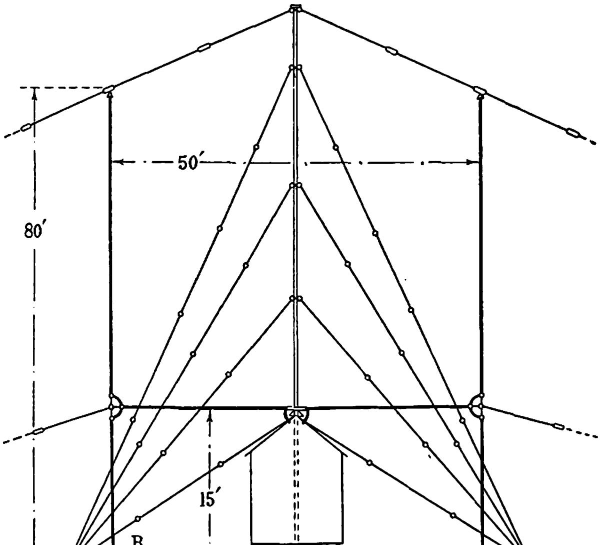

Fig. 1.—Aerial system.

B = box containing balancing condenser.

Operating Hut.—The hut is 15 ft. square and is thoroughly screened by means of 1-inch mesh wire netting with which the outside is covered. The 100-ft. mast passes up through the centre of the hut in order to ensure an equal effect on all four aerials.

Aerial System (*see Figs.* 1 *and* 2).—The four aerials approximately 80 ft. high are suspended from four radial stays of stranded steel which are anchored to the ground at points 400 ft. out from the mast. These stays are " broken " by suitable insulators into 20-ft. lengths.

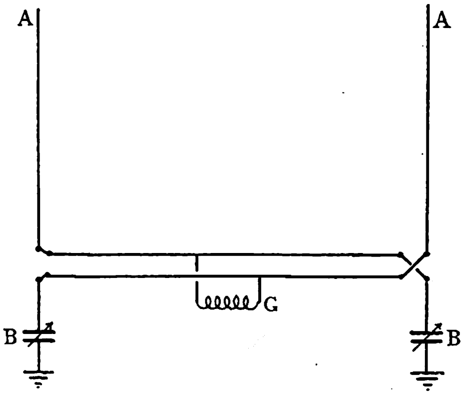

Fig. 2.—Diagram of aerial connections.

G = field coil of goniometer.
B = balancing condensers.
A = aerial.

The system of stays supporting the mast is also broken up by insulators into lengths not exceeding 15 ft. Each aerial is stretched tight to anchor pegs in the ground vertically under its point of support, and is broken at a point 15 ft. above the earth by an insulated length containing the spacing element for the horizontal leads.

Horizontal Leads.—The twin horizontal lead-in wires are attached to the insulators on the spacing piece in the aerial wire, which keeps them 6 in. apart in a horizontal plane. They are strained to insulators attached to battens on the mast at a point just above the roof ridge of the hut. Connections are made to the aerial by soldered " tags." A separate down-lead is attached to each of the eight horizontal wires and these are

passed through the roof of the hut by means of lead-in insulators.

Earth Connections.—Each earth connection consists of four cylindrical holes 4 ft. deep and 2 ft. apart, arranged symmetrically round the foot of the aerial. Each hole contains a piece of metal sheet bent in the form of a cylinder to fit the hole. The holes are then filled in and rammed down. The four wires are "commoned" and soldered to the earth terminal of the balancing condenser.

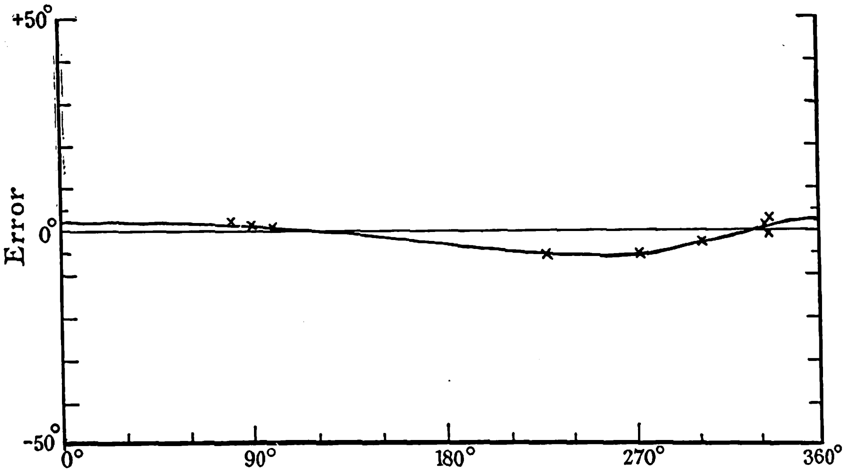

Fig. 4.—Calibration curve for ground waves.

TABLE 1.

Comparison of Standard Deviation for Balanced Adcock and Direction-Finding Loop.

Date	Time (G.M.T.	Station	D.F. loop		Adcock (Bal.)	
			Number	S.D.*	Number	S.D.*
3. 5.28	19.15–20.15	Bournemouth	28	30·6	81	10·44

11. 7.29	20.15–21.30	London	121	0·62	60	0·29
18. 7.29	20.15–21.30	London	117	0·63	71	0·3
9. 8.29	19.25–20.00	Cardiff	45	25·6	47	3·95
15. 8.29	19.10–20:00	Cardiff	40	19·46	48	2·23
22. 8.29	19.40–20.20	Dublin	60	3·84	58	1·98

* S.D. = standard deviation. † Night error too severe to take standard deviation (see Fig. 5c).

Note:—The standard deviation is obtained by taking the root-mean-square value of the variation of individual observations from their arithmetical mean.

Balancing Condensers (*see Fig.* 2).—These are variable condensers* (maximum capacity 0·0003 μF) of commercial pattern entirely enclosed in a metal "plymax" box (10 in. × 10 in. × 8 in.) which is fixed to wooden pegs driven into the ground. A short-circuiting switch is mounted on the outside of the box. When the aerial system is correctly balanced these condensers have a value of approximately 60 $\mu\mu$F.

---

* These condensers may be replaced by fixed condensers as soon as the correct value has been found: they do not have to be readjusted on changing wavelength unless the natural wavelength of the aerial is approached.

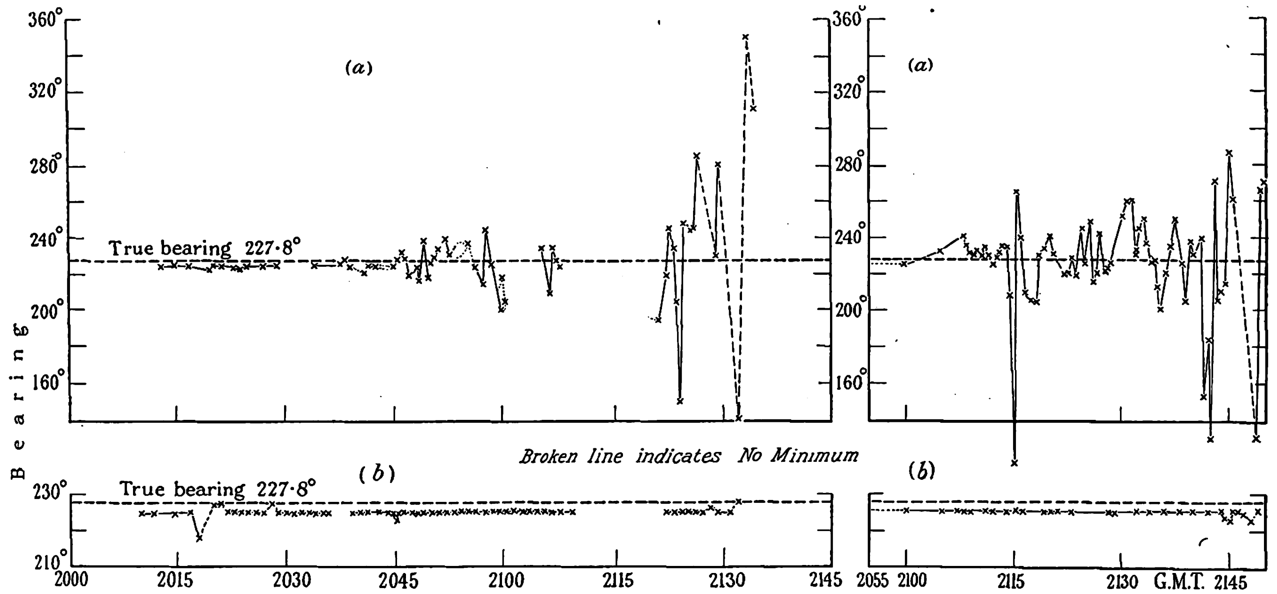

FIG. 5A.—Comparison of simultaneous bearings on (a) direction-finding coil system, and (b) Adcock system. Transmitter: Bournemouth (329 m). Left-hand 10.7.28; right-hand 11.7.28.

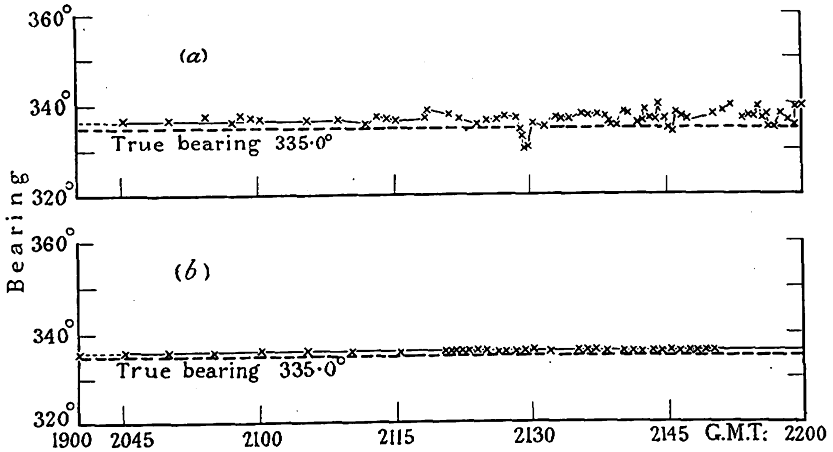

FIG. 5B.—Comparison of simultaneous bearings taken on (a) direction-finding coil system, and (b) Adcock system. Transmitter: Daventry (491 m), 18.7.28.

Interior Connections.—The interconnections between the horizontal leads necessary to complete the arrangement shown in Fig. 2 are made inside the hut at roof-level. Each lead, however, is broken at the point of entry into the hut by means of a switch controllable from the ground by means of a rod. The four down-leads to the goniometer are brought down the sides of the mast.

Goniometer and Receiver Apparatus.—These do not differ in any important way from the installation of a standard Bellini-Tosi direction-finding system.

Balancing the System.—As explained later, the object of the balancing condensers is to make the impedance of the lower half of the system equal to that of the upper half with respect to e.m.f.'s generated in the horizontal members of the aerial system by the horizontal electric component of the received waves. This is achieved on each aerial separately by the device shown in Fig. 3. Each of the four aerials in turn is connected to its earth through both field coils of the goniometer in the manner shown, and the point of junction of the field coils is connected to an earth at the centre of the aerial system; actually the screening wire of the hut is good enough. A local carefully-screened high-frequency source is set going to inject an e.m.f. into this centre earth-lead, thus sending a current which branches off into each field coil. One branch passes along one horizontal lead into the aerial, and the other passes along the other horizontal lead to earth through the balancing condenser. The relative intensity of these two currents can now be determined from the position of the search coil necessary to obtain a "minimum" from this local signal, and by adjusting the balancing condenser until this minimum occurs with the search coil at 45° to each field coil they are made of equal intensity. The system is then balanced.

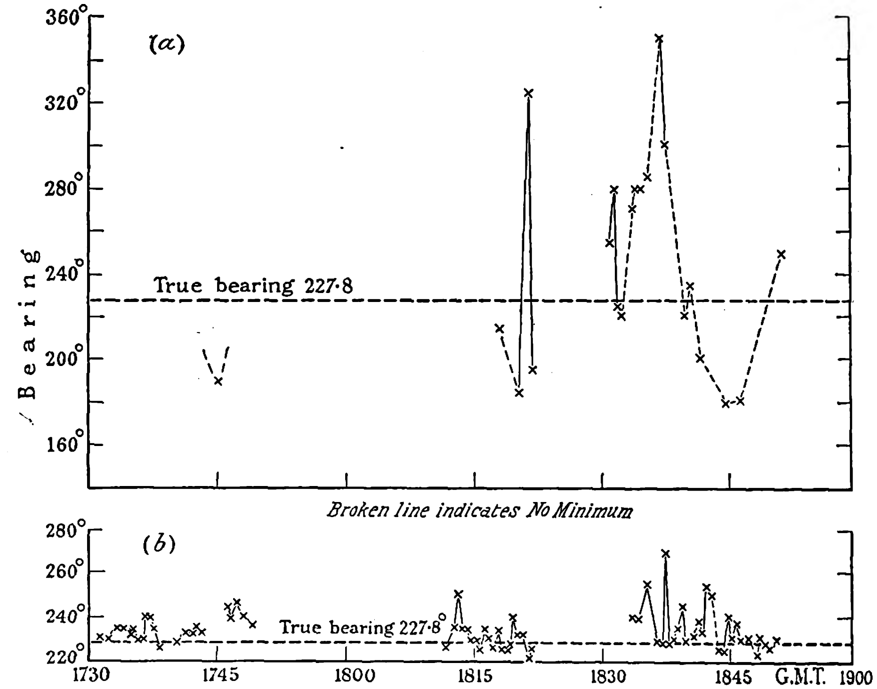

FIG. 5c.—Comparison of simultaneous bearings taken on (*a*) direction-finding coil system, and (*b*) Adcock system. Transmitter: Bournemouth (329 m), 15.10.28.

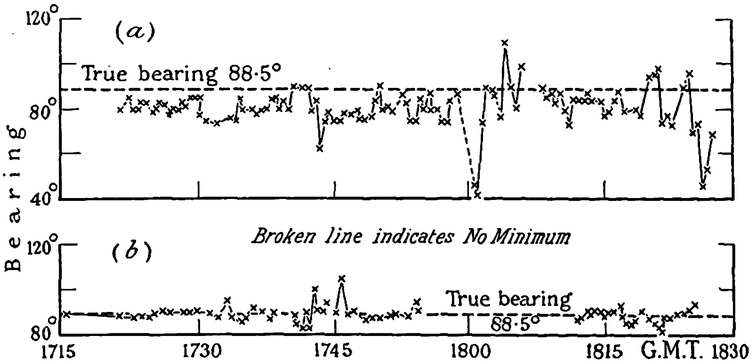

FIG. 5d.—Comparison of simultaneous bearings taken on (*a*) direction-finding coil system, and (*b*) Adcock system. Transmitter: Langenberg (468·7 m), 27.11.28.

(3) TESTS.

The apparatus was subjected to the following tests:—

(*a*) Calibration for ground waves and range tests.

(*b*) Tests during "night effect."

- (i) Comparison with closed-loop direction-finder.
- (ii) Effect of balancing condensers.

(*c*) Calibration by means of downcoming waves from kite transmitter.

A description of these tests, with their results, is given in this section.

(*a*) ***Calibration for Ground Waves and Range Tests.***—This test was carried out in the usual manner by taking bearings of a number of distant transmitting stations in as many different directions as possible. Broadcasting stations in the United Kingdom were for the most part observed and the observations were made in the daytime when ground waves only were being received. The calibration curve is shown in Fig. 4 and compares favourably with those obtained from other forms of direction-finding systems under these conditions. No difficulty was experienced in obtaining sharp minima. The range of the installation with standard forms of amplifier appeared to be not noticeably different from the Bellini-Tosi or other system.

(*b*) *Tests during "Night Effect."*

(i) A series of observations of bearings of distant transmitting stations extending over a period of about 18 months have been made in which the performance of the Adcock system, as described in this paper, was compared with that of a rotating-coil direction-finder under conditions of "night effect." Most of the observations were taken over a period of one or two hours just after sunset.

Table 1 gives a complete summary of all the results obtained during these tests. It gives the standard deviation for each period of observation and for each type of direction-finder. The curves in Figs. 5A, 5B, 5C, 5D, and 5E show the observed bearings plotted with respect to time of observation in a few selected cases chosen to include both the best and worst from the point of view of the Adcock direction-finder.

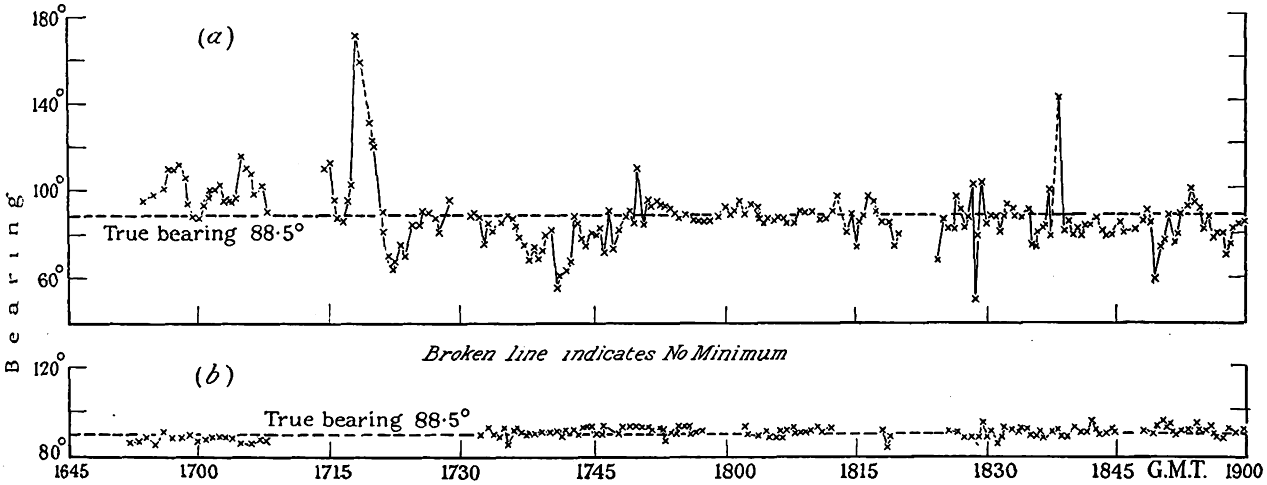

FIG. 5E.—Comparison of simultaneous bearings taken on (*a*) direction-finding coil system, and (*b*) Adcock system, 29.11.28.

Both the tables and the curves show in an unmistakable manner the superiority of the Adcock system over the loop system, and little further comment is necessary. It should be pointed out, however, that in cases where the night effect is very severe, this method of presenting the results tends to underestimate the magnitude of the disturbance on the loop, since, in these cases, no reading whatever can be obtained on the loop over large portions of the period of observation. With the Adcock, on the other hand, such lapses are so extremely rare that the curves and the table give a just account of its performance. It should further be borne in mind, when considering the Adcock results by themselves as an indication of its suitability for a practical direction-finding system, that the particular circumstances in these tests were deliberately chosen to be those of the worst possible "night effect" obtainable. Thus, for example, on longer waves or over sea, nothing so marked as the state of affairs indicated by Fig. 5C is ever experienced.

(ii) Separate tests were made to prove the efficacy of the method of "balancing" introduced in this system. These tests consisted in taking alternative sets of observations on the Adcock only, of about ¼-hour duration each, with and without the balancing condensers in the earth leads (see Fig. 2). The results are shown in Fig. 6 and in Table 2, and clearly indicate the improvement obtained by the use of the condensers.

TABLE 2.

Comparison of Standard Deviation for Balanced and Unbalanced Adcock.

Date	Station	Unbalanced		Balanced	
		Number	S.D.*	Number	S.D.*
10.10.28	Bournemouth	5	9·52	27	5·77
25.10.28	Bournemouth	16	10·29	37	2·07
1.11.28	Bournemouth	20	28·1	49	8·1
25.7.28	Manchester	51	14·9	59	3·3

* S.D. = standard deviation.

Returning to a consideration of Fig. 5, it will be noticed that most of the curves show a residual error of a few degrees obtained on the Adcock system, while in one case (Fig. 5C) during the occurrence of exceptionally bad "night effect" on the loop direction-finder the maximum error of the Adcock was as high as 40°. The question naturally arises whether these errors are instrumental and curable or whether they are due to actual lateral deviation and therefore incurable. Some advance towards answering this question is given by the tests with artificially produced downcoming waves, which will now be described.

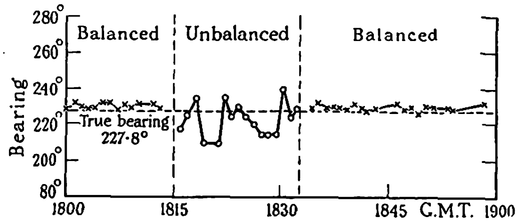

FIG. 6.—Effect of balancing condensers.

(*c*) *Calibration by means of Downcoming Waves from Kite Transmitter.*—In order to arrive at the cause of the residual errors experienced in the Adcock system during "night effect," it was necessary to calibrate the system with a source of artificially produced downcoming waves with a known and suitable degree of horizontal polarization. These waves were produced by means of a transmitter raised several hundred feet above the receiver by means of a kite. The transmitter consisted of the simplest form of valve oscillator directly coupled to a light flexible aerial wire 100 ft. long, twisted in with the string of the kite. The arrangement is shown diagrammatically in Fig. 7.

In order to reduce weight the high-tension and the valve filament-current were supplied from small dry cells of the grid-bias or flash-lamp type. The capacity of these cells was enough to give at least 6 hours' running, and this was enough for the purpose of one test. The whole transmitter weighed about 2½ lb. The kite was borrowed from the Meteorological Office and is the type used for carrying up scientific instruments. With the complete arrangement it was possible to work with the transmitter 200 or 300 yards away from the Adcock aerial, and with waves arriving at an angle of incidence varying from 80° to 30°. The inclination to the vertical of the transmitting aerial, which corresponded to the angle of the kite string, varied from about 30° to 60°, and this varied the angle of polarization of the waves in a corresponding manner.

A complete set of measurements consisted in a simultaneous determination of:—(1) The true bearing (ϕ) of the transmitter, (2) the apparent bearing (A) as observed on the Adcock system, (3) the angle of incidence (θ) of the downcoming waves, and (4) their angle of polarization (α). Of these, ϕ was measured with sufficient accuracy by means of a sighting arm pivoted about a vertical axis and provided with a pointer and scale, and θ and α by sighting through a transparent protractor fitted with a plumb bob.

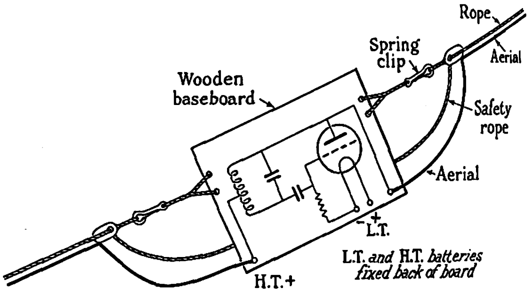

FIG. 7.—Kite transmitter.

In Fig. 8A are shown the results of these tests, the error (ϕ − A) being plotted against the angle of polarization of the transmitter for various angles of incidence. On each curve is also plotted the corresponding error for the closed-loop direction-finder, as calculated theoretically and verified experimentally. A careful study of these curves, which should be compared with those in Fig. 17, gives a clear impression of the extent to which each system is affected by abnormally polarized waves, and shows again the superiority of the Adcock system. To take one example, Fig. 8A(*c*) shows that a wave arriving with an angle of incidence of 75° (15° to the horizontal) and polarized with its electric force at an angle of 60° to the vertical, will give rise to an error of 24° on the loop direction-finder but only 7° on the Adcock.

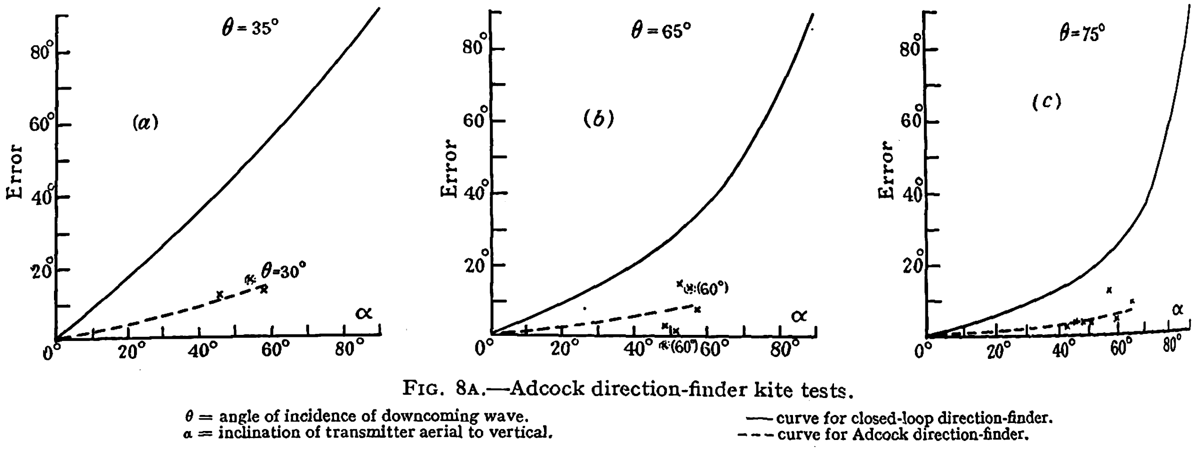

FIG. 8A.—Adcock direction-finder kite tests.

θ = angle of incidence of downcoming wave.
α = inclination of transmitter aerial to vertical.
—— curve for closed-loop direction-finder.
– – – curve for Adcock direction-finder.

On the other hand these kite experiments show that residual experimental errors do exist, so that, considering the two tests together, it would appear that the residual errors experienced at night are likely to be due to a predominatingly large extent to instrumental error and are therefore curable. This conclusion is of some importance as it points to the desirability of a careful theoretical consideration of the system with a view to its further successful development.

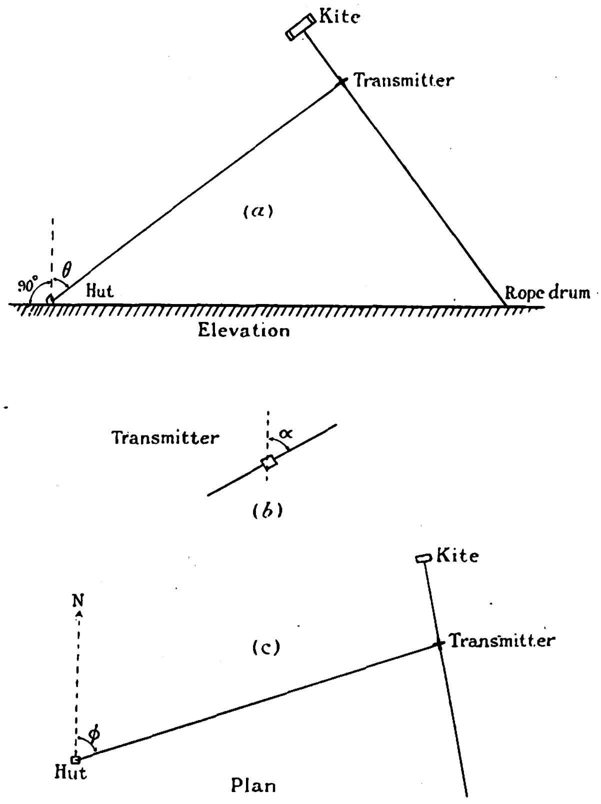

FIG. 8B.

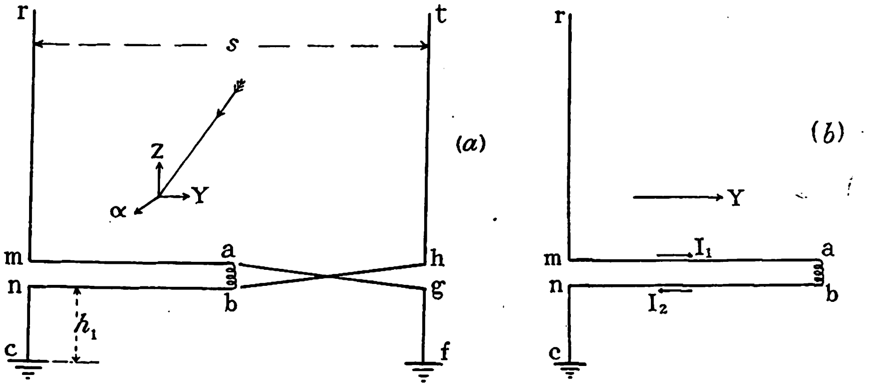

FIG. 9.

THEORY OF BALANCED ADCOCK SYSTEM.

The circuit shown in Fig. 9(*a*) represents a balanced Adcock "element" under the influence of a downcoming wave with horizontal polarization. The condition for correct balancing of the system is that the horizontal electric component of the received field shall induce no current through the field coil "a b." This implies in the first place that the impedance Z_1 of the circuit "r m a b h t" shall be equal to that (Z_2) of the circuit "c n b a g f." If the aerials are untuned with natural wavelength well below that of the working wavelength, this condition is achieved by making the capacity of the balancing condensers equal to that of the aerial circuits. It is interesting to note that the values of the condensers found by the practical method of balancing described above confirm this.

Let I_Y = current through field coil due to Y, due to abnormally polarized wave,
Y = abnormally polarized electric component,
a = horizontal magnetic component at right angles to Y, and
Z_3 = impedance of circuit "c n b a g f."

Then we have for the current through "a b"

$$I_Y = \frac{Y_s}{Z_1} - \frac{Y_s}{Z_2} + \frac{\omega a s h_1}{c Z_3}$$

when Z_1, Z_2 are the impedances defined above and h_1 is the height of the horizontal portion above the ground. By balancing up the condensers we make $Z_1 = Z_2$ but we are still left with the component produced by the magnetic field of the downcoming wave in the loop "c n b a g f," and, since the ratio a/Y varies with the angle of incidence of the wave and the magnetic components are not necessarily in phase with the electric components, it appears impossible to balance this out.

It would at first appear that this component could be eliminated by making h very small, i.e. by having the horizontal leads very close to the ground. Unfortunately, however, in doing this, the capacity to earth of the horizontal limbs becomes no longer negligible, with the result that the balancing condensers are seriously "short-circuited" by distributed capacity to earth along the wire. There is probably, however, a most favourable height which could be found by a series of careful experiments or possibly by calculation.

We have considered the balancing of the circuit "r m a b h t" against the circuit "c n b a g f." It remains to consider the behaviour of the circuits "r m a b n c" and "t h b a g f," both representing possible paths for currents generated by the Y component. Fig. 9(b) shows one of these circuits drawn separately.

It would at first appear that, so far as this circuit is concerned, since the Y component induces equal and opposite e.m.f.'s in the two limbs "m a" and "n b," no current due to this field component would flow through the field coil "a b" under any conditions. This would only be the case if the circuit under consideration were a closed circuit.

In an open circuit, owing to the dominating importance of "displacement currents" which originate, so to speak, at all points on the aerial and result in an unequal distribution of current over the aerial, it is clear that equal e.m.f.'s introduced into the circuit at different points will give rise to unequal currents at any specified point in the aerial. Hence the Y component, although inducing equal and opposite e.m.f.'s in "m a" and "n b" respectively, actually will in general give rise to a residual resultant current in the circuit which passes through the field coil and is thus a possible source of errors. It will be noted, however, that equal e.m.f.'s in "m a" and "n b" will induce equal currents if the current distribution curve is symmetrical about "a b," i.e. if, when the aerial is normally excited, the current maximum occurs at the centre of the field coil. Fortunately, this can be achieved by inserting a balancing condenser in the earth lead just as before, and the value of the balancing capacities required in the two cases appears to be approximately the same.

It is extremely difficult to calculate the extent of the error produced under any given circumstances, but the following cases give some idea of their importance.

Case 1. *Unbalanced System.*

(a) *Effect of Magnetic Component* (a).

Let I_Z = current through field coil produced by normally polarized field (Z),
I_a = current through field coil produced by abnormally polarized magnetic component (a),
X_a = impedance of aerials, and
X_b = impedance of loop.

Then

$$\left.\begin{aligned} I_Z &= \frac{\pi s}{\lambda}\cdot\frac{Zh}{X_A} \\ I_a &= \frac{\omega a s h_1}{c X_b} \end{aligned}\right\} \quad \ldots\ldots \quad (1)$$

If $\mathcal{E}$ be the error in degrees we have (neglecting phase differences)

$$\tan\mathcal{E} = \frac{I_a}{I_Z} = \frac{a}{Z}\cdot\frac{X_A}{X_B}\cdot\frac{h_1}{h}\cdot\frac{\omega\lambda}{c\pi} \quad \ldots \quad (2)$$

Take $h_1 = 10$ ft.; $s = 50$ ft.; $h = 60$ ft.;

$X_A = 1\,000\omega$; $R_A = 30$ ohms; $X_B = 400$ ohms (approx.)

Practical experiments have shown that a/Z frequently exceeds the value $a/Z = 0\cdot5$. It is found from (2), using this value, that errors exceeding 10° may result from a system of this type.

(b) *Effect of Electric Component.*—The first effect of the electric component referred to is not readily calculable, but the second effect is more manageable and this may be termed the "current distribution effect."

Neglecting the mutual capacity of the two horizontal leads in Fig. 9(a) it is permissible to assume sinusoidal current distribution along the aerial according to a law

$$I = K\sin\frac{2\pi x}{\lambda}$$

where x is the distance of the point under consideration from the top of the aerial and K is a constant depending on the height of the aerial and on the amount of series inductance.

It is now necessary to make the assumption that the residual current induced by the Y component is equal to the difference between the *mean currents* in horizontal limbs produced by a "lumped" e.m.f. of the same value acting alone in the middle of each limb, or symbolically that

$$I_Y = K\left(\sin\frac{2\pi x_1}{\lambda} - \sin\frac{2\pi x_2}{\lambda}\right)$$

where x_1 and x_2 are the respective distances of the centre points of the horizontal limbs from the aerial tip, and the constant K is given by

$$K\sin\frac{2\pi h'}{\lambda} = \frac{Ys}{2X_A} \quad \ldots\ldots \quad (3)$$

where h' = total length of aerial.

As before, $$I_Z = \frac{\pi s}{\lambda}\cdot\frac{Zh}{X_A}$$

so that

$$\tan\mathcal{E} = \frac{I_Y}{I_Z} = \frac{K\left(\sin\frac{2\pi x_1}{\lambda} - \sin\frac{2\pi x_2}{\lambda}\right)}{(\pi s/\lambda)\,(Zh/X_A)} \quad . \quad (4)$$

Since $\lambda >> h$ and $x < h$ we may write sines equal to angles, so that, substituting for K in (4), we obtain

$$\begin{aligned} \tan\mathcal{E} &= \frac{(Ys/2X_A)\,(\lambda/2\pi h)\,.\,\left[2\pi/\lambda(x_1 - x_2)\right]}{(\pi s/\lambda)\,(Zh/X_A)} \\ &= \frac{Y}{Z}\cdot\frac{x_1 - x_2}{h'}\cdot\frac{\lambda}{2\pi} \\ &= \frac{Y}{Z}\cdot\frac{\lambda}{2\pi h}\cdot\frac{x_1 - x_2}{h'} \quad \ldots\ldots\ldots \quad (5) \end{aligned}$$

It is possible to evaluate this as follows:—

$\lambda = 300$ m; $h = 20$ m; $h' = 40$ m;
$x_1 = 16$ m; $x_2 = 7$ m; $x_1 - x_2 = 9$ m.

Former experiments show that Y/Z may frequently exceed the value $Y/Z = 0\cdot5$.

Hence $$\tan\mathcal{E} > 0\cdot5\cdot\frac{300}{2\pi 20}\cdot\frac{9}{40}$$

which shows that this effect under the particular circumstances may give rise to errors exceeding 14°.

Case 2. Balanced System.

Effect of Electric Component (Y).—If the balancing has been properly carried out the effects of the Y component should now be negligible either on the circuits "rmabnc" and its pair or on the circuits "rmabht" and "cnbagf."

Effect of Magnetic Component.—We are, however, still left with the magnetic component acting on the loop "cnbagf." The error from this source is given as before by

$$\tan \mathcal{E} = \frac{a}{Z} \cdot \frac{X_A}{X_B} \cdot \frac{h_1}{h}$$

The value of X_A for the aerial system in question has already been given as about 1 000 ohms. The value of X_B is obtained from the value (C_B) of the balancing condensers, and the inductance (L) of the loop "cnbagf" and that of the field coil. The inductance of the loop is of the order 8×10^{-5} henry; the capacity of the condensers is of the order $1{\cdot}0 \times 10^{-10}$ farad, making the total impedance approximately 2 500 ohms.

Hence $$\frac{X_A}{X_B} = \frac{1}{2{\cdot}5} \cdot \frac{h_1}{h} = \frac{1}{6}$$

Again taking the maximum value of a/Z to be $0{\cdot}5$, we have

$$\tan \mathcal{E} = 0{\cdot}029$$

and the possible error is less than 3°.

This theoretical comparison of the balanced Adcock with the unbalanced Adcock shows the latter to be liable to errors of much greater magnitude than the former, and is, in general, in agreement with the experiments.

(4) CONCLUSIONS AND FUTURE WORK.

Considering the work as a whole, it is seen that the type of direction-finder described, which may be called a balanced Adcock direction-finder, constitutes a simple practical form of direction-finder which, compared with present existing practical types, has greatly improved characteristics with regard to downcoming waves. In other words it constitutes a system which, although not more complicated than other systems or more difficult to operate, is far less subject to night effect or to "aeroplane effect." The actual extent of the improvement is well represented by the kite tests shown in Fig. 8 and the night-effect tests of Fig. 5, while the degree to which this improvement is due to the addition of the balancing condensers is shown by Fig. 6.

Both theory and experiment, however, show that the system is not entirely free from what may be termed "avoidable error," that is, error caused by the polarization of the waves as distinct from the unavoidable error which would be caused by their actual deviation from the straight path.

Future development work clearly lies in the direction of removing the residual error which is still inherent in the system, i.e. in devising a system for which the curves of Fig. 8 show zero error for all values of θ and α.

Now an extension of the theory outlined above to other forms which the Adcock principle may take shows that any unbalanced Adcock system in which the vertical aerials are connected to the goniometer by continuous horizontal leads is liable to errors resulting from the action of horizontally polarized waves.

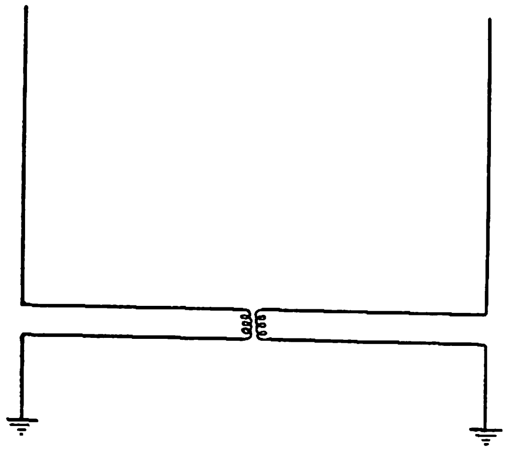

FIG. 10.

Four ways may be distinguished in which this action may take place:—

(*a*) The action of the horizontal electric field on a long horizontal pair of conductors which are in circuits of different impedance, but both in series with the field coil of the goniometer.

(*b*) The action of the horizontal electric field on a long horizontal pair of conductors forming part of the same circuit containing a field coil, but in which the current distribution is not uniform.

(*c*) The action of the horizontal electric field on a long pair of horizontal conductors giving rise to currents in the vertical aerials by virtue of the *electrostatic* coupling between the horizontal conductors and the vertical aerial.

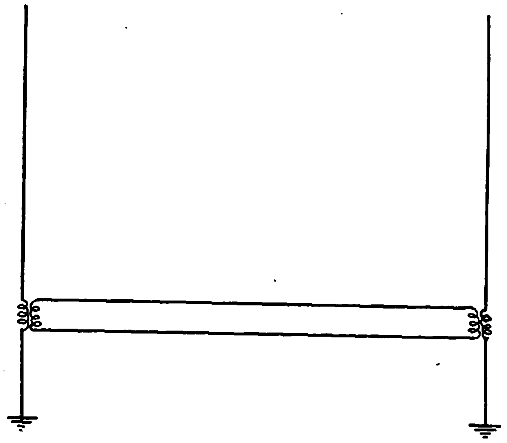

FIG. 11.

(*d*) The action of the horizontal magnetic field on the closed loop formed by a single conductor, the ground and the lower parts of the vertical aerials when this closed loop contains a field coil.

These effects are not all present in any given system. At least three types of circuit exist which come under the above classification of an unbalanced Adcock system, and each behaves differently in this respect:—

(1) *Direct-coupled Type*.—This is as shown in Fig. 3 of Adcock's patent specification,* in which the aerials are directly connected to each other and to the field coil of the goniometer. This is subject to errors of classes (*a*), (*b*) and (*d*).

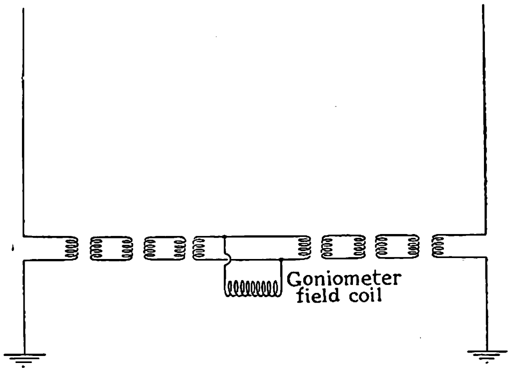

FIG. 12.—" Chain "-coupled Adcock direction-finder.

(2) *Loose-coupled Type* (*Fig*. 10).—In this the aerial circuits are magnetically coupled to the field-coil circuits, the coupling coils being at the centre of the system. This is subject to errors of class (*b*) only.

(3) *Loose-coupled Type* (*Fig*. 11).—In this the arrangement is the same as (2) except that the coupling coils are situated near the aerials. This is subject to errors of class (*c*).

Thus each type is subject to error of some form. In every case it is the horizontal leads which give rise to the error, and although balancing by condensers results in great improvement it has been demonstrated in at least one case to leave residual imperfections. It therefore appears that a perfect system would demand the abolition of these leads altogether. This may be virtually achieved by substituting for these leads a series of magnetically coupled circuits, each circuit occupying a comparatively short length of space between the aerial pairs. Fig. 12 illustrates the general principle. The actual number of " links " in the chain here shown has no special significance; theoretically the greater the number the more perfect the system becomes. Fig. 13 shows a particular arrangement when the new principle is introduced in its most practical form. Here the number of links is reduced to two for the sake of avoiding technical difficulties.

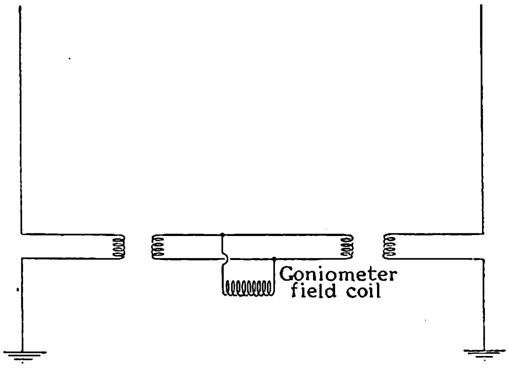

FIG. 13.—Simplest arrangement of chain coupling.

Development of the Adcock system therefore involves in the first instance the testing of this principle and this will be attempted if occasion arises.

Part 2. SHORT WAVES (12 TO 60 M).

(1) Description of Closed-Loop Direction-Finder.

The loop consists of a single conductor forming a square with a side of 3 ft. This conductor is stretched tight at the centre of an enclosing brass tube of 1 in. square section. The 3 ft. square frame formed by the brass tube is electrically continuous except at the centre of the top side, where there is a gap ⅛ in. wide, the frame being kept rigid at this point by a small ebonite junction-piece fitting tightly into the ends of the tube.

The mechanical construction is shown in Fig. 14. The frame is welded to a hollow brass vertical axis A 1½ in. diameter which rotates in the fixed brass bearing B and carries the pointer P. The leads L from the single-turn loop are brought down the interior of this axis and terminated on the slip-rings S. Before this is done the wire is strained tight so that it remains rigid in all parts of the tube. At the corners of the brass frame the wire passes over ebonite spacing-pieces E, which allow the wire to slip over them when it is tightened.

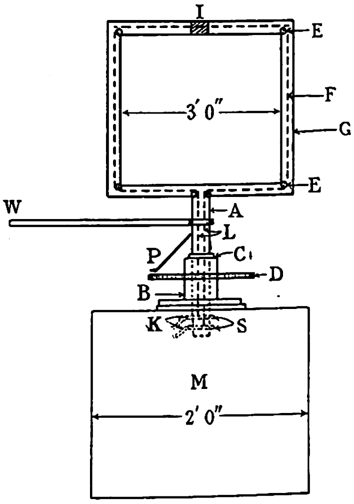

FIG. 14.—Rotating-loop direction-finder for short waves.

A = brass vertical axis 1¼ in. diam.
B = brass bearing 3 in. internal diam.
C = brass collar.
D = aluminium scale.
E = ebonite spacing-pieces.
F = direction-finding loop.
G = outer brass pipe.
I = insulated gap.
K = brushes.
L = leads.
M = metal-lined box with amplifiers, tuner, etc.
P = pointer.
S = slip-rings.
W = wooden handle.

---

* *Loc. cit.* (same as Fig. 2, without balancing condensers).

The bearing B consists of a brass cylinder with bottom flange of 3 in. inside diameter and 8 in. long. The inside of the cylinder forms the bearing for the vertical axis, while the outside of the cylinder is machined to take the circular aluminium scale-plate D (8 in. dia.) which is marked off in degrees. This can be rotated relatively to B by undoing a locking screw on occasions when it is required to set the scale to read true bearings. The bearing B is bolted to the centre of the top of a double metal-lined box (plymax) 2 ft. cube and a hole is cut in the top of the box sufficiently large to allow the slip-rings on the vertical axis to pass through. The metal-shielded loop is erected by simply placing the axis in the bearing B so that it rests on the collar C. The lower part of the axis with the slip-rings then projects about 3 in. down into the interior of the box and makes contact with the brushes K, which are "sprung" aside while the loop is lowered into position. The lid of the box is at the side and has a 1-in. overlap. In order to ensure good contact, however, two clamps are mounted on each of the four sides of the box and are screwed up when the lid is in position. The frame is rotated by means of a light wooden handle W clamped to the vertical axis. The slip-ring brushes are connected to the terminals of the coupling coil which forms the input of the amplifier.

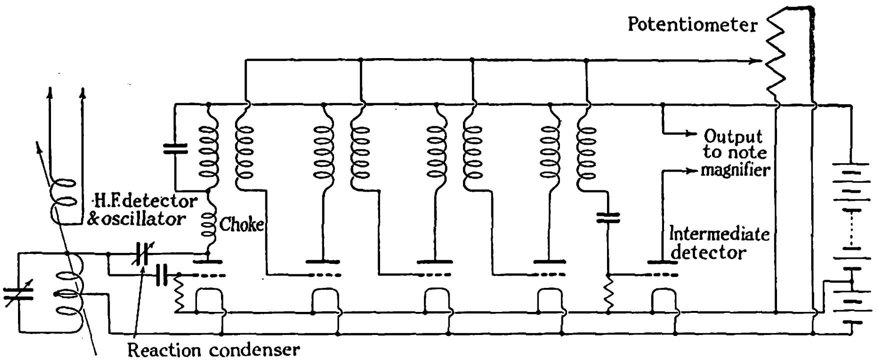

FIG. 15.—Circuit diagram of direction-finder supersonic amplifier.

The amplifier is mounted on a wooden shelf about 1 ft. from the top of the box, the battery being placed beneath. It consists of a 6-valve super-heterodyne receiver of commercial pattern, the valve filament being supplied from a 2-volt cell. A single-stage magnifier unit is also employed. The single tuning condenser is controlled externally by a suitable extension rod. The receiving loop remains untuned, being simply loose-coupled to the inductance of the rectifying and oscillating valve of the super-heterodyne. Heterodyne reception of continuous-wave stations is effected by allowing the intermediate-frequency stage to oscillate and controlling it to maximum sensitivity by means of a potentiometer. The receiver as a whole is exceptionally simple to operate, there being only one tuning control. The circuit diagram is given in Fig. 15.

The advantages and suitability of this instrument for short-wave working lie mainly in the form of screening employed, and are:—

(1) Complete absence of antenna effect, resulting in very sharp and accurate bearings.
(2) Robustness of loop, since it is enclosed in a metal pipe.
(3) Loop may be approached and, on the higher wavelengths, the screen even touched without appreciably altering bearing or weakening signals.

(2) DESCRIPTION OF ROTATING ADCOCK DIRECTION-FINDER.

The system consists of two spaced vertical aerials fixed at the ends of a rotating horizontal arm, the aerials being connected in opposition as shown in Fig. 16(*a*). Each aerial is made up of two 5-ft. lengths of $\frac{3}{4}$-in. dia. aluminium tube. The horizontal arm is in two 5-ft. lengths of $1\frac{1}{2}$-in. dia. brass tube, the two lengths being joined at the centre by a brass sleeve or union piece [Fig. 16(*c*) and (*d*)]. In a later model a single length of tube is used for the arm. The twin horizontal leads connecting the two aerials together are stretched tight in the brass tube at a distance of $\frac{3}{4}$ in. apart and at the centre are brought out to two terminals for connecting to the primary of the transformer.

The transformer and its mounting are shown in Fig. 16(*b*). The primary and secondary windings are separated by an "electrostatic" screen E which serves also as a mechanical support for the former. The screen consists of a cylindrical cage (8 in. high × 4 in. dia.) of fine vertical wires spaced $\frac{1}{8}$ in. apart. The method of winding the cage is perhaps of some interest. At the top the wires are supported by an ebonite disc which is carried on three brass legs fixed at their lower end to a brass ring to which the lower ends of the cage wires are all commoned. This ring is screwed to an 8-in. square brass baseplate (6) which carries the structure for supporting the 10-ft. horizontal arm. This brass plate is fixed to a brass tube (9) which forms the bearing, rotating about a fixed inner brass tube (10). This tube (10) has the down-leads spaced inside it and carries the transformer secondary at its top end, while its lower

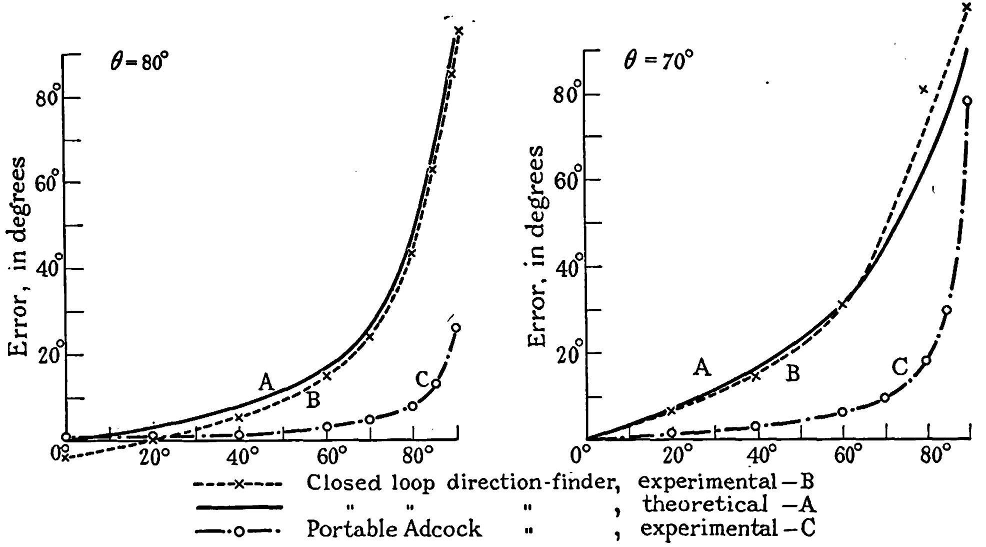
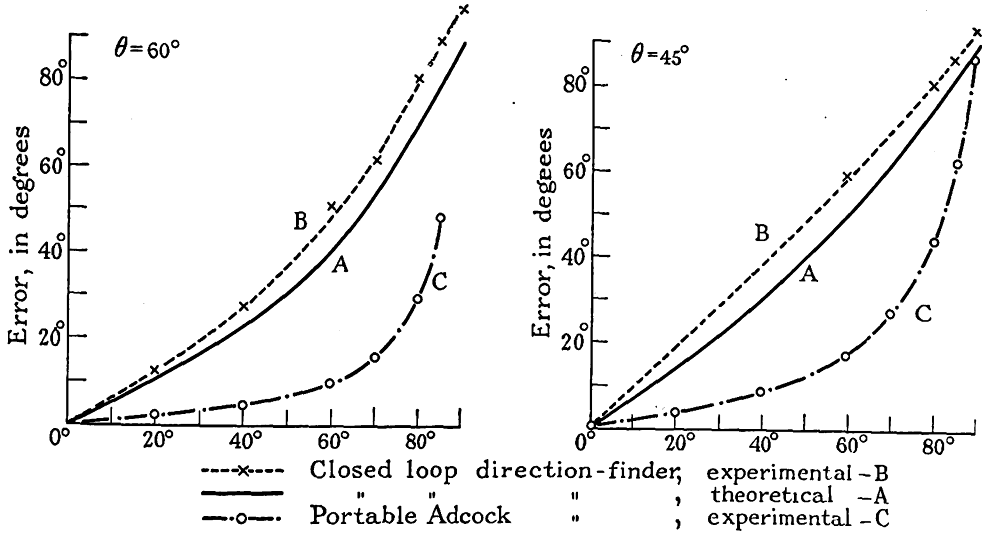
A = aluminium rod aerial. B = junction pieces. C = ebonite spacing block. D = brass socket. E = electrostatic screen. G = brass tube with down leads. H = bearing. M = metal-lined box with amplifiers, etc. P = metal pipe. S = screen. T = brass ring with clamping screw. U = horizontal leads. V = terminals. W = scale and pointer. X = handle (projecting at right angles to horizontal arm). Y = connecting leads. (1) metal screening cover. (2) supports for horizontal pipe. (3) ebonite former for primary. (4) electrostatic screen. (5) ebonite former for secondary. (6) brass baseplate. (7) primary winding. (8) secondary winding. (9) outer rotating tube. (10) inner fixed tube.

end projects downwards into the top of the amplifier and tuner box. The secondary coil (8) consists of a few turns wound on a 2-in. dia. ebonite former (5) which plugs into valve sockets on the top of the fixed tube (10). The primary coil (7) is wound on a 4-in. dia. former (3) which slides over the screen (4). Thus the primary coil rotates with the aerial system but the secondary remains stationary, and since the coils are concentric there is no change in the mutual inductance. In this way direct mechanical connection between the rotating and fixed portions of the system is avoided.

The amplifier, its box, scale and scale mounting (B in Fig. 14) are actually the same as used for the screened direction-finding loop already described, though in this case the brass cylinder B no longer acts as a bearing but as a mounting for the scale and a support for the tube (9) which is locked inside it.



FIGS. 17 and 18.—"Aeroplane effect" direction-finding tests. $\lambda = 21$ m.



FIGS. 19 and 20.—"Aeroplane effect" direction-finding tests. $\lambda = 21$ m.

The aerial rods fit into brass sockets screwed to ebonite blocks mounted on brass collars sliding over the ends of the horizontal arm. The aerial rods carry terminals at their lower ends, and these are connected to the horizontal leads.

(3) Description of Tests.

The two types of direction-finders which have been described above have been subjected to a series of tests with the object of ascertaining their performance under varying circumstances. In particular, an attempt has been made to calibrate these instruments with respect to their behaviour when under the influence of downcoming waves of abnormal polarization.

As in the case of the medium-wave Adcock direction-finder described in Part 1, these latter tests are of two kinds:—(i) Tests with natural downcoming waves by observations on commercial transmitting stations at varying ranges and times of day, and (ii) tests with artificial downcoming waves provided by an elevated local transmitter—in this case not on a kite but fixed on the top of a 40-ft. telegraph pole.

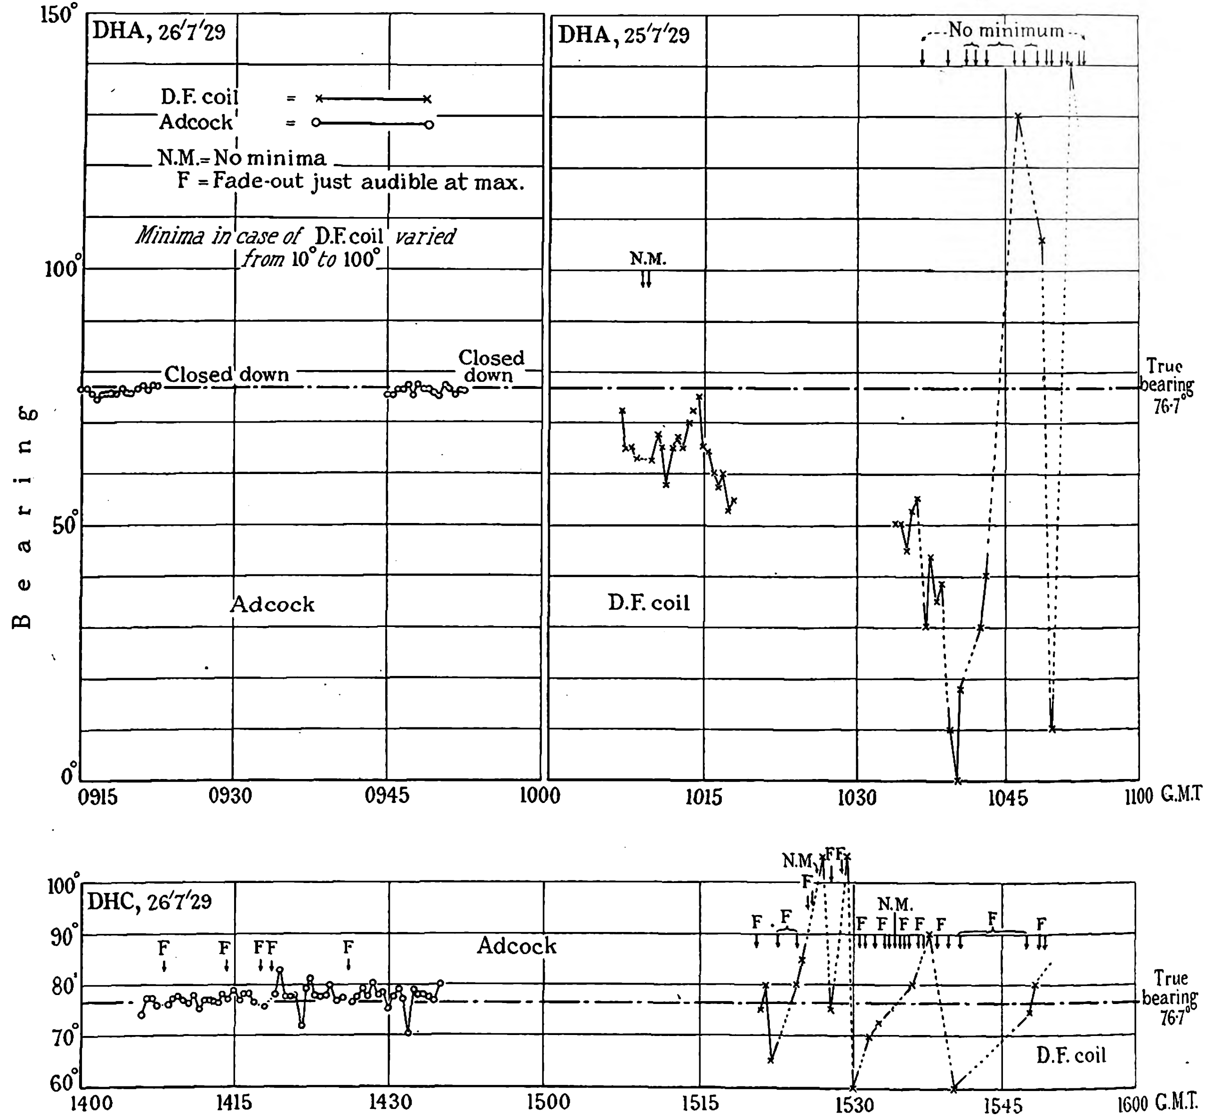


FIG. 21.—Comparisons of bearings on short waves taken by portable direction-finding coil and portable Adcock coil. Transmitters: Nauen [DHA (26·2 m) and DHC (22·7 m)].

The tests are divided into the following sections:—

- (a) Tests with local transmitter.
  - (i) Transmitter on ground.
  - (ii) Transmitter elevated 40 ft. above ground.
- (b) Effect of immediate surroundings.
- (c) Tests up to limit of ground-ray range.
- (d) Long-range tests.

Test (a)(ii) gives the inherent liability of the direction-finding sets to instrumental error, while the remainder give practical information about the conditions under which the sets can be effectively used. A consideration of the two tests together enables some conclusions to be drawn with regard to the nature of the propagation of short waves.

Tests (a) (i) and (b) were made with the loop direction-finder only but they may be assumed to hold good for both instruments, for the two were frequently compared at close range from ground transmitters and found to behave similarly under these conditions.

(a) *Local Transmitter Tests.*

(i) With a low-power transmitter situated in the middle of a large, flat, open space and at a distance of 100 yards from the direction-finding set, the maximum error was 2·0° on all wavelengths from 16 to 40 m.

(ii) An important test carried out with the local transmitter was that of working with the transmitter in the air in order to provide a source of downcoming waves.

The transmitting aerial consisted of an aluminium rod 15 ft. long fed at the centre from a simple form of valve oscillator. This aerial was pivoted on a horizontal axis on the top of a telegraph pole 40 ft. above the ground. Directional observations were made on the ground at different distances from the foot of the pole with both types of direction-finding apparatus, in order to ascertain the error in observed bearing produced by the horizontally polarized component of the downcoming waves. The distances between transmitter and receiver were altered in successive stages to correspond to angles of incidence of the downcoming wave of 80°, 70°, 60° and 45° respectively, and at each site a series of observations was made for different inclinations of the transmitting aerial varying from 0° (vertical) to 90° (horizontal), thus providing waves of varying polarization.

The error ($\mathcal{E}$) which should theoretically be produced on the loop direction-finder in any given case is given by a simple calculation as

$$\tan \mathcal{E} = \tan \alpha \, . \cos \theta \, . \frac{1 + \rho_h}{1 + \rho_v} \quad . \quad . \quad . \quad (1)$$

where $\mathcal{E}$ = observed error,
θ = angle of inclination to vertical of transmitting aerial (polarization angle),
α = angle of incidence of downcoming wave, and
ρ_h/ρ_v = reflection ratio of ground to horizontally and vertically polarized waves respectively.

The results of the tests are summed up in the set of curves given in Figs. 17 to 20. Each figure is for a different angle of incidence (θ), and the curves each show the direction-finding error with respect to α, (*a*) being the theoretical error curve for the loop, (*b*) the experimental error curve for the loop obtained from (1), and (*c*) the experimental curve for the Adcock direction-finder.

The theoretical loop curves agree very closely with the practical loop curves, and in all cases the Adcock errors are seen to be notably less than the loop errors. The extent of the superiority of this type of Adcock direction-finder over the loop type for observation on downcoming waves is exactly represented by these curves and cannot be expressed in any better way. It is of interest, however, to write down one or two examples. Thus, for a wave arriving at an angle of incidence of $\theta = 80°$ (10° to horizontal) and polarized with its electric force at $\alpha = 45°$ from the vertical, the error on the loop is 10°, while on the Adcock it is less than 2°. Again, for $\theta = 45°$, $\alpha = 60°$, the error on the loop is 60° and that on the Adcock 18°.

The cause for the existence of the residual error revealed in Figs. 17–20 is probably the asymmetry introduced by the earth's surface. A successful attempt was made to reduce these residual errors by shortening the lower limbs of the aerials. The curve obtained by cutting 2 inches off these aerials is shown in Fig. 22 for one angle of incidence. Tests with other angles of incidence, however, still showed an improvement, but not so great.

(*b*) *Effect of Immediate Surroundings.*—These tests were undertaken mainly to provide information affecting choice of site for short-wave working. Observations were made to determine the effect of local contour variations, villages, individual houses, boundary walls, etc. The general conclusions arrived at were that, provided the same precautions as to choice of site were taken that are taken with longer-wave direction-finding apparatus, the same general accuracy with respect to such local effects will be obtained as is obtained with the longer waves.

A few examples are given below to illustrate the nature of these tests.

(i) Observations were made in a large field at a distance of about one mile from the Leafield transmitter. The field was approximately level and had an area of about 100 acres. Eighteen different positions were investigated in this field on a wavelength of 17 m. Eleven showed no error exceeding 1°, and individual readings could be taken to within ½°. Of the remaining seven for which the error was greater than this, one was within 10 yards of a cottage and had an error of 7°, and six were within 200 yards of a small village which lay between them and the transmitter. The errors increased steadily as this village was approached, reaching 2½° at a distance of 100 yards, while at closer range the minima became too flat to allow observations to be made. Although the field was within a mile of the transmitter, the intervening ground was by no means level. The waves in their passage had to pass over a deep fold in the hills which cut obliquely across their path. This feature, as the general freedom from error indicates, did not cause their course to deviate to any appreciable extent.

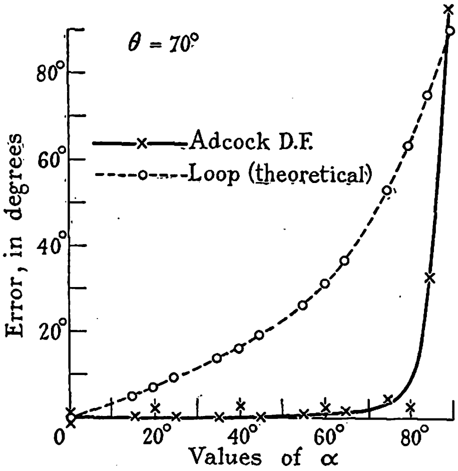

FIG. 22.—Tests on rotating Adcock direction-finder. Balanced aerials:—top half 5 ft., bottom half 4 ft. 10 in.

(ii) Observations were made on the error produced by a single tree 70 ft. high. At a distance of 10 ft. from the tree the maximum error was 40°; as the distance was increased this rapidly fell off until at 30 ft. it was 10° and at 100 ft. it was negligible.

(iii) Observations made near a stone boundary wall about 3 ft. high showed no appreciable error even when the distance away was only a few feet.

(*c*) *Ground-Ray Tests.*—The two types of apparatus (loop and Adcock pair) have been thoroughly tested on a wavelength of 24 m over a range of from 5 to 150 miles, i.e. up to the point where the ground ray disappears.

TABLE 3.—*Short-Wave Direction-Finding Observations on Adcock and Coil Portable Direction-Finding Apparatus.*
Transmitter at Chelmsford (5SW, $\lambda = 24$ m)

No.	Date	Time, G.M.T.	Place	Nature of site	Distance	True bearing	Error (mean of several observations)		Remarks
							Coil	Adcock	
					Miles				
1	5.6.28	Mid-day	Terling, Essex	Many local trees. Site otherwise good	6	223°	− 0·3°	− 0·3°	—
2	5.6.28	Evening	Bee's Farm, near Halstead	Bad. On grass space in centre of cross-roads	15	208°	+ 7°	+ 6°	—
3	6.6.28	Mid-day	2 miles N. of Sudbury on side of Sudbury–Melford road	Bad. D.F. only 60 yards from wires and very small field	24	205°	− 8°	− 9°	Marked fading
4	6.6.28	Evening	Thorpe Morieux, Suffolk	Good, open site in sloping field (5° to S.W.)	32	209°	+ 3·5°	+ 1·4°	Fading very strong, very difficult to take readings
5	7.6.28	Mid-day	Ixworth, Suffolk	By roadside after heavy rain. Bad site	43	202·5°	− 1·2°	− 2·5°	Fading very slight, but flat on coil and difficult to get bearing
6	7.6.28	Evening	New Buckenham, Norfolk	Very good site on large flat common	58	206·5°	—	—	"Night effect" too bad to take bearing
7	8.6.28	Mid-day	New Buckenham, Norfolk	Very good site on large flat common	58	206·5°	—	− 1·5°	Considerable fading
8	1.8.28	Mid-day	Wansford, Huntingdonshire	Good, open site 200 yards from North Road	73	148·5°	− 3·5°	− 3·5°	Signals rather faint and minimum flat and ill-defined
9	2.8.28	Mid-day	Waddington	Very good site on plateau	110	158°	− 3·0°	− 8°	Minimum very flat on both systems and all but impossible to obtain
10	2.8.28	Evening	Waddington	Very good site on plateau	110	158°	—	—	No minimum obtainable on either system
11	3.8.28	Mid-day	5 miles N. of Doncaster on Selby Road	Good site, though well-wooded district	150	152°	—	—	No minimum obtainable on either system

The plan of these tests was to limit the observations to one transmitting station only (Chelmsford 5SW, $\lambda = 24$ m), and to make these observations as nearly as possible simultaneously on both systems and at gradually increasing distances from the transmitter in approximately the same direction. The observations were made in a northerly and north-westerly direction from Chelmsford, the maximum and minimum distances from the transmitter being respectively 150 and 6½ miles. Observations were made at some sites at mid-day and at others in the evening about an hour before sunset, while again in some cases the same site was investigated in the morning and in the evening. At night it becomes difficult to take readings even at a distance of 30 miles, owing to fading effects. In the daytime 70 miles appears to be the limit, though at 110 miles it was possible to get a rough bearing. The results are shown in Table 3. The maximum fixed error observed, where observations were possible, was 9°. This was probably an error local to the site, which in this case was a bad one. On the whole, the results within the range of possible bearings stated are good and compare favourably with those obtained on longer waves under the same conditions.

It was noticeable in contrast to medium- and long-wave direction-finding experience that there were no "variable errors." When fading and the ordinary symptom known as "night effect" occurred, the changes were too rapid to enable bearings to be taken during a swing.

(*d*) *Long-Range Tests.*—To give some idea of the working of the apparatus at points beyond the "skip distance" a short series of observations were taken at Slough on the Nauen stations AGB. The loop receiver gave very large errors, the minimum shifting to all parts of the scale indifferently. At other times there was a faint indication that the very flat minimum oscillated about the true bearing. On the Adcock, however, the minimum, though shifting rapidly over a small arc, which would sometimes be as great as 10°, could always be found to average within 2° or 3° of the true bearing. The curves in Fig. 21 show the nature of the results obtained.

(4) CONCLUSIONS.

(i) The results obtained on the long-range tests (*d*), taken in conjunction with the local tests with the elevated transmitter (*a*) and those within the skip distance (*c*) (see Table 1 and Figs. 17 to 20), confirm the conclusions arrived at by Eckersley* from experiments of a somewhat similar nature. The variable errors and flatness of minima observed at distances exceeding 20 miles (and less than, say, 500 miles) are undoubtedly due to downcoming waves. The fact that at such ranges these effects were of equal extent on both loop and Adcock direction-finders is a clear indication that these downcoming waves are scattered or laterally deviated in the course of their reflection from above, for had the waves remained undeviated laterally the Adcock direction-finder would have shown less errors than the loop, as is clearly illustrated by the curves of Figs. 17 to 20.

---

* *Loc. cit.*

(ii) With either of the instruments described, direction-finding is possible on a wavelength of 24 m up to a distance of 70 miles in the daytime and 30 miles at night (these results applying to summer season only). Up to a distance of 20 miles the bearings are sharp and accurate to within 2°, provided a good open site is found (say 100 yards clear of obstacles in all directions). At distances greater than 20 miles minima become flatter and flatter until they become too flat to read, on both types of direction-finder. At much greater distances, say more than 500 miles, the Adcock pair gives fair indications of bearings of errors not greater than 5°, while the loop direction-finder is practically useless on account of flatness of minima and extent of bearing variation.

(iii) The Adcock direction-finder, though not completely immune, is much less subject to errors due to downcoming waves (provided, of course, they are not scattered) than the loop apparatus, to an extent which is best expressed by the curves of Figs. 17 to 20, and it is for this reason more suited for use with aircraft or for long-distance working from ground stations. At close ranges to ground stations (say within 20 miles), where the downcoming radiation is weak, scattered or very steeply inclined, since there is nothing to choose in accuracy of results the loop direction-finder is to be preferred, being more compact, robust and portable.

This work was carried out as part of the programme of the Radio Research Board and is published by permission of the Department of Scientific and Industrial Research. The author wishes to acknowledge his indebtedness to the staff of the Radio Research Station at Slough and the assistance of many of his colleagues in the work. He would also like to thank Mr. Watson Watt for valuable suggestions relating to the presentation of the results. Much of the observational work was carried out by Mr. Chapman and Mr. Munro, and Mr. Hayman assisted in some of the experiments.

Discussion before the Wireless Section, 2nd April, 1930.

Mr. N. E. Davis: The author has obtained an excellent result in a difficult and patient research toward the elimination of "night effect" in radio direction-finding—a problem to which the research department of the Marconi Co. also continues to devote considerable time. The full practical realization of the Adcock principle for eliminating "night effect" depends almost entirely on providing a non-radiating link between the vertical aerials and the radiogoniometer. The problem is to devise a practical method of transferring energy from the vertical aerials to a receiver situated at ground-level, in such a manner that only the normally polarized components of the wave give directional indication. I should like to mention the method which we have developed for providing a solution of this problem, and the practical results so far obtained. The Marconi adaptation of the Adcock principle for indicating the incoming direction of short-wave radiation relies firstly upon effective screening of the horizontal members, and secondly upon nullification, so far as this is possible, of re-radiation from the screen to the active vertical aerials. The success obtained led us to believe that similar methods applied to the Adcock principle on the medium and longer wavelengths would probably provide a solution to the elimination of night errors in practical direction-finding. Owing to the increasing importance of producing reliable direction-finders as night navigation aids for aircraft, it was decided to make initial experiments on wavelengths of the order of 900 to 1 000 metres. For this experiment, four vertical aerials 70 ft. high were erected with a spacing of 100 yards. This represents a spacing of approximately $\frac{1}{10}$ wavelength. Each of the aerials was terminated in a screening box situated about 5 ft. above the ground and in the same vertical line as the aerial. A single conductor completely shielded in copper tubing and carried about 2 ft. above the ground constituted the horizontal lead-in arrangement from each aerial. This was led to a carefully shielded radiogoniometer in the hut. The ends and centre of the horizontal shields were earthed. Observations on this system over a period have shown that with this adaptation of the Adcock principle it is possible to guarantee an accuracy of 2° to 3° under the worst conditions of "night effect," on a wavelength of the order of 1 000 m. Our experimental apparatus as set up has a direction-finding range of the same order as that of the ordinary loop direction-finder, and it will fulfil commercial or service requirements. We are not yet certain what wave-range can be obtained on a given installation, when keeping within the above-mentioned limits of accuracy. The research department of the Marconi Co. thought that it might add to the interest of the meeting and to the discussion, as well as to the scope of the paper, if I were to show a few lantern slides of the arrangement of our experimental station of medium wavelength. [Mr. Davis here exhibited four slides illustrative of the Marconi Co.'s station.] Tests on wavelengths of the order of 450 to 500 m give every hope of an all-round direction-finding accuracy closely approaching that obtained on the longer wavelengths.

Mr. S. B. Smith: The medium-wave apparatus is of particular interest to most of us, as it is on these waves that radio navigation can be successfully carried out. I should like to ask the author his opinion regarding a suitable wave-range for his apparatus; no doubt commercially it would be ideal to operate the equipment on all usable wavelengths, but does a 2 : 1 wave-range *without rebalancing* represent what he considers to be practical? Eckersley's work on the short-wave Adcock system indicates that it is possible to obtain accurate indications though they may bear little relation to the geographical position of the transmitter, provided the feeder system connecting the aerials to the radiogoniometer is really efficiently screened, and it does seem that, if a solution on these lines can be obtained, balancing schemes, which always present practical operating difficulties, will not be required. The tuned Bellini-Tosi system can be made to give very accurate results in daytime, but the need for frequent and accurate rebalancing made the development of the so-called "aperiodic system" a real necessity. Recently one has read a good deal about directive beacon transmitters of various types, and of their utility as an aid to air navigation; it does seem to me that if night ranges greater than 100 miles overland are required, then the Adcock method in some form must be a natural development, and the present loop methods will become obsolete. The problem of producing a radio beacon free from night effect may become even more difficult than that of the direction-finder, since it appears likely that the equisignal beacon method of transmission will not prove to be free from night effect when applied to an Adcock aerial system, unless very careful symmetry be maintained between each aerial and the feeder system. In plotting the deviation curves on the Adcock and loop arrangements I notice that the author has omitted to record any observations on the Adcock aerials when quite large variations are present on the loop; why not give definite observations in such cases? It has been our custom in plotting swings greater than 90° to reverse the sign of the observations. The chain-coupled Adcock direction-finder shown in Fig. 12 suggests another method which in practice may be even more difficult to realize; this consists in coupling each aerial to a rectifier, radiating a local carrier from a central aerial, and passing a beat tone over four lines to a central hut. It should then be possible by this frequency change to construct a line of such constants that at the fundamental frequency it is *non*-radiating, while the changed frequency can be arranged to reproduce the desired results at the radiogoniometer, possibly at low frequencies. We tried this scheme on a wavelength of 15 000 m in 1923, but the test failed owing to the small receiving power of the aerial. The spacing between the aerials was only 1/200th of a wavelength. In comparing night variations on direction-finders spaced about 2 wavelengths apart it has been found that the deviations are far from synchronous, and although the variations do usually occur on both aerials a very small interval may pass before the variation will be reproduced on the second direction-finder.

Mr. C. E. Horton: The main results of the author's work are entirely in agreement with my own experience. With regard to the last sentence on page 1056, to the effect that the range of the installation with standard forms of amplifier was not noticeably different from that of the Bellini-Tosi system, I think it might legitimately be inferred from this that the Adcock is just as sensitive as the Bellini-Tosi direction-finder on medium wavelengths. A Bellini-Tosi system with square loops of 20-ft. side constitutes a satisfactory and sensitive receiver for wavelengths between 200 and 20 000 metres. Would an Adcock direction-finder be equally sensitive under the same conditions of space and wavelength range? I think that its sensitivity would be less, because the impedance of the aerial system of the Adcock apparatus on long waves compares unfavourably with that of the Bellini-Tosi equipment. The aerials used in the author's experiments are very large—80 ft. high and with 50-ft. spacing. A Bellini-Tosi system of corresponding size would give a large response. With a medium-wave Adcock system of the size of an ordinary frame coil it would be very difficult to get sufficient signal strength. With regard to residual errors in the author's system, it seems to me to be unfortunate that he did not use another system which has been employed in the Navy and which, while not theoretically faultless, gives very good results—possibly better than those in the paper. I refer to the method of eliminating all horizontal pick-up by using lead-sheathed cables. All horizontal leads take the form of paper-insulated cables several feet underground, as used by Mr. Eckersley in his short-wave work. For ground of ordinary conductivity this is a simple and satisfactory way of arranging Adcock aerials, and it would be of interest if the author were to continue his work by making a direct comparison between this method and his own. I am particularly interested in direction-finding in ships, where I found that the Adcock system was difficult both to install and to work. It is assumed in the theory that two aerials of equal height have equal e.m.f.'s induced in them, and serious errors will result if equal pick-up is not obtained on all the aerials. Two vertical aerials of exactly equal dimensions installed in a ship are generally found to differ perceptibly in receiving power, and it is only by careful adjustment, usually varying with the frequency, that exact equality of induced e.m.f.'s can be obtained. I refer chiefly to battleships, where the congestion of the metal work on the upper deck considerably affects reception. It is possible that equal difficulty is not experienced in merchant ships. On page 1068 the author refers to the necessity of a good open site (say 100 yards clear of obstacles in all directions). Such conditions are not found on a battleship, and remembering that an error of 2½° was obtained in a bearing owing to a village 100 yards distant, the effect of a funnel a few feet away and the difficulties associated with short-wave direction-finding in ships can be appreciated. Oddly enough, better results have been obtained on very short waves of the order of 12 m than on waves of the order of 30 or 40 m.

Mr. J. F. Herd: The difference in the behaviour of the closed-coil receiver and that of the Adcock in the presence of abnormally polarized downcoming waves is beautifully demonstrated by the small elevated transmitter (with which the author's curves of Figs. 17 to 20 were obtained). While the transmitter is giving normal polarization, the closed-coil receiver gives good and accurate minima. When the transmitter is tilted so as to give abnormal polarization the closed-coil receiver gives a minimum which is visibly inaccurate. This is particularly obvious if the coil is kept set at the minimum for the transmitter and the transmitter is then swung. Very considerable re-orientation of the coil is necessary to give even the inaccurate minimum. Repeating this experiment with the Adcock aerial, while the polarization is normal the directional indication is exactly similar to that obtained with the closed-coil receiver. When, however, the transmitter is tilted by the same amount as in the coil experiment, the minimum indication does not wander. This is again particularly obvious if the Adcock aerial is kept set at the transmitter minimum, and the transmitter then tilted, when no change of minimum is discernible. With reference to the medium-wave apparatus, it would be interesting to have a comparison between the results obtained by Dr.

Smith-Rose and the author when working in their original elevated hut, and those given by the present Adcock system (of Figs. 1 and 2) working at ground-level.

Dr. R. L. Smith-Rose: When Mr. Barfield and I wrote our paper* some three years ago we left the Adcock direction-finder literally in the air. The apparatus was suspended between the poles carrying the aerial system. The work of bringing the system down to earth, which the present author has carried out, may seem to be a simple operation so far as the hut is concerned, but the difficulties encountered in connection with the rest of the apparatus can only be fully appreciated by those who have had considerable experience of this class of research work. On looking through Mr. Adcock's patent recently I was surprised to find how completely its originator had appreciated the nature of the problem even so early as 1916. He has described in full a number of methods whereby the difficulties due to the downcoming horizontally polarized electric waves could be overcome. It appears, however, that his conception of this matter was rather too early for it to be fully appreciated by those responsible for the application of direction-finding to navigation. In the present paper the author has shown very clearly, in such diagrams as Figs. 17 and 18, the possibility of considerable errors, of 20° or more, being obtainable with the ordinary closed-loop direction-finder when used in making observations upon the transmissions from aircraft subtending an angle of elevation at the ground of the order of 10°. As the diagrams in the paper show, these errors can be reduced to about one-tenth of their magnitude by the use of the Adcock aerial system. I would suggest that it is important that the development of the apparatus in the direction of its practical application should be proceeded with as rapidly as possible, in order that it may be retained as an entirely British invention. I believe that no other country is at present using it for practical direction-finding, although the system is being used in America for studying the propagation of waves. In connection with the theoretical part of the first section of the paper given on pages 1059 to 1061, I should like to ask the author whether he has not taken into account twice some of the e.m.f.'s induced in the aerial circuit. It appears to me that the equation in col. 2 of page 1059 contains an expression of the current as derived from the electric force acting on the aerial system, plus the same quantity as derived from the magnetic force acting on the system. I would suggest that it is an axiom that, in dealing with electromagnetic waves and their effect upon aerials and loops, one may consider the effect of either the electric field or the magnetic field. By suitably manipulating the necessary equations one should obtain the same result from either method. For example, in the case of the induction of an e.m.f. in a closed loop by a stream of electromagnetic waves, one may take either the line integral of the electric force round the perimeter of the loop or the surface integral of the magnetic force intercepting the loop at right angles to its plane. Since the magnetic force is merely derived from the motion of the electric force the same result for the induced e.m.f. will be obtained for either case. I am aware that in certain cases, such as that of the reflection of waves from a conducting surface, it is possible to obtain a resultant magnetic component which is not equal to the resultant electric component in a certain direction, and the measurement of the ratio of the intensities of these components is used as the basis of the method of measuring the angle of incidence of waves upon a conducting surface. In this case, however, we are dealing with resultant fields in two directions, and a detailed consideration of the directions of the fields and of their motions will show that the conclusions stated above are not in any way invalidated. A portion of the analysis given on page 1060 is somewhat difficult to follow, apparently on account of one or two misprints and omissions in the nomenclature, which I have already pointed out privately to the author. I have always found the aerial system drawn in Fig. 9(*a*) a little difficult to follow, especially when one is attempting to visualize the conditions which are necessary for compensation of the e.m.f.'s induced in the horizontal portions. If, however, the aerial circuit is re-drawn as a simple impedance network, as indicated in Fig. A, it then immediately becomes apparent that in the presence of horizontal electric forces from the arriving waves the condition for obtaining low current through the field coil "a b" is that the reactance of the aerial must be equal to that of the earth connection beneath it, assuming that the four aerials and earth connections are identical in dimensions and configuration. This condition can be met either, as the author has stated, by introducing negative reactance into the earth lead or, alternatively, by introducing positive reactance into the aerial. Since in the case of the direction-finder it is desirable to maintain the natural wavelength of the aerial system well below that of the arriving waves, the alternative of introducing negative reactance into the earth lead is obviously the one to adopt. As the author has pointed out, a further condition to be met in order that a complete balance of the aerial system shall be obtained is that the current distribution in each aerial circuit shall be symmetrical about the centre point of the coil "a b." In col. 1 of page 1060 the author states that this condition is obtained at the same time as that of the equality of reactance by the use of balancing capacity in the earth lead. As the discussion of this condition is dismissed in a few lines and the conclusion is not quite obvious, I should like to ask the author whether he can elaborate this point a little and give a more detailed explanation. In con-

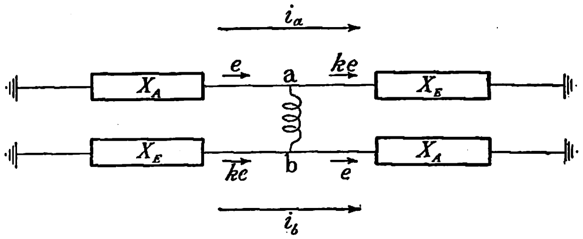

FIG. A.—Condition for zero current through "a b" is $X_A = X_E$.

---

* "The Cause and Elimination of Night Errors in Radio Direction-Finding," *Journal I.E.E.*, 1926, vol. 64, p. 831.

sidering the possibilities of the future development of the Adcock system, I am not clear from the discussion given in the paper to what extent the systems indicated in Figs. 12 and 13 are superior to that of Fig. 11, which appears to me to offer the most hopeful promise of success in the future. The author admits on page 1062 that the arrangement shown in Fig. 11 is subject to only one type of error, viz. that due to the effect of the electric coupling between the horizontal conductors and the vertical aerial. I would suggest that there is also the possibility of the induction of an e.m.f. directly into the loop enclosed by the horizontal conductors. I think that both these errors could be reduced to zero by a suitable arrangement of the horizontal conductors between the two vertical aerials. In the second part of the paper the author has shown that with the aid of modern receiving amplifiers it is possible to use direction-finders of either the closed-loop type or the Adcock type on wavelengths from 12 to 60 m with similar success, as far as the actual instrument is concerned, to that obtainable on wavelengths of 300 to 1 000 m. The author has displayed considerable ingenuity in this short-wave direction-finder in arranging the coupling coil between the rotating aerial system and the secondary circuit with no mechanical connection between them. The latter portion of the paper describing the results of observations on short-wave transmissions is important not only in showing the limitations of any system of direction-finding on these wavelengths, but also in demonstrating the utility of the two types of direction-finder in studying the propagation of short waves.

Lieut.-Col. H. P. T. Lefroy: In communication by line, the " rotation " of the go-and-return conductors, to avoid effective radiation from, or absorption by, those conductors, is a well-known and very useful arrangement; the pitch of such mutual twisting of the two conductors about each other is relatively long, and the frequencies dealt with are of the acoustic order. In 1921 I investigated the effect of such mutual twisting for radio frequencies, and found that the shorter the pitch the more complete was the absence of radiation from, or absorption by, a pair of go-and-return conductors. The higher the frequency dealt with, the shorter should be the pitch. I tried twists up to 10 per inch, using silk-covered wires of suitable gauge. The effect of such intensive twisting is greatly to increase the mutual capacity and reduce the inductance of the pair; the effective resistance is also increased. When such a sharply-twisted pair, joined at one end, was wound to form the secondary of a radio-frequency transformer, no sound could be heard in a telephone fitted, in series with a rectifier, across the other end of the pair, when the coil was suitably coupled to a primary coil carrying fairly strong damped oscillations. It seems possible that all undesired " pick-up effect " might be eliminated, in the Adcock direction-finder for short waves, if such an intensively-twisted pair were fitted to act as the horizontal leads, with the receiving coil connected, between the centre points of the two wires forming the pair, by a small fixed condenser at each end of that coil.

Air-Commodore A. D. Warrington-Morris: I am glad that this paper on Adcock aerials has been read, because the subject has recently been arousing considerable interest from the points of view both of Service flying and of civil aviation. Three of the civil aviation companies—the French, German and Belgian—are starting night services to Croydon. We have three directional stations—at Croydon, Pulham and Lympne—which by day normally guide the movements of the international aircraft. They do it very satisfactorily, and in foggy weather their function is an important one. Now that night services are being started it is necessary to produce direction-finding apparatus which will be of use after dark. The results obtained with the Adcock aerial are strikingly good, but I am not clear as to what is meant by " standard deviation." The author states that it is obtained by taking the root-mean-square value of the variation of individual observations from their arithmetic mean: I should like to know how this compares with what we call the " average error " (plus or minus). The distance between the two vertical aerials shown in Fig. 1 is given as 50 ft. I understand that accuracy, as well as pick-up value, is affected by the distance apart of such vertical aerials, and I should like to ask the author whether it was purely with a view to economizing in space and the cost of masts, or whether it was due to the difficulty of balancing, that he only allowed 50 ft. between the two vertical aerials. In connection with this last difficulty, is it necessary to re-balance the system after a change of wavelength? I recently saw a demonstration at Chelmsford of a Marconi-Adcock arrangement in which four 70-ft. masts were employed, and the leads-in were thoroughly screened. This seemed to me to be a simple and efficient method of attaining the object in view, i.e. the elimination of the effect of the horizontal aerial. A number of bearings on Hilversum were taken at night simultaneously with this equipment and an ordinary Bellini system. Whereas the maximum error with the Adcock system was about 2°, the Bellini apparatus gave errors of 20° or more. With regard to the author's conclusions as to short-wave direction-finding, he deals a blow to the installation of short-wave apparatus in aircraft when he indicates that it will never be a practical proposition, on wavelengths of 12 to 60 m, to take direction-finding bearings of a transmitting station at ranges exceeding 20 miles. I should like to ask him whether there is any hope of success on rather longer waves of from 60 to 100 m, provided that the power of the transmitting set is considerably increased. A range of about 200 miles is required.

Mr. T. L. Eckersley: I am glad that the author has thoroughly tested-out the behaviour of the Adcock aerial under what may be called horizontal polarization conditions. Although my main interest at present lies with short waves, direction-finding results on the long-wave band which might affect this long-outstanding problem are of great interest to me. The author has produced at least one method of obtaining bearings free from night error. There are, I think, other systems capable of achieving this result, and it is merely a matter of practical handling to determine which is likely to be the best. Regarding the circuit shown by the author, in which horizontal lead-in is balanced by horizontal lead-out action and then balanced by a condenser to earth, I would mention that about 1917 I made a similar suggestion in a report to the War Office. It is easy, however, to make a suggestion: it is to the application of the suggestion to a practical system that the real credit is due. With regard to short waves, the author has done much of the work which I had left to future developments. I am glad to find that he affirms in a general way the results which I obtained earlier with rather a different type of Adcock apparatus, but one which appears to have functioned very similarly to the Adcock aerial which he himself has used. The short-wave frame apparatus with its screened loop seems to be a good arrangement as it almost entirely eliminates the vertical effect. By means of careful balancing, however, it is possible with a frame to get almost perfect minima on short waves if everything such as batteries, receiver, etc., is shielded. At present we are using a receiver in which the batteries are external with a short-wave direction-finder, and it is only with a 2-ft. frame that we find it possible to anchor the leads outside in such a way that the amount of energy received on battery leads, etc., is negligible compared with the amount received on the frame. Such an arrangement dispenses with the necessity of having batteries inside a portable box, and to a certain extent this makes it easier to work. With regard to the Adcock arrangement for short waves, this seems to be an alternative method of obtaining signals free from " night effect," and, as the author points out, it is rather difficult at first to see why the balance should not be perfect. I agree with him that this is not possible because of the fact that the lower limbs of the vertical part are not exactly symmetrical with the upper part. In connection with the long-distance test, I should like to ask whether the author made any measurements on distant stations, such as New York, so as to gain some idea of the accuracy obtainable on these. On our system I have noticed a swinging of the bearing of about 3° or 4° on long-distance stations, for example Canada and New York, and I am not sure whether to attribute it to a real wobble of the bearing or to horizontal polarization effect. I think that far better balancing than can be obtained either with the author's or my own system is necessary in order to make certain of this. The question would be important from the point of view of beam transmission should a wobble of 3° or 4° be shown to exist. I think that the author has confirmed the presence of scattering and, perhaps in response to this, one may say that there is little hope of getting reliable direction-finding results in the " skip distance." As a matter of fact, errors up to 90° may be obtained in the case of the beam transmitter, and one never knows where this may occur. So far as we know at present, it is impossible to be certain of the bearing within the " skip distance."

Mr. F. Adcock (*communicated*): In the course of the discussion on the paper a speaker referred to a direction-finder which appeared to be remarkably free from " night error." In that equipment the horizontal insulated leads were screened by placing them within metal tubes which were carefully sealed and earthed at several points. I am interested in this method of reducing or avoiding " night error," as at one time I experimented with a direction-finder in which the horizontal leads from the vertical aerials to the operator's hut consisted of insulated wires simply laid on the surface of the ground. With this improvised arrangement the errors in bearings taken on aircraft were about one-quarter as great as those procured by means of a closed-loop direction-finder. As it was impossible to make further experiments it remained doubtful how far the improvement in accuracy would be maintained for other wavelengths and for different conditions of the soil on which the direction-finder was erected. One would expect a reduction in " night error " when the horizontal leads of a direction-finder are placed near the ground-level, but the complete elimination of the error in all circumstances is unlikely by this method, owing to the poor conductivity of the soil. So long as the soil in the vicinity of the direction-finder is fairly uniform in conductivity the re-radiated energy takes the form of the usual reflected wave, which should not unduly disturb the bearings obtained by the installation. On the other hand, horizontal conductors situated near the direction-finder would distort the reflected wave. Expressed in another way, oscillations present in horizontal conductors or in the earthed screens surrounding horizontal conductors may, owing to re-radiation or to electric or magnetic coupling, give rise to undesired oscillations in the vertical aerials. Owing to the relatively poor conductivity of soil it is impossible to " anchor " the screening tubes by any ordinary system of earthing. For these reasons it appears that there is some risk of error in direction-finding installations where the horizontal leads are carried in long continuous screening tubes which are earthed at several points.

Mr. R. H. Barfield (*in reply*): I am interested to hear that Mr. Davis is adapting Eckersley's screened " U " Adcock to practical direction-finding, and to see that it is giving good results. Experiments which I have carried out since reading the paper show that for short waves (20 metres) the screen can have but a negligible effect on the performance of the system, whether earthed or insulated. The ordinary unscreened " U " Adcock is amenable to fairly simple calculation, and it appears that the horizontal pick-up may be of the same order as the vertical pick-up under some conditions. For this reason it was dismissed some time ago. Mr. Adcock gives a criticism of the "U" Adcock screened and unscreened, with which I am in substantial agreement. He gives a figure for the performance of the " U " Adcock which, though somewhat more favourable, is of the same order as that obtained by a calculation.

In reply to Mr. Smith, the wavelength range of the balanced Adcock system with a given balancing capacity has no upper limit other than that of amplifier sensitivity since, for waves long compared with that of the aerial, the impedances which have to be balanced are both purely capacitative and therefore change equally with frequency. The lower limit occurs when the working wavelength begins to approach that of the aerials. It should therefore be possible to work with very large wavelength ranges. For reasons connected with the residual effect referred to in the theoretical analysis, the balancing of the condenser is not critical, and the case of the tuned Bellini system is therefore not a parallel one. In a commercial design of the system they would probably take the form of fixed condensers in sealed weather-tight boxes and would never require any attention. The interruptions in the Adcock observations, referred to by Mr. Smith, were due to causes such as adjustment of apparatus, changing of batteries, etc.

In reply to Dr. Smith-Rose, in assuming a sine-law distribution for the current in an untuned aerial, I have taken it for granted that the relative value of the current at two points in an aerial would be independent of the frequency of the e.m.f., provided the aerial was oscillating as a whole and not in harmonics. The introduction of positive reactance into the aerial circuit is a possible way of balancing an Adcock system. I rather fancy, however, that a resistance balance would in this case be also necessary. I have no proof that balancing the impedances in the manner described in the paper causes symmetry of current distribution about the field coil, but I think it is a very reasonable hypothesis. It is difficult to see about what other point the distribution could be symmetrical than the point which divides the aerial into equal impedances. The type of error to which the system in Fig. 11 is subject is set out in paragraph (3) on page 1062. I cannot see that any arrangement of the leads in Fig. 11 could prevent the horizontal length as a whole acting as an antenna which is effectively coupled to the vertical members. The superiority of Figs. 12 and 13 is that this antenna is *broken into short lengths* which are individually too small to have any effect. I do not think I am guilty of using the same field twice over to derive the current in one circuit, as Dr. Smith-Rose suggests. The fact is, the circuits are not the same. Consider the aerial system in Fig. B, which is the combination of a loop and a vertical aerial, and is in many respects analogous to the arrangement questioned by Dr. Smith-Rose, as shown by Fig. C. The current in the limb CE is given by the sum of two currents,

$$I = \frac{Eh}{Z_A} + \frac{2\pi Ehd}{\lambda Z_L}$$

where Z_A = impedance of aerial circuit
and Z_L = impedance of loop circuit,

which is the same as

$$I = \frac{Eh}{Z_A} + \frac{\omega AH}{Z_L}$$

where A = area of the loop. Here we are taking both E and H into account without any redundancy.

Mr. Herd asks how the balanced Adcock compares with the elevated hut Adcock as regards immunity from night errors. No tests of the latter were made with controlled downcoming waves, and as the night tests were comparatively few in number the basis for comparison is scanty. I am inclined to think, however, that the elevated hut Adcock had a slightly better performance than the balanced system. Its characteristic curves would probably be similar to those obtained with the short-wave rotating Adcock of Figs. 19 and 20.

I agree with Mr. Horton that the sensitivity of the Adcock receiver is not as great as that of a closed-loop system of similar dimensions. This is particularly true on long wavelengths. For a system such as that shown in Fig. 10 the ratio of the current in the goniometer field coil to that in a closed loop is given by:—

$$\frac{I_{\text{Adcock}}}{I_{\text{Loop}}} = \frac{hs}{A} \cdot \frac{Z_{\text{Loop}}}{Z_{\text{Adcock}}}$$

Mr. Horton also refers to the screened "U" Adcock as being possibly superior to the balanced Adcock, as explained above. I do not think this is the case. Mr. Horton suggests that a careful comparison of the two systems should be made. I am at present carrying this out and hope to extend the work to a comparative study of the many other possible modifications of the Adcock system. I sympathize with Mr. Horton in the difficulties which he meets in attempting to install an Adcock direction-finder on a battleship.

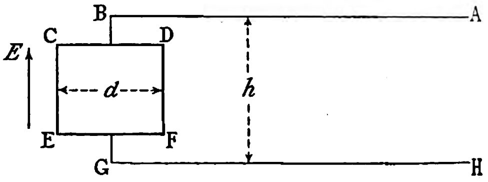

Fig. B.

Lieut.-Col. Lefroy's method of preventing pick-up on the horizontal leads by rotating them is sound in principle, but, on calculation, the amount of pick-up caused by the spacing of the wires is so small that rotation is in the nature of a refinement to which it would not be necessary to resort until the more important sources of error referred to in the paper have been eliminated.

In reply to Air-Commodore Warrington-Morris, the spacing of the vertical aerials certainly affects the pick-up value but not, I think, the accuracy during night effect, since the action of both vertical and horizontal fields is equally affected by any change in this dimension. The most important factor to be considered is the ratio of aerial height to wavelength, which should be made as great as possible. With the central mast arrangement an increase of spacing means a decrease in height; hence the spacing was kept as small as possible. As I have already pointed out in my reply to Mr. Smith, it is not necessary to re-balance on changing wavelength. I am interested to hear particulars of the performance of the Marconi Adcock system. As I have already said, I do not believe that horizontal pick-up can be eliminated or greatly reduced by screening. The "standard deviation" is not the same thing as "average error," but, as defined in Table 1, it is the root-mean-square. One reason why this value was used in preference to the other is that it gives a result free from permanent errors due to site, etc., in which we are not interested.

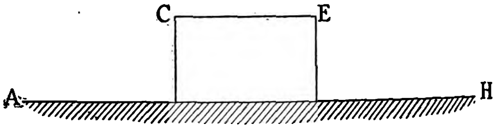

Fig. C.

In hearing from Mr. Eckersley that, in suggesting the possibility of balancing the Adcock system, I am forestalled by him by a matter of 13 years, I am rather flattered than discouraged and therefore gladly acknowledge his claim to priority. In developing the completely screened loop direction-finder I have always realized that the same result could be achieved by careful balancing. I think Mr. Eckersley will agree, however, that there is something attractively "fool-proof" about the screened loop which makes it superior for nearly all purposes. Though I should very much like to do so, I have not yet made any tests with the short-wave Adcock over very long ranges. The difficulty is to find time and staff for following up all the avenues opened by a given investigation, and, as Mr. Eckersley says, it will be well to wait until we have more perfect apparatus.

DISCUSSION ON

"THE HEAT PUMP—AN ECONOMICAL METHOD OF PRODUCING LOW-GRADE HEAT FROM ELECTRICITY."*

North-Eastern Centre, at Newcastle, 14th April, 1930.

Mr. T. Ritson: The title of the paper is rather misleading at a first glance, and the paper needs careful study before the author's meaning is fully grasped. It is only by the author's choice that electricity is used for this system; any other prime mover may be used as the operator, though the electric motor will probably be the most suitable in the majority of cases owing to its ease of control, absence of noise and other well-known advantages. In the application of the principle, available heat is transferred by the application of energy and not produced, so that I think the efficiency of transference (as defined in the paper) should not be compared directly with the efficiency of heat production by the direct conversion of energy. Perhaps it would be better to use some other term than "efficiency," because actually what is secured is a thermal advantage of heat transference. The system is very speculative in practice when one considers the amount of heat available for transference, but, given the correct combination of conditions, it should be a most economical method of using energy to obtain the desired result. I do not know how the space factor of the equipment compares with that of modern existing systems of heating, but if this is favourable and the possibility of obtaining a satisfactory heat source is secured, considerable progress should be made. The example of a swimming bath is given in the paper, and, speculatively, if the swimming bath were run in conjunction with a large refrigerating plant the combination of conditions might be satisfactory. There are many other such complementary instances of use, of which I will mention a smallholding, with a creamery or dairy requiring cold and forcing frames or greenhouses requiring heat; and a large hotel situated near the sea, with its vast store of heat.

Mr. T. Carter: In some ways the most significant sentence in the paper is that in which the author says that to the best of his knowledge no detailed experiments other than those carried out by him have ever been made on a refrigerator used primarily as a heat pump. The significance lies in the fact that the author has had the courage to prove the practicability of what was previously a purely theoretical proposal, and in so doing he has added one more to the already many uses of electricity in domestic or industrial applications. If he wishes, as he doubtless does, to familiarize electrical engineers with what to many of them may be a rather new idea, I suggest that in spite of his careful footnote on page 667 about the term "heating efficiency" it is not altogether easy to become accustomed to the thought of efficiencies greater than unity, greater, that is to say, than 100 per cent; and I think it would be better if he adopted another term, especially when in other parts of the paper he uses "efficiency" in the ordinarily understood sense. What the heat pump does, it seems to me, is largely to transfer existing heat from one place to another, adding to its temperature, more or less, on the way; and the less the temperature is raised, the greater is what the author calls the heating efficiency of the transfer. The heat transferred is a natural product, contained in a natural storehouse of atmosphere or ocean, and it appears from the formula for heating efficiency that a wind blowing from one place to another without change of temperature is carrying heat at an infinite efficiency, viewed from man's standpoint, since no artificial energy has to be put into the transfer at all. The ratio $T_2/(T_1 - T_2)$ is called the "coefficient of performance" of a refrigerating machine. The author uses the ratio $T_1/(T_1 - T_2)$, which in the ideal conditions is exactly equal to the coefficient of performance plus unity. Could he not use $T_2/(T_1 - T_2)$, and call it the coefficient of performance of the heat pump? Or, if he wants to use $T_1/(T_1 - T_2)$, could he not call it the "coefficient of operation"? But why cannot he use the same expression for efficiency, $(T_1 - T_2)/T_1$, as is used for the efficiency of the perfect heat engine, the heat pump being merely a heat engine working on a reversed cycle? If an electric motor happens to be used as a dynamo, does one describe its efficiency by a percentage greater than 100? By no means: the same kind of value serves both for motor and for dynamo, and so it might for heat engine and heat pump correspondingly. I have been trying to familiarize myself with the idea of the heat pump by using some analogies, imperfect, no doubt, as most analogies are, but still possibly helpful. I have thought of a 3-wire direct-current balancer, which transfers power from one side of a supply system to the other when the consumption is not equal on the two sides. A large load may be passing across the two sides in series, and the relative power of the balancer set may be very small, so that the efficiency of the whole operation is very nearly 100 per cent, considered on the ordinary lines of efficiency. This means that a small piece of additional apparatus is effecting a transfer or something within its capacity to deal with in such a way that it makes it serve some definite purpose in a very much larger system. So, too, the stoker in the boiler house does not produce the energy of the boiler fire, but merely puts the fuel where its inherent potential energy can combine with another and generate heat; and what has to be paid for is not the energy itself, which is a natural gift, but its release. I have thought, again, of a lake in a hollow on a hill-top, the water of which cannot be used to do any work unless a pump is installed to raise it up to the lip of the hollow, from which it can then flow down the hill-side. If the surface of the water is H_2 feet above sea-level, and the lip of the hollow H_1 feet above sea-level, the efficiency of the arrangement, calculated as the author calculates for the heat pump, is $H_1/(H_1 - H_2)$. Here, as in the heat pump, the body moved does not use its own energy for any part of the transfer from the useless to the useful place: a definite amount of power is used to make the inherent energy available in a particular way. I have thought, finally, of a postal order. If I hand 7d. to the post office, I can use one of the 7 pennies to make the other 6 carry their buying power to any place I choose. The penny is money with a purpose quite different from that of the 6 pennies. They are circulating coins, but it, like the energy of the electric motor in the heat pump, is absorbed in the machinery of the transfer, the feeding, clothing, sheltering, and entertaining of the post-office staff; and the author, I imagine, would agree that the efficiency of the transaction, calculated in his way, is 700 per cent. I should like to close with a quotation from Prof. J. A. Ewing's book, "The Steam-Engine and Other Heat-Engines," published in 1894, because it seems to me to express a principle of which we are only now beginning to realize the full importance. "Burning fuel to warm a room by a few degrees is a wasteful way to utilize heat, even if all the heat of combustion be conceived to pass into the air of the room. The high-temperature heat produced in the combustion of coal or gas could warm a much larger volume of air to the same extent if it were applied to drive an efficient heat-engine, which in its turn drove a reversed heat-engine or warming machine to pump up heat through a short range from the diffused store of heat which is contained in the atmosphere or in the ocean. This is because a heat-engine can be arranged to take advantage of the high temperature at which heat is produced in the burning of fuel, whereas any direct communication of this high-temperature heat to a comparatively cool body, such as the air of a room, is thermodynamically bad. It is interesting, and may some day be useful, to recognize that even the most economical of the usual methods employed to heat buildings, with all their advantages in respect of simplicity and absence of mechanism, are in the thermodynamic sense spendthrift modes of treating fuel." The author has left us in his debt by showing us in his paper one way of putting to practical use, instead of finding merely interesting, the process described 36 years ago in the words I have quoted.

---

* Paper by Mr. T. G. N. Haldane (see page 666).

Mr. H. W. Clothier (*communicated*): Most of the speakers are concerned about the use of the term "efficiency" to describe the gain in heat energy claimed by the author for his system; but what matters chiefly is that the heat acquired from an external source with a comparatively small expenditure of motive power shall be put to a useful purpose in the efficient heating of a building. I agree with the author that the system which he describes should have the close attention of the electrical industry. I feel sure that this will lead to the working out of some practical applications; the use of electricity as a prime mover of the heat pump should be encouraged, if only on the off-chance that more electricity will be required for topping-up by means of immersion heaters. In a discussion * on the recent paper by Messrs. Monkhouse and Grant I gave comparative costs of heating a house by central heating from a coke boiler and by hot-water storage from an electric night-load. It would be of interest if the author could add to this comparison a statement of the corresponding cost of using the heat-pump system for the same purpose, on the assumption, let us say, that his suggestion of using sewage water as a source of low-grade heat could be put into practice. It may seem at first sight to be a rather far-fetched suggestion; but it is conceivable that it might lead to useful results in other situations where external water is available under similar conditions of temperature.

Mr. T. G. N. Haldane (*in reply*): I have been taken to task both by Mr. Ritson and Mr. Carter for the manner in which I have used the expression "heating efficiency" in connection with the heat pump. The main objection seems to be that my definition of the expression (which is carefully explained in the footnote on page 667) leads to efficiencies greater than 100 per cent. Now Mr. Ritson and Mr. Carter may very well object on principle to the suggestion that any machine can have an efficiency of over 100 per cent, and I would share their objection to my use of the expression "heating efficiency" if it were not for the fact that by universal custom and usage 100 per cent heating efficiency is said to be that which would be obtained if the whole of the heat of combustion of a given quantity of fuel or the whole of the heat equivalent of a given quantity of electrical energy were usefully employed for heating purposes. It is accordingly customary to refer to the efficiency of a coal- or coke-fired boiler as being a certain figure less than 100 per cent, depending on the fraction of the heat of combustion usefully employed, and the electric radiator is said to have a heating efficiency of 100 per cent because the whole of the heat equivalent of the electrical energy consumed is usefully employed for heating purposes. It may be unfortunate that the heating efficiencies of boilers and electric radiators are so measured, but neither Mr. Ritson nor Mr. Carter could have expected me to try to alter such universal practice. I had therefore little option but to accept the existing use of the definition "heating efficiency" and so give to the heat pump efficiencies running into several hundred per cent. As I remark in the footnote in the paper, this may be objectionable from a purely thermodynamic point of view, but I believe it is really descriptive of the practical operation of the heat-pump system. Mr. Carter goes so far as to draw a comparison between the expression "heating efficiency" and the efficiency of the transference of money by means of postal orders, and asks whether it would be reasonable to call the efficiency of a sixpenny postal order 700 per cent (I think he means 600 per cent) since by expending one penny we can transfer sixpence from one place to another. I would reply that if, previous to the invention of postal orders, we had been in the habit of spending sixpence in order to transfer sixpence and had called the efficiency of this process 100 per cent, then it would be reasonable to call the efficiency of the sixpenny postal order method 600 per cent.

---

* See page 685.

I think Mr. Ritson and Mr. Carter feel that the heat pump is cheating because in their view it does not "create" heat as does a burning lump of coal or an electric radiator. To them the heat-pump process is only a transference of heat. It is essential, however, to bear in mind that the reversed-cycle heat engine is not merely transferring heat from one place to another, but in separating two quantities of heat is altering the temperatures and so actually creating something which was not there before. In other words, a given quantity of heat at one temperature is really an entirely different commodity from the same quantity of heat at another temperature. The process of the heat pump is to depress by an infinitesimal amount the temperature of the infinite quantity of heat of our surroundings, and so produce a limited quantity of heat at a temperature sufficiently high to be of use. Viewed in this way the heat pump is actually producing useful heat in very much the same way as the lump of coal produces useful heat when, in the process of combustion, its stored potential heat energy is converted into a useful form.

Mr. Carter's suggestion that the expression "coefficient of performance" or "coefficient of operation" should have been used in place of "efficiency" is open to the objection that it would almost inevitably have been confused with the coefficient of performance as used in refrigerating engineering, and moreover it would, in my opinion, have been far less descriptive of the actual operation of a heat pump.

The various analogies which Mr. Carter suggests are both ingenious and helpful, but, like all analogies, if they are pushed too far they break down. For instance, in Mr. Carter's analogy of a lake in a mountain hollow, the water of which has to be raised to the lip of the hollow by mechanical energy before it can fall to the valley below and so do useful work, he is comparing the quantity of water with the quantity of heat produced by a heat pump. Unfortunately these quantities are not comparable, one being a measure of mass and the other of energy. A more or less exact analogy can only be obtained if in place of heat we substitute the rather abstract conception of entropy and compare this with the quantity of water in the hydraulic analogy.

I am glad to find that Mr. Clothier is less critical of the expression "heating efficiency" and supports my contention that the use of the expression is justified, at least by works, if by nothing else. Mr. Clothier suggests that to the interesting figures of the annual cost of heating a dwelling-house, which he gives in the discussion on the paper by Messrs. Monkhouse and Grant, should be added a corresponding figure for heating by the heat pump. The heating of an ordinary dwelling-house is not at present a very favourable application of the heat pump, pending the development of cheaper small-size refrigerators, and an estimate of the cost is somewhat difficult owing to its dependence on the special circumstances of each particular case. Assuming, however, that sufficient radiator surface is available to operate the heating system at the comparatively low temperature suited to the heat pump, but that a large proportion of the heating is done during the day at day rates, I estimate that the annual cost of a heat-pump system would be slightly higher than that of the electric thermal-storage system, i.e. about £160, as compared with £150 10s. This makes no allowance for the advantage of abundant ice or cold storage, nor for the possibility of cooling the house in summer. I would refer Mr. Clothier to an interesting article by Monsieur Guarini which appeared in the issue of *Cold Storage* of the 17th April, 1930, dealing with small-scale heating by means of the heat pump.

DISCUSSION ON

"THE HEATING OF BUILDINGS ELECTRICALLY BY MEANS OF THERMAL STORAGE."*

WESTERN CENTRE, AT CHELTENHAM, 14TH APRIL, 1930.

Mr. W. J. Bache: Great difficulty is experienced in the satisfactory heating of a series of rooms such as the Cheltenham Town Hall by hot water. Conditions may vary every night in every room and constant complaints of overheating or underheating are the result. Electrical heating with thermostatic control would give much more satisfactory results.

Mr. H. R. Beasant: I doubt the utility of estimates of running costs based on such a low unit price, the price given by the author being exceptional and not generally available. Important advantages are to be gained by the use of electricity, e.g. convenience, ease of control, cleanliness and smaller space required for installation, and these in many cases justify the use of electricity at a higher unit charge. For premises where the period of use of different rooms varies considerably, the method of direct heating (e.g. by tubular heaters) appears to offer the better solution, especially where low night rates are not available. As an instance of this, a greenhouse where certain difficulties prevented the erection of a heating chamber and flue was heated electrically by tubular heaters controlled by a thermostat, to the satisfaction of the owner, although the price of energy was 1d. per unit.

Mr. J. M. Bowman: What will happen to the supply engineer if a multiplicity of thermal-storage connections is made to the distribution mains? For the smaller undertakings this would necessitate a complete re-laying of the distributing system and an increase in the capacity of the generating stations. Are any experiments being made with a view to providing an element which will give a maximum heating capacity at, say, half the present consumption of watts? I would refer to the rapid strides made in illumination, where the number of watts consumed per candle power has dropped very considerably—with a much greater efficiency as the result.

Mr. W. Burton: To fill up the valleys in the load curve has long been the ideal of the supply engineer, and this ideal can be achieved in another way, giving equally good results, if we encourage the use of 100 per cent load-factor supplies with, if necessary, certain restrictions during the peak hours of the winter months. The load curve will thus be raised to such an extent that the existing peaks will be small in comparison. This method is used in the London Underground Railway system, where the supply is always on except just at the peak hours. The ordinary supply undertaking load-curve is troublesome during a few months in the winter, and it would certainly pay to have the maximum demand reduced throughout the year. It is quite conceivable that if a large night load were encouraged it might ultimately result in the peaks appearing at the wrong places. We should aim at improving not only the power station load-factor but also the load factor on the system generally, so as to make the maximum use of cables, transformers, distributors, etc. If a 24-hour system could be adopted instead of a 12-hour system the maximum demand would be considerably less, for given heating requirements. It is interesting to note how the load factor may be improved by adding a constant 24-hour supply in the case of a load curve having the ratio of day to night load equal to 6 : 1; a constant addition of about 150 per cent of night load improves the load factor to 59 per cent. With a practicable arrangement for filling up the valleys the same additional amount at off-peak times improves the load factor to 61 per cent. It should be noted that there are practical difficulties in the way of filling up the valleys exactly, as this is dependent for the most part on time-switch operation. Reference is made to the use of water as a storage medium, and although it has the merit of cheapness the buildings have to be specially arranged and large radiator systems have to be fitted to make use of the heat. It is difficult to provide water piping round a big building, and when installed such a system is not nearly so flexible as direct electrical heating. It is much simpler to arrange for the wiring of a building, and the heaters themselves may be placed in the most convenient positions or they may be split up into a number of units so disposed about the room that uniformity of heating is obtained. Local automatic control is easy, and a predetermined room temperature can be obtained by the most inexperienced operator. There is no question of trial and error, as the thermostat needs only to be set to a given value. Since the electrical radiators are all at the same temperature the more remote rooms receive the same amount of heat as those near the supply, whereas it is a common occurrence to find that in the case of water-heated rooms those near the supply derive most of the benefit from it. Again, with electrical radiators the heating of the rooms is more rapid, as all the units attain their maximum temperature in a few minutes. The oil heating system is still on trial, and it may be that when the present difficulties of oil leakage, etc., have been surmounted this system will be used for heating buildings; at present it requires three transmissions of heat, viz. electrical energy to oil, oil to water, water to room. It is interesting to note that earth currents have not so far proved troublesome, and presumably this is due to the fact that the water in the electrode heaters forms combined delta and star loading, thus disposing of any triple-frequency currents. The author has made out a good case for thermal-storage electrical heating in the Newcastle Motor Depot, but it is probable that a more flexible arrangement would be obtained with electrical radiators. The following figures represent the capital and running costs of the heating supply to a large school holding 1 800 children. For heating by electricity, coke, gas, and oil the capital costs are £4 700, £6 300, £6 600, and £7 000, respectively; the corresponding running costs are £1 610, £1 250, £1 740, and £1 440 per annum, respectively. It will be seen that the capital costs of the electrical system are very much lower than those of the others, while the annual costs occupy a good position when the cleanliness and minimum of attention required are taken into account. This comparison makes no mention of the great savings in building charges which are possible by the electrical system. A heating system similar to that in the Newcastle Motor Depot, but of the direct tubular type, has been adopted for power-station heating with advantage. It would seem that for very large buildings the electrical storage system has a great field, but the direct heating system should receive serious consideration for smaller buildings.

---

* Paper by Lieut.-Col. S. E. MONKHOUSE and Mr. L. C. GRANT (see page 657).

Mr. J. E. Gamage: As the question of the electric heating of greenhouses has been raised during the discussion the following information may be of interest. The first installation of this character was made in the North of England for a grower of orchids, who used large greenhouses for growing this and other tropical plants. He had previously had to depend upon hot-water pipes connected to a coke-fired boiler for the maintenance of a uniform temperature and the required degree of humidity. During the winter months many kinds of tropical plants die off quickly if they are subjected to a lower temperature than about 60° F., so that constant attention to the coke boiler was required to keep the temperature of the greenhouse at this figure. Firing late at night, early in the morning and several times during the day proved tiresome, especially as a lower temperature was sufficient in some of the greenhouses containing semi-tropical plants. The obvious remedy, therefore, was to supply the houses with separate heating installations, and a special waterproof type of tubular heater was designed for the purpose. The orchid house was equipped with 80 ft. of tubular heaters having a total loading of 16 kW, the heaters being connected directly to a 3-phase network. To preserve the proper saturation of the atmosphere the heaters are constantly covered with water, and accurate temperature control is effected by means of an adjustable air-thermostat working in conjunction with a 3-pole ironclad contactor. The chief features of the heaters are the load of 200 watts per foot length and the fact that they are designed as watertight elements capable of being constantly immersed in water. The advantages of this system are the maintenance of an equable temperature under easily controlled conditions, a cleanliness such as is impossible with coal-fired or coke-fired methods and, further, there are no products of combustion inimical to plants to vitiate the atmosphere. It would appear from the discussion that while the heating of large buildings by thermal-storage means is the only economical electrical method, for smaller buildings, particularly where the whole of the building is not necessarily always in use, direct heating by radiant heaters of tubular or other types is an economical proposition. As this is a day load it necessitates the provision of current at a higher price than night heating warrants, but this is compensated by the use of these heaters only at such times as the individual rooms are in use and the temperature conditions render it necessary.

Mr. W. Hill: I should like to ask the author for more details as to the connections on the boilers used in Newcastle, as such information would explain better the absence of leakage trouble. Is the boiler fitted with an earthed or shielded neutral or is it without a neutral? Previous speakers have made out an excellent case for direct electrical heating rather than thermal storage, and it occurs to me that a consumer can afford to pay three or four times as much for heating by the direct method as he can for heating by thermal storage. In the former case he will only have the heating on for 48 hours per week as against 24 hours per day for a 7-day week (i.e. 168 hours) if he chooses the latter alternative.

Mr. W. A. H. Parker: A previous speaker has advocated obtaining the 100 per cent load-factor consumer so as to avoid the necessity of obtaining off-peak loads to fill up the valleys. Whilst this high load factor is almost impossible, if we could improve the load conditions of the ordinary power consumer, who has a load factor of, say, 15 to 20 per cent, by inducing him to use the supply for thermal-storage purposes during periods of light load, it would enable the supply authority to sell at a reasonable price. It appears to me that good use could be made of the Wilkinson "change-circuit" system in this direction. I am pleased that the author has not fallen into the error made by those engineers who consider that as the plant is already in existence they can sell off-peak supplies at the bare cost of the coal consumed. I believe that there is a large field for thermal-storage supplies and they must bear their fair share of the total capital charges of the system. The unit charge of 0·3d. may appear small to us in this area, but I do not think that we need despair, as there is some demand for energy at about 0·5d. per unit. Electric heating offers something more than the ordinary heating system and, in my opinion, no other equipment can show such a close temperature-control—an advantage which the up-to-date consumer will appreciate. The slide showing the temperature record for one day was a revelation to me, and if the author could arrange for the record of the outside temperature to be placed on the same slide it would emphasize the constancy of temperature inherent in the system under discussion. The figures for the heat loss in lagging are interesting, and they compare favourably with those obtained by tests on the domestic hot-water storage tank. The author stated that one reason why the small immersion heater was adopted in the case of the L.C.C. offices was that it was feared that earth currents might be present with the electrode type. This difficulty, however, might have been avoided by installing a double-wound transformer, and it would be interesting to know whether there would have been any saving in the cost of the heaters which could have been set off against the cost of such transforming plant. The equipment adopted by the author appears to me to suffer from one disadvantage as compared with the tubular heating system in that it does not provide for individual automatic control—a very attractive feature where the rooms are not all used at once—and it may be that the capital cost of the water heating system, including radiator pipes, etc., is greater than that of an electric tubular heating plant. In a tubular heating system which has been installed locally the heaters have a total capacity of 45·82 kW and the capital cost is about £10 per kW. The cubic content of the offices is 76 930 cub. ft., giving a loading of 600 watts per cub. ft. Automatic control is arranged by the installation of several thermostats set at 65° F. and the annual consumption is approximately 80 000 units per annum or, say, 1 unit per cub. ft. per annum. The number of units consumed per day shows a considerable variation, especially during the cold snaps. The figures for the last five months—November, December, January, February and March—are 358, 352, 381, 550 and 450 units per day, respectively.

Mr. R. A. Parsons: A comparison between the unit system and the thermal-storage systems shows that the current consumptions of either are practically the same, whilst the number of watts consumed per cubic foot of space heated are identical. In either case there is a marked variation between the current consumption for a very cold winter and that for a mild one. Some information regarding the types of electrical heating systems most suitable for greenhouses of the residential size and for large glasshouses would be welcome.

Mr. P. J. Plevin: If the figure of 0·08 watt-hour per cub. ft. per deg. F. represents the consumption of electricity over the 8-hour storage period (this is not quite clear from the paper), the Banca Commerciale Italiana di Roma absorbed heat at an average rate of 0·034 B.Th.U. per hour per cub. ft. per deg. F. over the first winter's working. The corresponding figure for the Newcastle Motor Depot can only be obtained by assumption, because the mean temperature-difference between the inside and outside of the building during the 8-months' working period is not stated, but if this be taken as 10 deg. F. the average rate was 0·025 B.Th.U. per hour per cub. ft. per deg. F. in this case. Even the first-mentioned figure is well below values now commonly employed in computing the heat requirements of buildings, which seems to indicate that the facility and accuracy with which heat in the form of electricity can be measured (not only over short tests but over long periods of operation under varying conditions) may lead to a revision of present ideas on rates of heat consumption. The cost comparison in Appendix I seems to flatter the electrical alternative. If the calorific value of coke be taken as 11 500 B.Th.U. per lb. the efficiency of the coke-fired alternative works out at 32 per cent, a very poor figure. The efficiency of 50 per cent assumed in the table giving a comparison of the number of B.Th.U. purchasable for 1d. from coke, oil, gas and electricity is a much more reasonable one. Tests on coke-fired heating boilers indicate efficiencies of 70 per cent and over, but such figures cannot, of course, be expected under ordinary running conditions. If an efficiency of 50 per cent be taken instead of the 32 per cent assumed, the estimated coke consumption would be reduced from 90 tons to 57 tons, thus increasing from about £8 to £53 the cost difference in favour of the coke-fired alternative. Furthermore, is the price of 0·3d. per unit, taken as the basis of the electrical alternative in Appendix I, really an economic figure and can it be maintained? Power companies seem willing enough just now to supply current for electric storage purposes during light load periods at even lower prices, but what would happen should this load increase to such a degree that the day and night loads on the supply system became equal? Consumers taking supplies under similar conditions during the day could then not unreasonably demand equal terms. It is true that the improvement in load factor would cut down the standing charges and certain other components of generating and distributing cost per unit (the fuel-cost component of generating cost would not be greatly affected), but would this reduction make up for the loss in revenue which would result from a general reduction in tariff? Any electrical heating system is inherently wasteful because its efficiency is limited to that of the generating station which supplies it, and this efficiency—while generating stations continue to reject to cooling water 60 per cent of the heat which they produce—must remain a low one. Nevertheless, despite objections from the economic standpoint, the electrical storage system seems to offer advantages where heating installations in city buildings are concerned, not the least of these being the freedom from the dirt and nuisance of fuel handling, storage and combustion which it affords in crowded areas. A definite cash value cannot be assigned to amenities such as these, but they may, in such cases, go far to outweigh the heavier cost of electrical heating.

Mr. J. W. Spark: From the supply engineer's point of view the first considerations are the load factor and diversity which this class of load will bring. I find from the paper that the load factor is only 28 per cent and although the diversity is very desirable it does not in the least help to remove the valley in the summer load-curve, since for the four summer months the system is out of commission. I am not satisfied, therefore, that the flat rate of 0·3d. per unit, advocated in the paper, is justified. From the user's point of view, the system carries with it all the advantages and disadvantages of hot-water central heating, which, I submit, is not comparable in point of efficacy with a low-temperature tubular electric heating system where the heating units are placed where they will be most effective. In the Cheltenham Town Hall, for instance, which has a flat glass roof, a heating system employing hot-water radiators at practically floor-level would not be satisfactory. A hot-water radiator sets up rapid convection and produces a deposit of burnt dust which is detrimental to decorations; there is a consequent increase in the cost for re-decorating, which is not the case with tubular electric heating. In the system advocated by the author the automatic heat control is operated at one point, so that the temperature in the whole of the building will be varied irrespective of the requirements of the different rooms. With a hot-water system, owing to the comparatively high thermal capacity of the transmitting medium, the changes in temperature are bound to be sluggish and they will not follow the variations of the outside temperature in the satisfactory manner characteristic of tubular heating, where simple thermostats are installed in various parts of the building. Whatever the merits of the system may be, the examples given in the paper apply to large new buildings in large centres, whereas existing buildings of more modest size have usually to be dealt with. Whilst I have no experience of an electrically heated building of any size, I have dealt effectively with the Banqueting Room at the Guildhall, Bath, where other systems have failed. The room to which I refer is a beautiful example of the Georgian period with delicate decorations and pictures of considerable value. The cubic capacity is 93 642 cub. ft. Tubular heaters have been installed round the skirting and round the cornice of the room, coloured to harmonize with the decorations, and in order to retain the original two fireplaces "Magicoal" fires have been fitted. The total load is 26·4 kW for the tubular heaters and a 3-kW bar has been fitted in each fireplace; these latter are really more for psychological effect than for actual heating. Thermostat control is used, so that any predetermined temperature is maintained. For the first 12 months interesting and surprising figures were obtained. The room was in use 58 times during the year, so that the heating had to be started up with cold walls each time. The total hours of actual occupation were 185 and the consumption was 3 904 units, so that at the rate of 1d. per unit—the figure which I am able to justify—the total cost was £16 5s. 4d., or an average of 5s. 7d. each time the room was occupied. I submit that no other system of heating can produce such results. One outstanding difficulty which I have experienced in introducing electric heating of buildings is the obstruction of even well-known architects, who, I suppose, have had no experience with electric heating. I have twice had my proposals turned down at this source recently without being given any figures to show whether or not they compared with the alternative schemes. I am interested to learn that with the boilers described, using electrodes connected directly to the e.h.t. 3-phase system, there is no circulating-current trouble.

Mr. L. W. Barnard: Electric heating should be very useful in schools and churches. Old churches are invariably lofty buildings and it is necessary to distribute heat to the upper part as well as to supply a little heat low down. Electric heating is ideal for this purpose.

Lieut.-Col. S. E. Monkhouse and **Mr. L. C. Grant** (*in reply*): Mr. Beasant appears to regard 0·3d. per unit as an exceptionally low figure; he will find this price and lower ones available in many parts of the country, for instance in London, Manchester, Birmingham and on the North-East Coast. There does not appear at present to be any sign of the thermal-storage load exceeding the available capacity of the plant and mains.

In reply to Mr. Burton, the radiator capacity required with electrical thermal storage is not greater than with other forms of central heating. The temperature of the radiating units is frequently controlled individually by a modification of the ordinary screw-down control valve. Mr. Burton's figures for heating the school seem to be rather high, as regards both the capital and running charges. His coke system appears to have an efficiency of 10 per cent. We are aware that coke-fired systems are not particularly efficient, but it has been noted that an efficiency of 30 to 40 per cent can be obtained. Mr. Burton appears to have the impression that electrical thermal-storage is suitable only for very large buildings, but installations from 50 000 to 2 500 000 cubic feet are in use, and the electrical thermal-storage system has been equally successful with all.

In reply to Mr. Hill, the majority of electrode boilers have a definite internal neutral point, which is usually connected to the boiler shell. In his comparison of electrical thermal storage and direct heating, he has apparently forgotten (*a*) that the electrical thermal-storage system can be shut down at a moment's notice, and (*b*) that a direct heating system switched on for, say, 48 hours in a building which is occupied for 48 hours per week would be inadequate unless a considerable amount of extra heating capacity were provided for the first few hours.

In reply to Mr. Parker, the outside temperature-range during the week shown on the slide was from 25° F. to 45° F., during which the internal temperature was maintained at 63° F. with a variation of ± 1 degree. It has been pointed out that the electrical thermal-storage system can be arranged for individual automatic control. Mr. Parker should compare his figure of £10 per kW (capital cost) for the tubular system, with the figures which we have given for electrical thermal storage, namely £3 to £5 per kW.

If Mr. Plevin compares his efficiency figures for coke-fired boilers with those given by others who have taken part in the discussion, he will find that the latter figures are considerably lower than those mentioned in the paper. Perhaps he has omitted to include stand-by losses.

We do not follow Mr. Spark's argument, and we see no reason why, with an electrical thermal-storage system, radiating units should not be placed just where they are required. Moreover, we have emphasized the fact that, with an electrical thermal-storage system, the radiating system can with monetary advantage be built to run at a lower temperature than with other heating systems, thereby eliminating the dust and dirt troubles. Of the three methods, namely, electrical thermal storage, the ordinary hot-water system and tubular electrical heating, the first runs at the lowest temperature and the third at the highest temperature, and the third would thus set up the most rapid air currents. With regard to his figure of 5s. 7d. for heating electrically the Banqueting Room at the Guildhall, Bath, with electrical thermal storage the cost would be rather below 2s. The electrical thermal-storage system is not sluggish in action. At a cost of about 30s. per room, automatic control gear can be installed which will enable the temperature to be controlled directly, or the heating to be completely shut off.

DISCUSSION ON
"WATER PENETRATION EFFECTS IN LEAD-SHEATHED POWER CABLES."*

Dr. N. A. Allen (*communicated*): The author is to be congratulated on giving prominence to an important fact which has long been realized by power-cable engineers, namely, that the 24-hour immersion in water previous to conducting pressure and insulation tests on power cables serves little, if any, useful purpose, except perhaps in the case of 660-volt cables. A series of tests which we carried out seven or eight years ago in the testing laboratories of Standard Telephones and Cables, Ltd., illustrated this very clearly. A short length of 7/14 S.W.G. concentric 660-volt cable (insulation thickness 0·080 in.) was placed under water, with the ends clear, and a $\frac{1}{8}$-in. diameter hole was cut through the lead. Insulation-resistance, electrification, capacity and a.c. pressure tests were carried out at intervals of a few hours until water had penetrated to such an extent as to cause breakdown. Fig. A shows that the reduction of insulation resistance within 24 hours was in this case sufficient to condemn the cable, but the cable did not actually break down until the immersion period had reached 103 hours. It was also established, by cutting out the faulty section, that the water penetration was local, since the insulation resistance of the remainder was normal. The conclusion reached in this experiment was that the water test might enable faulty sheathing to be detected, but since faults which might exist would not be $\frac{1}{8}$-in. diameter holes, but pinholes so small as not to be detected by careful ocular inspection, the value of applying the test was thought to be somewhat doubtful. In any case, since defects rarely exist, and since low-tension cables are generally armoured, it is considered much more satisfactory not to expose the lead-covered cable to water at all, but to pass the cable direct from the lead press through a bath of hot compound of an impervious and elastic nature, thus sealing effectively any minute holes which might exist in isolated cases. Such a layer of compound adhering to the lead sheath forms an excellent basis for the various layers of armouring afterwards applied, and materially assists in increasing the efficiency of the protective coverings as an anti-corrosion medium. Another series of tests was also conducted with a length of 3-core, 0·007 sq. in., 6 600-volt cable, in an identical manner. In this case the insulation resistance was still at a satisfactory level after 475 hours, at the end of which period breakdown took place at 18 000 volts (a.c.) during one of the periodic pressure tests. This is illustrated in Fig. B. The conclusion reached in the second experiment was that the 24-hour immersion in water previous

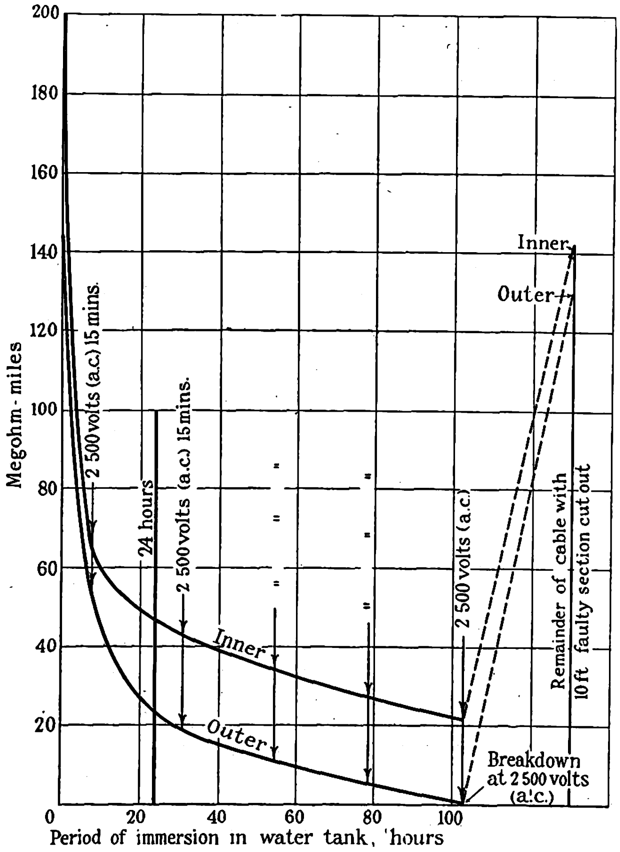

FIG. A.—Immersion test on 7/14 S.W.G. concentric cable with $\frac{1}{8}$-in. diam. hole in lead sheath.

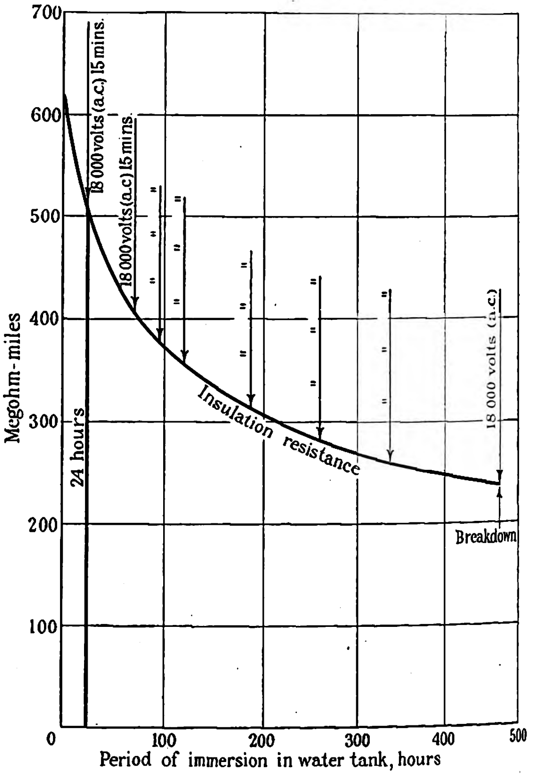

FIG. B.—Immersion test on 0·007 sq. in., 3-core, 6 600-volt cable with $\frac{1}{8}$-in. diam. hole in lead sheath.

* Paper by Mr. E. A. BEAVIS (see page 434).

to carrying out standard tests is of no assistance in detecting lead-sheath faults on high-tension power cables.

Mr. F. Farmer (*communicated*): I have conducted a series of tests for three years with a view to determining the time required for water to penetrate sufficiently far into the insulation of a cable to cause a breakdown. In these tests, however, arrangements were made to simulate as nearly as possible operating conditions where a cable lies, say, in a wet duct and is subjected to a breathing action consequent upon regular cycles. The cable sample under test was 15 ft. long, 8 ft. of which was submerged to a depth of 4 inches in a trough filled with water taken from a typical city manhole (simulating a flooded duct), and three holes $\frac{3}{16}$ in. diameter were made through the lead sheath in such a position that they lay on top of the cable in the trough. The ends of the cable were suitably terminated in order to be connected to the high-voltage side of a bank of transformers. Low-voltage current to the capacity of the cable (1 500 amperes per sq. in.) was circulated through the conductors and this was switched on in the morning and off in the evening, the potential meanwhile remaining on continuously. The type of cable was 2/0 A.W.G. (about 0·1 sq. in.), three round conductors, paper-insulated, $\frac{9}{32}$-in. paper on the conductors with a $\frac{7}{32}$-in. paper belt and a $\frac{1}{8}$-in. lead sheath over all. The cable was rated at 24 kV. The set was shut down momentarily once per week for insulation-resistance and temperature measurements to be made, the insulation-resistance readings being taken with a 1 000-V or 2 500-V megger. One conductor failed to the sheath after a total immersion of 368 days. The insulation resistance to earth and to each of the other two conductors ranged from 10 000 megohms to 1 000 ohms, the former reading being the highest of the range of readings (10 000 to 4 000) during the main period of the test, and the latter reading being observed at the close of the experiment. This was the insulation resistance to earth of the faulty conductor. Dissection of the faulty cable showed that the water had penetrated the belt, spreading over a 4-in. diameter area immediately under the lead and decreasing in extent towards the fillers. After soaking the filler in the immediate vicinity of the fault, the tapes of the faulty conductor were next attacked. Fifty of the 64 tapes (5 mils thick) were affected, presumably before electrical failure took place. Thus, under normal operating conditions, a period of over one year was required to penetrate $\frac{7}{32}$ in. of comparatively loosely wrapped belt paper and about $\frac{9}{32}$ in. of tightly wrapped conductor paper, all well-impregnated. Similar tests are being run with both a joint filled with black asphaltic compound and a length of shielded conductor cable. After a period exceeding 2 years the joint is still operating, while 2 years have now elapsed since the second cable was installed. During the whole of this time regular load cycles have been impressed on both cable and joint. The insulation-resistance readings are up to the present as high as when the tests were first started, and show no indication of the extent of the penetration of water into the insulation. American practice has for some years omitted the " tank " test as unnecessary, and operation reports show the omission to have been warranted.

Mr. T. L. Horn (*communicated*): In the year 1914 some paper-insulated lead-sheathed cables were manufactured for the undertaking with which I am connected. They had to stand a test pressure of 50 kV, and at my instigation they were not tanked. Up to the present time these cables have given no trouble. Following my experience, for the past 6 years none of the e.h.t. cable for the same undertaking has been either run through a water bath or put in a tank, and, although the cable has lain in water in many places, no trouble has been experienced. For many years it has been my opinion that the tanking of e.h.t. cables is likely to lead to more trouble than it prevents, and experience has so far confirmed this view.

Mr. E. A. Beavis (*in reply*): The results given by Dr. Allen are of interest as they represent tests carried out on different types of cable, and bring additional evidence to bear out the conclusions put forward in the paper. With regard to the experiment on the low-tension sample shown in Fig. A, the water appears to have penetrated the insulating material rather quickly as the insulation of the inner conductor has become affected almost as soon as that of the outer, and from the results given by the curve the sample is undoubtedly condemned before the standard immersion period has expired. The question as to whether such a fault occurring in practice in a drum length of cable would become so definitely apparent on the initial test after the 24-hours' tanking is somewhat uncertain. To some extent it would depend upon the general order of uniformity obtained for the insulation resistance of low-tension cable and in particular upon the range of values concerned with other drums of the same batch. When these are subject to wide variations the increased difficulty of detecting a fault of this nature is apparent.

Mr. Farmer's remarks afford a practical idea of the time taken for faults of this nature in high-tension cables to show up under operating conditions. It would appear that the continual heating and cooling of the insulation, consequent upon the loading cycles, has had little effect in aggravating the defect, judging by the period taken for breakdown to occur. The megger test is of course only a rough-and-ready measurement of the insulation resistance and will not give any indication of the nature of the electrification characteristics of the cable. It is possible that with a delicate galvanometer and a steady battery some indication of faulty insulation may show itself in the case of these experiments, either as unsteadiness or as a faulty charging-current curve, particularly if reverse currents be employed. This matter is, however, somewhat removed from the question of the standard specified test, but the experimental evidence contributed shows conclusively once more the inadequacy of the water-immersion procedure.

Mr. Horn's remarks hardly need comment. He is to be congratulated on an early policy of waiving the matter of tanking for e.h.t. cables, and has possibly been saved much worry and anxiety by this foresight. It is quite time that serious attention should be given to this subject, and the present standard specifications revised at least on the question of tanking, thereby relieving to some extent the individual responsibility undertaken in this respect by many consulting engineers and inspectors.

DISCUSSION ON

"ALTERNATING-CURRENT TESTS ON HIGH-SPEED TELEGRAPH CABLES."*

Mr. A. L. Meyers (*communicated*): On page 453 the corrections for tests on long coils are given in terms of the corrected constants instead of the test values; hence the second-order terms are erroneous. The author should have expanded the inverse function arc tanh *Pl* in place of the direct function. In connection with the damp-surface error in leakance testing, it is my experience that errors of much more than 10 per cent may arise from this cause. In fact, the example given indicates an error of over 50 per cent. The chief disadvantages of the Wein bridge shown in Fig. 6 disappear at audio frequencies if the Wagner earth is eliminated. Not only is double balancing dispensed with, but an earthed tank may be used. The correct connections for the screens are surely as given at (*d*) in Fig. 7; the capacity of *R* to its screen may be compensated for by an equal air condenser across the unknown arm. Turning from testing to telegraphy, the arguments on page 449 [section (2) (*b*)] appear to imply that frequencies above the reversal or "dot" frequency *f* are not essential to signal formation. Milnor † states that frequencies as high as 1·5 *f* are desirable for recorder and 1·65 *f* for relay reception. It is also necessary to question the remark at the commencement of section (2) (*c*)—that distortion on modern continuously-loaded telegraph cables is less than on unloaded cables.‡ I feel that the author does not fully appreciate the information to be gained from the departure curves in Fig. 26. These curves furnish a more delicate determination of the presence and position of irregularities § than the frequency plot of impedances in Fig. 28. Thus he cannot from the latter detect the disturbance from the resistance termination of the sea earth; but it is clearly visible at 0·015 and 0·044 sec. in the former, and gives a velocity of propagation (for an impulse of 60 volts) of 7 000 nautical miles per sec. The main irregularity found in the cable is confirmed at 0·017 sec. by Fig. 26, but its position is found to be about 60 instead of 47 nautical miles from the end. The smoothness of the cable curve at 0·030 sec. makes the existence of a reflection at 90 nautical miles very doubtful. The position of the irregularity suspected in the sea earth is verified at 0·009 sec. The author does not state that the attenuation results plotted in Figs. 34 and 36 are values obtained at Bamfield when transmitting from Fanning. Table A compares the attenuations given in the paper, for sinusoidal alternating current, with those measured by the present writer at Fanning, transmitting southwards, at the R.M.S. sending voltage stated. The differences of the tests in the two directions are attributed to unsymmetrical reflections; if these occur at quasi-infinite distances their effect on the attenuation is eliminated to a first approximation in the mean. Hence the last column should be used in estimating the cable constants. Comparing these figures with those in the paper, it will be seen that the deduced constants require approximately the following corrections: inductance 1 per cent less, capacity 1 per cent greater, sea-return resistance less at the higher frequencies (0·235, 0·31, 0·37 ohm per nautical mile at 30, 40, 50 cycles per sec., respectively). The slope of the sea-return resistance curve now decreases instead of increasing with frequency, and is theoretically more satisfactory. The following suggestion for the cause of the difference between the head-end loss for sinusoidal and for square-topped sending voltage, shown in Fig. 34 and Table 7, is due to Mr. D. E. Clarkson. On re-plotting the experimental results on a basis of maximum instead of R.M.S. voltage, the two sets of results are in good agreement. This indicates that the apparent discrepancy is not to be attributed to suppression of hysteresis loss by harmonics, but to the phenomenon of hysteresis being dependent on maximum values of flux density. No mention is made of the effect of the earth's magnetic field on the high-permeability

TABLE A.

Frequency, cycles/sec.	Northwards		Southwards		Mean of both directions			
	$V_s = 0$	$V_s = 60$	$V_s = 0$	$V_s = 60$	$V_s = 0$	$V_s = 60$	H.E.L.*	$a_0 \times 10^3$

§ Similar curves were used for this purpose as an aid to duplexing the Bay Roberts–Horta (1928) cable; see L. S. COGGESHALL: *Journal of the American I.E.E.*, 1930, vol. 49, p. 219.

mumetal loading, either in factory tests or as estimated for the cable *in situ*. Published figures on this point would be of considerable interest. The difference between the realized (19 or 20 per cent) and the anticipated (15 per cent) drop in inductance on laying may perhaps be due to this cause. The aspect of the paper to which I attach most importance is its insistence on the need for accurate tests on loaded cables to determine their performance and estimate their constants. In combination with factory tests this leads to the possibility of the accurate prediction of the performance of future cables. When designing to meet a guaranteed attenuation, a margin of safety has of course to be allowed. Largely as a result of the accurate work outlined by the author, the margin required has been reduced to about 8 per cent of the total attenuation. A further outcome is the isolation of a small loss—the after-effect—hitherto overlooked on loaded conductors. The discrepancy of 3 to 5 per cent obtained in the resistance of three loaded Atlantic cables * may be due to neglect of after-effect resistance. It appears that the least accurate factor determined by tests on laid loaded cables is that of the sea-return resistance. It is true that, assuming ideal conditions, the sea-return impedance can be calculated,† but it is doubtful how far these conditions are realized in practice. Application of the same principles of testing to unloaded cables would accurately determine the resistance in question, and the need for such tests to compare with calculation is evident.

Dr. E. W. Smith (*in reply*): Among the many significant points raised by Mr. Meyers the most important are those connected with reflections, the evidence of which are the departure and impedance/frequency curves, and the different results of the attenuation tests in the two directions. The departure curves referred to, taken with a sending current decreasing from 110 to 80 mA, are not, however, comparable with the impedance/frequency curve for a current of 1 mA. The resistance termination of the sea earth, being designed to simulate the seaward portion of the cable for interference currents of small magnitude, will naturally give marked reflection for larger currents, and (as noted on page 465) the location of irregularities in general changes with testing current. The additional attenuation tests given by Mr. Meyers are of interest. Given the average inductance near one terminal of the cable higher than that near the other, I should expect, at the higher-inductance end, higher head-end loss and higher received voltage. These conditions do not consistently hold at either terminal, but the differences between the tests are capable of partial explanation when corrected for differences in the impedances under test conditions at the two terminals. With regard to the difference between head-end loss for sinusoidal and for square-topped sending voltage, the theory supported by Mr. Meyers is verified by the experimental results at 50 and 33·5 cycles per sec., but not by those at 20 cycles. From such tests on other cables as are available, I consider the theory of hysteresis suppression by harmonics to be more tenable. With regard to testing, in using the Wien bridge I have found screen-connection scheme (*a*) of Fig. 7 preferable to (*d*), as the correction is usually negligible in the former case only. The elimination of the Wagner earth from the bridge impairs its accuracy, and the disadvantages (ii) and (iii) given on page 452 remain. The effect of the earth's magnetic field on the permeability of the loading is small when the loading is in the form of wire. A specimen orientated magnetic North-South retains about 98·5 per cent of the inductance obtained when the effects of the earth's field are eliminated by screening. The chief cause of distortion is the variation of attenuation with frequency, but while frequencies higher than the reversal frequency f are certainly necessary for good signal formation, the attenuation at f cycles has been found to be the chief factor in design. For an unloaded cable the ratio of the attenuation at $1\cdot5f$ cycles to that at f cycles is approximately $\sqrt{1\cdot5} = 1\cdot22$. Although this ratio is less than 1·22 for the Bamfield–Fanning II Cable, it is certainly greater in the case of other continuously-loaded cables.

INSTITUTION NOTES.

Council for the Year 1930–1931.

The scrutineers appointed at the Ordinary Meeting held on the 1st May, 1930, have reported to the President that the result of the ballot to fill the vacancies which will occur on the Council on the 30th September next is as follows:—

President: C. C. Paterson, O.B.E.
Vice-President: R. K. Morcom, C.B.E., M.A.
Hon. Treasurer: E. Leete.
Ordinary Members of Council: (Members) F. W. Crawter, A. Ellis, E. W. Hill, R. P. Sloan, C.B.E., V. Watlington, M.B.E.; (Associate Member) R. Grierson; (Associate) J. F. W. Hooper.

The Council for the year 1930–1931 will therefore be constituted as follows:—

President.

C. C. Paterson, O.B.E.

The Past-Presidents.

Colonel R. E. Crompton, C.B.
James Swinburne, F.R.S.
Sir R. T. Glazebrook, K.C.B., D.Sc., F.R.S.
W. M. Mordey.
Sir John Snell, G.B.E.
Charles P. Sparks, C.B.E.
Roger T. Smith.
Ll. B. Atkinson.
J. S. Highfield.
F. Gill, O.B.E.
A. Russell, M.A., D.Sc., LL.D., F.R.S.
W. B. Woodhouse.
R. A. Chattock.
W. H. Eccles, D.Sc., F.R.S.
Sir Archibald Page.
Lieut.-Col. K. Edgcumbe, T.D., R.E.T.(Ret.).
Col. Sir Thomas F. Purves, O.B.E.

Vice-Presidents.

P. V. Hunter, C.B.E.
R. K. Morcom, C.B.E., M.A.
A. H. Railing, D.Eng.
B. Welbourn.

Honorary Treasurer.

E. Leete.

Ordinary Members of Council.

A. R. Cooper.
F. W. Crawter.
A. Ellis.
R. Grierson.
T. G. N. Haldane, M.A.
S. Harcombe, M.A., B.Sc.
E. W. Hill.
J. F. W. Hooper.
J. M. Kennedy.
Sir Philip Nash, K.C.M.G., C.B.
F. W. Purse.
E. E. Sharp.
E. H. Shaughnessy, O.B.E.
R. P. Sloan.
Lieut.-Col. W. A. Vignoles, D.S.O.
V. Watlington, M.B.E.
R. S. Whipple.
Prof. E. Wilson.

And the Chairman and immediate Past-Chairman of each Local Centre.

Graduateship Examination Results: May, 1930.

*Passed.**

Ainge, F. J. (Weeford).
Altham, T. F. (Hersham).
Armstead, H. C. H. (London).
Bailey, W. N. (Birmingham).
Baker, C. H. (Monkseaton).
Barrett, E. D. (Chelmsford).
Bell, R. (London).
Berry, J. B. (Kelty).
Billson, F. W. (Wolverhampton).
Birch, H. (Sutton, Surrey).
Bower, C. W. (Sheffield).
Boyce, J. S. (Plymouth).
Brassington, F. (Arnold).
Brook, C. B. (Huddersfield).
Brown, G. V. (Glasgow).
Buckley, S. E. (London).
Buffery, G. H. (Portland).
Burford, G. G. (London).
Caldwell, J. (Newtown Stewart).
Candler, J. E. (London).
Cattan, G. (Palestine).
Chapple, S. H. (London).
Charlton, T. C. (London).
Chittenden, P. A. (London).
Christie, R. F. (Manchester).
Clough, A. W. (Manchester).
Cole, F. J. (London).
Collier, A. S. (Manchester).
Colquhoun, J. B. (Glasgow).
Craster, T. Y. (Alnwick).
Crew, W. S. (Sunderland).
Davies, W. T. (South Farnborough).
Dixon, A. (Glasgow).
Donaldson, A. (Preston).
Dudley, H. (Countesthorpe).
Eagling, O. A. (Norwich).
Easton, H. (Manchester).
Edwards, H. G. (London).
Edwards, N. H. (London).
Faithfull, E. W. (Seaton).
Fowkes, F. K. (Codnor).
Gallop, C. C. (Newcastle-on-Tyne).
Geach, E. A. (Chichester).
Goddard, M. W. (London).
Gould, B. W. (Bletchley).
Gray, C. A. (Manchester).
Greenall, G. D. (Nottingham).
Hacking, A. (Nottingham).
Hallett, L. W. (London).
Hancock, C. G. (Hull).
Harknett, S. G. (Chelmsford).
Hawksley, E. (Mansfield Woodhouse).
Hawley, P. A. (Stafford).
Henderson, S. T. (Manchester).
Heslop, J. P. (Birmingham).
Hewitt, T. H. (Leigh, Lancs.)
Hime, M. W. (Rugby).
Hinchingbrooke, The Viscount (London).
Hodkinson, J. C. (Manchester).
Jeffrey, L. F. (Birmingham).
Johnson, R. A. (Doncaster).
Keene, R. N. (London).
Kelso, A. (Rosyth).
Knights, G. (Manchester).
Laing, D. P. McN. (Glasgow).
Lash, A. R. (Caernarvon).
Lawson, C. J. V. (London).
Lever, V. (Oldham).
Lightbown, J. (Blackburn).
Linley, F. (Manchester).
Lumby, F. (Manchester).
Maltby, J. H. (Harrow).
Mayer, V. (Manchester).
Midforth, J. D. (Dundee).
Milligan, J. W. C. (London).
Milne, W. H. (Preston).

---

* This list also includes candidates who are exempt from, or who have previously passed, a part of the Examination and have now passed in the remaining subjects.

Passed—continued.

Mitchell, H. L. (Holmfirth).
Morley, J. E. (Chatham).
Mullane, A. J. (Cardiff).
Newing, A. (Bradford).
Newsam, C. A. (Blackpool).
Palmer, E. H. K. (Harrow).
Parsons, A. G. (Dudley).
Philp, H. (Glasgow).
Pilkington, G. D. (London).
Pilsbury, R. C. (London).
Pinhorn, R. V. F. (London).
Powell, A. N. (Birkenhead).
Price, A. J. (Blackpool).
Price, B. T. L. (Newport, Mon.).
Rawson, J. E. (Todmorden).
Rowe, P. F. (Dublin).
Sainsbury, E. G. (Birkenhead).
Sands, P. C. (Nottingham).
Saunders, A. E. (Southampton).
Sclar, D. (London).
Smith, A. G. (Leeds).
Smith, H. D. R. (Chislehurst).
Smith, R. (Eastwood, Notts.).
Smith, S. C. (London).
Soulsby, G. E. W. (Dipton).
Stonehill, D. H. (Palestine).
Sutcliffe, W. D. (Manchester).
Swash, K. N. (Chester).
Taylor, J. R. (Hull).
Thornhill, W. (Manchester).
Todd, W. G. (Great Yarmouth).
Tull, A. W. (Portsmouth).
Tyack, F. G. (London).
Underhill, C. (London).
Vickers, S. (Carnforth).
Watkin, T. I. (St. Helens).
Whittaker, D. (Ipswich).
Whittingham, W. T. (Bradford).
Woodward, G. L. (Bush Hill Park).
Woolman, J. A. (Birkenhead).

Passed Part I only.

Atkins, C. J. (London).
Badham, W. (Cardiff).
Brown, L. R. (Portobello).
Chowdhury, M. K. (London).
Clark, R. E. (Southsea).
Cooke, C. H. C. (Westcliff-on-Sea).
Galle, G. A. (London).
Horsington, L. R. (Lee-on-Solent).
Jones, H. H. (London).
Kinross, R. I. (London).
Manning, C. C. (Preston).
Messenger, A. R. (Andover).
Pathak, C. C. (London).
Pearce, F. B. P. (Bexley Heath).
Penny, A. G. (London).
Pratt, J. H. (Edinburgh).
Pridding, J. A. (Barry, Glam.).
Sharpe, H. A. (Manchester).
Slee, W. J. G. (Lancaster).
Tancred, B. J. P. (Liverpool).
Thomas, E. C. (Southampton).

Passed Part II only.

Highfield, J. W. (Birmingham).
James, G. A. (London).
Kerridge, K. E. (Hull).
Kuriyan, K. T. (London).
Lindsey, G. T. (Romford).
Ralphs, L. C. (Tipton).
Tatton, E. (Stockport).

Further results, relating to candidates who sat for the Examination abroad, will be published later.

The Benevolent Fund.

The Committee of Management of the Benevolent Fund desire to draw the attention of the members to the last page of the cover of this issue of the *Journal*, on which will be found particulars of certain publications, etc., offered for sale on behalf of the Fund.

Informal Meetings.

120th Informal Meeting (13th January, 1930).

Chairman: Mr. C. F. Mounsdon.

Subject of Discussion: " Efficiency " (introduced by Mr. A. Morgan).

Speakers: Messrs. J. R. Bedford, J. H. C. Brooking, E. Kilburn Scott, S. B. Jackson, N. Prentice, R. Grigg, S. W. Melsom, J. A. H. Lloyd, C. F. Mounsdon.

121st Informal Meeting (27th January, 1930).

Chairman: Mr. W. A. Ritchie.

Subject of Discussion: " High-Tension Distribution" (introduced by Mr. G. V. Twiss).

Speakers: Messrs. J. R. Bedford, R. S. Odd, A. F. Harmer, J. H. C. Brooking, N. Prentice, C. Wade, D. H. Stewart, A. G. Hilling, C. F. Mounsdon, R. C. Anderson, J. F. Shipley, E. Kilburn Scott, S. B. Jackson, G. H. Holding, W. Lang, F. B. Allcock, C. W. Prescott, H. D. Barlow.

122nd Informal Meeting (3rd February, 1930).

Chairman: Mr. A. Morgan.

Subject of Discussion: " Maintenance of Telephone Plant " (introduced by Mr. H. G. S. Peck).

Speakers: Messrs. E. S. Ritter, D. H. Stewart, J. R. Bedford, C. W. Prescott, W. H. Grinsted, W. Wheeler, C. S. Kieran, E. J. Reed, P. J. Ridd, A. Morgan, R. Grigg, J. F. Perrin.

123rd Informal Meeting (17th February, 1930).

Chairman: Mr. E. S. Ritter.

Subject of Discussion: " The Nickel-Iron Battery and its Uses " (introduced by Messrs. M. E. Fox and W. E. Warrilow) and " The Lead Battery and its Uses " (introduced by Mr. E. C. McKinnon).

Speakers: Messrs. A. J. Bousfield, A. C. Hardy, S. B. Jackson, W. A. Erlebach, F. R. Perris, J. F. Perrin, G. L. Drury, A. F. Evans, S. A. Stevens, H. V. Schofield, G. L. Rose, J. R. Bedford, P. F. Grove, —— Sutton, W. S. Sholl.

124th Informal Meeting (3rd March, 1930).

Chairman: Mr. H. T. Young.

Subject of Discussion: " Push-button Control " (introduced by Mr. J. J. Fisher).

Speakers: Messrs. J. R. Bedford, A. Morgan, J. Eck, J. F. Shipley, T. S. Martin, W. A. Erlebach, S. B. Jackson, A. N. D. Kerr, T. N. Lockett.

125th Informal Meeting (17th March, 1930).

Chairman: Mr. M. Whitgift.

Subject of Discussion: " High-Tension Substation Control Gear " (introduced by Mr. A. F. Harmer).

Speakers: Messrs. A. Morgan, S. B. Jackson, C. O. Milton, J. P. S. Pillans, C. F. Mounsdon, W. E. Bradshaw, J. F. Shipley, G. H. Holding, W. L. Wreford, W. R. Hackworth, J. R. Bedford, A. T. Scott, H. Lloyd Williams, R. Leach, P. A. Jackson, W. Wilson, S. W. Melsom, F. O. Harber.

126th Informal Meeting (31st March, 1930).

Chairman: Mr. J. R. Bedford.

Subject of Discussion: "Loud-speakers" (introduced by Captain P. P. Eckersley).

Speakers: Messrs. A. G. Warren, A. J. Gill, J. F. Herd, H. J. Neill, E. J. Reed, W. Day, F. A. Cobb, H. R. Clarke, E. S. Ritter, — Whitehead, E. C. S. Megaw, F. R. Brindle, A. B. Howe, P. Voigt.

Elections and Transfers of Members.

At the Annual General Meeting held on the 15th May, 1930, the following elections and transfers were effected:—

Elections.

Associate Members.

Bull, Reginald Alfred, B.Sc.(Eng.).
Boles, Geoffrey Coleridge, Commander R.N.(Ret.).
Bradock, Gordon Higson.
Carr, Cuthbert James, Lieut.-Comdr. R.N.
Clark-Nichols, Edward Christopher.
Clyne, Thomas Maurice.
Cross, William Herbert.
Gilbert, Thomas Charles.
Goddard, Leonard Douglas, Captain R.S.
Haynes, William, Lieut.-Commander R.N.
Hopkirk, Kenneth Robert, B.A.
Horne, Leonard Ralph, B.Eng.
Hunt, Keith Flashman, B.Sc.
Lendrum, Harold Leslie, Lieut. R.E.
McGill, Ernest William.
Mathieson, Thomas Barclay.
Pevzner, Levy.
Reynolds, Raymond Douglas.
Sparrow, Albert Victor.

Associates.

Barnicoat, William James.
Binns, Joseph.
Bond, John Alfred.
Hart, Edwin Caithness.
Hine, William Charles.
Naudain, Willis A.
Newberry, William Edward.
Plummer, Alec Frederic.
Powell, Dick.
Pring, Francis Ernest.
Sherriff, George William.
Warren, William.

Graduates.

Berkeley, Julius John C.
Bridges, James.
Costello, James, B.E.
Evans, Arthur Frederick E.
Grieveson, John Alan, B.A.
Hebard, Hugh Charles, B.A.
Hunter, Ian Wilson, B.Sc.
Mathewson, Eric Walter, B.E.
Philip, Mathew, B.A.
Ruff, Harold Robert, B.Sc.(Eng.).
Simpson, Geoffrey Elliott, B.Sc.
Womersley, Donald Charles.

Students.

Alexander, John Montague.
Anderson, Murice Hector.
Ashford, James Leslie.
Barge, Rupert Maurice.
Chapman, Kenneth George.
Clarence, Walter Anthony.
Conly, Patrick.
de Necker, Jan Daniel J.
Digyani, Jai Krishen.
Donnelly, John Francis.
Dumra, Harichand Motiram.
Ellis, Robert Henry.
Hearn, John.
Hughes, Stanley Owen.
Hutchinson, Samuel Watson.
Jessel, Geoffrey.
Kapur, Roshan Lall.
Ladell, John Ernest C.
Larkin, Alfred Spencer.
Laycock, Leonard Spencer.
Leighton, Gerald Crocker.
Oldhams, Arthur Stanley.
Partridge, Wilfrid Howard.
Paul, Robert Hoisington, B.A., B.Sc.
Pickup, Harry.
Rao, Karavadi Gopala.
Savage, Francis Montague.
Sengupta, Amulya Nath.
Singh, Harbans.
Smith, Clifford.
Smith, George Ernest.
Smith, Robert Frederick.
Stevenson, Ian Douglas.
Thorn, Arthur Eldred.
Turtle, Albert Edgar.
Ward, Leslie Ernest.
Whitaker, Frank.
Wilcox, Thomas Webster.
Wolff-Schoemaker, John Prosper.

Transfers.

Associate Member to Member.

Besly, James Campbell.
Blackmore, Robert.
Fletcher, George Herbert.
Gil, Joseph Valderrame.
Glasse, Alfred Onslow.
Hoseason, Donald Bright.
Landau, Szymon I.
McColgan, Albert John.
McHaffie, Hugh Gunn.
Margary, Thomas Alfred G.
Smith, Clarence Herbert.
Waters, John Henry.

Associate to Associate Member.

Leary, John Francis.
Rennie, William.

Graduate to Associate Member.

Benson, Robert Hamilton.
Black, Richard Henry.
Damp, John William.
Devereux, Reginald William, B.Sc.(Eng.).
Fry, Eric Charlton.
Hodgson, Arthur Geldart.
Horwood, Hyman.
Hunter, Charles Moore.
McMahon, Alfred Joseph, B.Eng.
Martin, Reginald Ian.
Newman, Samuel Emil.
Palfrey, Harry James D.
Pedrick, Sydney.
Smith, William Francis, B.Sc.(Eng.).
Sowter, George Alfred V., B.Sc.(Eng.).
Swinney, John.
Vickers, Harold Edwin.
White, William George, B.Sc.(Eng.).
Whitney, Herbert Edwin.

Student to Associate Member.

Mathews, Henry Mends.
Rowe, Charles.
Southin, Charles Frederick.
Whitcher, Athol Eric Jaime, B.Sc.(Eng.).

THE BREAKING PERFORMANCE OF HIGH-POWER SWITCHGEAR AND OF A NEW FORM OF QUENCHED-ARC SWITCH.

By L. C. GRANT, Member.

[*Paper first received* 14*th April*, 1928, *and in final form* 21*st November*, 1929; *read before* THE INSTITUTION 23*rd January*, *before the* EAST MIDLAND SUB-CENTRE 21*st January*, *before the* NORTH-EASTERN CENTRE 27*th January*, *before the* TEES-SIDE SUB-CENTRE 5*th February*, *before the* NORTH MIDLAND CENTRE 25*th February*, *before the* WEST WALES (SWANSEA) SUB-CENTRE 28*th February*, *and before the* WESTERN CENTRE 10*th March*, 1930.]

SUMMARY.

The difficulty of breaking the high short-circuit powers of large modern systems has an important bearing on the security of electrical distribution. The oil switch, as usually constructed, is in some ways a fortuitous device and, as will be shown in this paper, the very act of breaking a circuit under oil, and thus bringing a high-temperature arc into contact with the oil, results in pressures being set up which are not necessarily dependent upon the actual circuit power being broken. Briefly, it can be shown that even with fixed prebreaking conditions the formation of the arc and the oil pressure set up within the tank will vary. Moreover, such factors as the effect of phase angle, the influence of the layout of the system and, in another sense, the speed of breaking and the effect of oil head, have important effects upon the process of circuit rupture. The author has carried out an investigation in an attempt to assess the effect of these and other factors and to determine whether material improvement is possible without radical changes in design.

The author's investigation has led him to conclude that the fundamental limit of breaking capacity, that is the short-circuit power which can be broken time after time by a given switch without breakdown, is for the largest examples of present designs of oil switches rather below 1 million kVA and that the present breaking-capacity rating of oil circuit-breakers is correct only if a certain factor of reliability is taken into account. For high-power breakers this factor expressed as a percentage appears to be about 96·5 per cent, and indicates that such circuit breakers can be relied upon in 96·5 operations out of 100, or, in other words, that there is a 3·5 per cent chance of breakdown. In order to eliminate this element of breakdown the breaking-capacity rating should be divided by a factor which the author's tests indicate to be 2·5. Moreover, the limitation of the short-circuit current by means of reactors may be responsible for troubles not hitherto identified with such a cause.

A circuit breaker embodying entirely new principles has been evolved and tested under short-circuit conditions. Its performance is superior to that of the usual oil switch, and a unit of a given size and weight is capable of breaking many times the power broken by an oil switch of similar dimensions, while its performance appears to be wholly consistent.

Throughout the paper, tests are quoted and illustrated by oscillograph records wherever possible, but it is, of course, quite impossible, while keeping the dimensions of the paper within reasonable bounds, to give anything more than a skeleton selection of the tests carried out. A few details of the tests and equipment used may, however, be of interest.

The majority of the tests were carried out on a 6 000-volt, 6 000-kVA, 40-cycle alternator. Other tests were carried out at 11 000 volts with a 10 000-kVA, 25-cycle alternator, and at 6 000 volts with a 25 000-kVA alternator.

The power used in the tests varied between 500 kVA and 270 000 kVA. In all, some 800 tests were carried out, in most of which such factors as periodicity, kVA and power factor were kept reasonably constant. Factors which could not be so readily controlled were investigated by carrying out groups of rapidly repeated tests from which a selection was made in such a way that the results bore directly upon the point being investigated. This may appear to be rather a roundabout method, but it was found that groups of tests could be usefully co-ordinated and, for instance, results rejected from one group used in another. In addition to this group of 800 tests, at least an equal number was available which, although not directly forming a part of the work described in this paper, were sometimes used for comparison.

The switching apparatus consisted of several model switches; 4 of these were of an experimental character, while the remainder, 5 in number, were of commercial or semi-commercial form. Compared with power-system conditions, the majority of the tests were carried out on a reduced scale, the switchgear being reduced in size so that it could be overstressed if necessary with the power available. With a 50 000-kVA source of power, the switch models were regarded as being $\frac{1}{64}$th of their commercial cubical content, with the object of obtaining a switch with a commercial maximum rupturing capacity of about 50 000 kVA, and comparing its performance with a full-scale switch on 1 500 000 kVA. Such a full-size switch, as the author has already suggested, would be about the largest commercially available, and thus one which would be likely to be used in practice on a short-circuit power of 1 500 000 kVA. With a larger source of testing power a correspondingly larger switch was employed. The largest used (excluding the quenched-arc switches) could break a maximum power of about 200 000 kVA.

In no group of tests were fewer than 5 repeated tests carried out under similar conditions—a relatively small number, perhaps, for many conditions—but when there arose good reason to believe that closer investigation was necessary, as many as 25 repeated tests were sometimes made. The work described in this paper has been carried out—at intervals —during a period of about 8 years.

TABLE OF CONTENTS.

(1) Introduction.

The effect of inherent and external factors on the breaking performance of an oil switch.

(2) Nature of switch distress and the difficulty of gauging it.

(3) Unreliability of break energy as a measure of distress.

(4) Investigation of existing switching conditions.

Single-break and multi-break switches.
Speed of break.
Oil volume and air cushion.
Effect of power broken.
Symmetry of current.
Phase angle and power factor.

TABLE OF CONTENTS—*continued.*

(5) Conclusions to be drawn from these tests.

  The ratio of maximum to average distress.
  The security of a system in terms of liability to circuit-breaker failure.
  Calculation of breaking capacity.

(6) Cause of distress variation.
(7) New designs of switching apparatus.

  Arc stability.
  The arrangement and action of the quenched-arc switch.
  Performance.
  Comparative performance.
  Effect on security of system and power-supply economics.

Bibliography.
Appendix.—The limitation of short-circuit current.

(1) INTRODUCTION.

The term "nominal short-circuit power" is used throughout this paper to indicate the product of the short-circuit current and the open-circuit voltage. With a quick-acting switch the first complete cycle of current could be taken as this short-circuit current, but in a slow or deliberately delayed switch it would perhaps be fairer to take the cycle immediately before the commencement of movement of the switch. In this paper the first cycle of current has been taken.

The tests recently carried out by Sporn and St. Clair * and other investigators show the difficulty of designing a circuit breaker capable of dealing with high short-circuit powers. Inductance coils and high-reactance generators have been used to limit the short-circuit power. Such limitation is of great value in ensuring the security of busbars and other parts under short-circuit conditions, but, unless a proper value of reactance is selected, alterations in the phase angle which outbalance the current reduction may be produced. (Similar effects could be produced if ohmic resistance were used for the limitation of short-circuit current, but, of course, the permanent insertion of resistance has, for obvious reasons, not been applied.) Oil switches employing resistance steps have, however, been used to some extent, and it will be seen later that such switches may offend in this respect. Between the ill effects of the high short-circuit current and the possible increase in phase-angle difficulties when current limitation is resorted to, it appears in practice to be difficult to produce in large power systems switching conditions which are certain under all circumstances, or, in other words, to ensure that 100 per cent security is obtained with the switchgear under all breaking conditions. If the author's tests be accepted, it can be said that when dealing with short-circuit powers greater than about 800 000 kVA the 100 per cent security of the oil circuit-breakers is impaired to some extent, and it is the assessment of this reduction in security which has been one of the objects of the present investigation. This matter is dealt with in detail in Section (5).

Irrespective of the different values of short-circuit current which may be obtained from time to time, there is a very remarkable variation in the distress set up even when an oil switch is made to break the same amount of power on successive occasions. Thus an oil switch operating at its maximum rated breaking capacity will, because of this variation in distress, operate a certain number of times successfully, but under continued testing would also be subject to a certain percentage of failures.

Spurck, Hilliard, Sporn, St. Clair and Slepian, the British Electrical and Allied Industries Research Association and others* have recently carried out investigations of the problems of circuit rupture. One of the results has been to show that the process of circuit rupture is very complicated. In the present investigation it has been found that, with circuit breakers of existing form, consistent breaking performance and mechanical stress could not be obtained.

It has become very important both to users and to designers to have more exact knowledge of the effect of circuit conditions on the breaking performance, and, as it is possible for the switchgear to be subject to stresses which are very difficult to cope with commercially, it is necessary to have more knowledge of the nature of these stresses and of the frequency of their occurrence. The formulation of a method of assessing the security of a power system will thus be possible. To determine these factors it becomes necessary (1) to investigate, either experimentally or otherwise, the nature of the stress which can be set up in an oil switch, (2) to find the best value for design factors such as speed of break and air cushion, (3) to determine the effect of the external or circuit conditions, and (4) from a consideration of operating data to determine the frequency of operation of switchgear under working conditions, and the range of magnitude of the power involved in such operation.

The paper deals also with a recently evolved circuit breaker, which has been called the "quenched-arc switch," by means of which high powers can be broken safely and in which it would appear that complete control of the action is possible. Its operation is consistent and reliable and is a marked improvement over that of the ordinary type. This apparatus is of simple construction and of relatively small size as compared with the conventional form of oil switch.

(2) NATURE OF SWITCH DISTRESS AND THE DIFFICULTY OF GAUGING IT.

Preliminary.—One of the greatest difficulties is the initial one of defining distress. Pressure is set up inside an oil-switch container when it operates, but this pressure takes various forms. Impulses of high magnitude are obtained but are not necessarily dangerous. On the other hand, sustained pressures of much lower values may be very dangerous, and the two effects are perplexingly mingled in practice. The reliable measurement of such pressures is difficult and the results are of doubtful interpretation, even where obtainable. The ejection of oil and flame during the breaking process is a secondary effect due chiefly to faulty construction, and can be remedied by baffling any openings between the inside of the tank and the external atmosphere. The top plate and tank should be stiff, well machined and well bolted together, while venting arrangements, insulator orifices and similar parts should be so constructed that ejection of oil or flame is not possible. Such measures, however, do not limit the mechanical distress due to the internal pressure; on the contrary, they may sometimes increase it.

---

* See Bibliography.

* See Bibliography.

Further difficulty is experienced from another complication. It is frequently assumed that an oil switch arranged to break a definite amount of power a number of times will, on each occasion, produce the same symptoms of distress. Actually, the distress varies within wide limits.

It is sometimes stated that distress is proportional, either completely or in part, to arc kVA, arc energy or arc kW-seconds (to quote the various terms used to denote the product of the current and the voltage across the arc during the arcing period and the time of arcing). The author uses the term " break energy " to denote the same factor. The justification of this term is that it implies all the energy released at the break, whereas " arc energy " and " arc kVA " imply only the energy produced by the arc—an important distinction, since a considerable proportion of the break energy can be absorbed by the contacts. An oscillograph record of the voltage across an oil switch during the opening process includes, amongst other things, true arc voltage (or the voltage across the gaseous part of the circuit) and the voltage employed in overcoming the resistance of the circuit in the vicinity of the contacts. The former is available for action on the oil and produces a gas pressure, but the latter produces heat energy which may be disposed of without producing pressure effects. For instance, large contacts exert a heat-absorbing effect, with a corresponding reduction in the amount of energy available for heating and cracking the oil.

It may be mentioned here that heavy contacts have proved to be of great advantage in oil switches and, other things being equal, the switch with the heavier contacts will give the better breaking performance. The larger the heat capacity of the contacts, the lower is the surface temperature reached and, therefore, the less will be the volatilization of the contacts and the generation of oil gas. Fig. 1 illustrates very well the severe burning which takes place with contacts of insufficient heat capacity.

The variation in distress for a given short-circuit current is very remarkable. Tests were carried out in which, as far as practicable, all variable factors were kept constant. The resultant break energy varied enormously but, what was much more remarkable, the distress varied in a totally different manner and independently of the break energy.

A series of tests was carried out on a somewhat reduced scale with a maximum available short-circuit power of about 80 000 kVA, and other tests employing a maximum power of 160 000 kVA and 250 000 kVA. Switches of various designs were built. These were so proportioned that, with the power available, they would be subjected to approximately the same relative conditions as would high-power switchgear on a large modern system. These switches could be fitted with heavy and light tanks, but most of the quantitative results were carried out with a heavy tank fitted with a special device for indicating distress.

It is difficult to find a reliable method of indicating distress. Several devices employing plungers and diaphragms were tried and some appeared for a time to give fairly consistent results. Prolonged testing of these showed that there were serious inconsistencies, which led to their abandonment. A fundamental shortcoming of such arrangements appears to be that the moving portion employed as a medium for passing on the pressure indicates to some extent its own characteristics, rather than real pressure or stress on the oil switch. The indications given by apparatus of this character will depend on such factors as the amplitude and duration of the pressure wave or wave train.

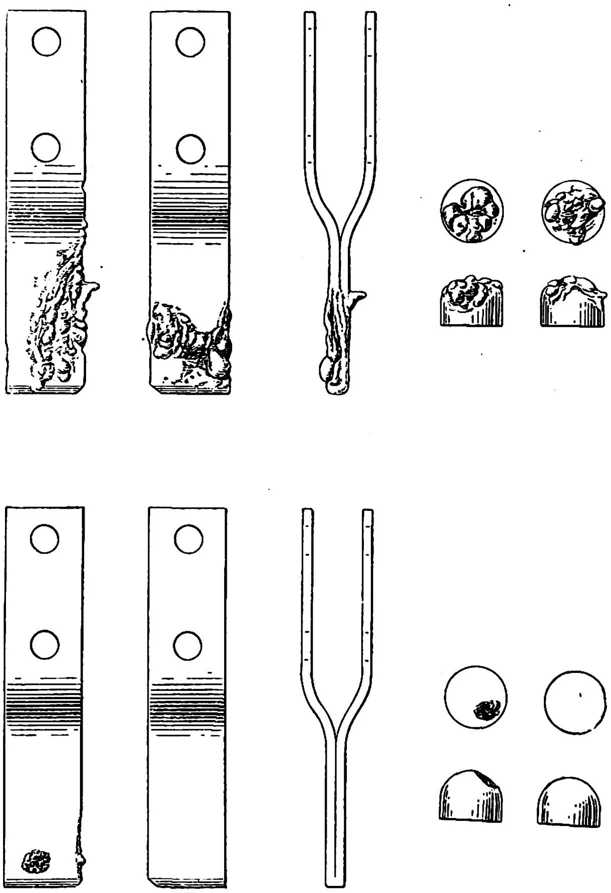

FIG. 1.—Burning of contacts of insufficient heat capacity.
This figure also illustrates the effect of phase angle.

For some time it seemed almost as though the only reliable way to measure distress was the somewhat heroic method of bulging or bursting tanks, but a more economical method was developed and preliminary tests were made to determine a suitable size. The pressure set up in the oil acts directly on a renewable disc fitted into the tank wall, without intervening plungers and their corresponding disturbing results. The relative deformations corresponding to the maximum safe stresses on heavy and light tank switches respectively were experimentally determined. The figures given in the paper are believed to be fairly accurate over the lower and middle ranges; the maximum figures are perhaps rather too low, so that the figures relating to maximum distress may be correspondingly low. Any such errors would tend to strengthen the author's contentions. Other apparatus found to be useful in the tests included an automatic cinematograph camera and a high-speed camera capable of taking a short series of pictures at the rate of 2 000 per sec.

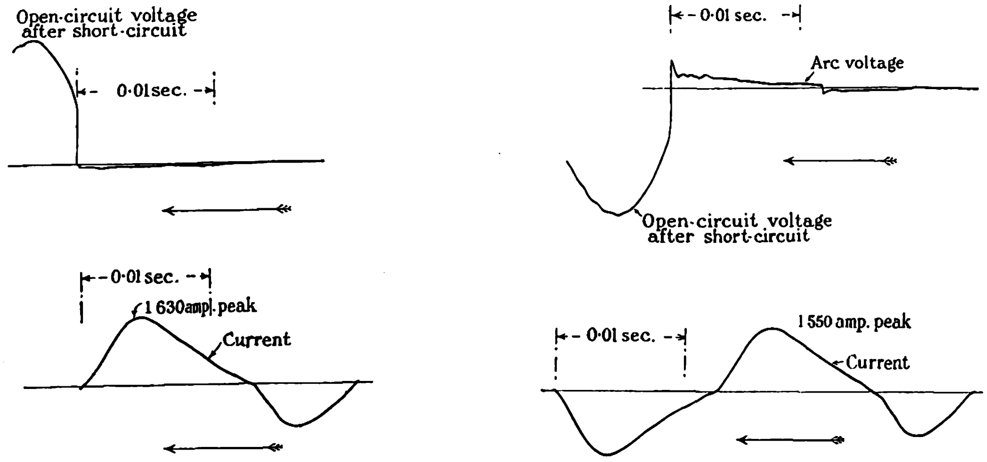

Fig. 2. Fig. 3.

Oscillograms of two tests wherein voltage, frequency and current were held simultaneously constant.

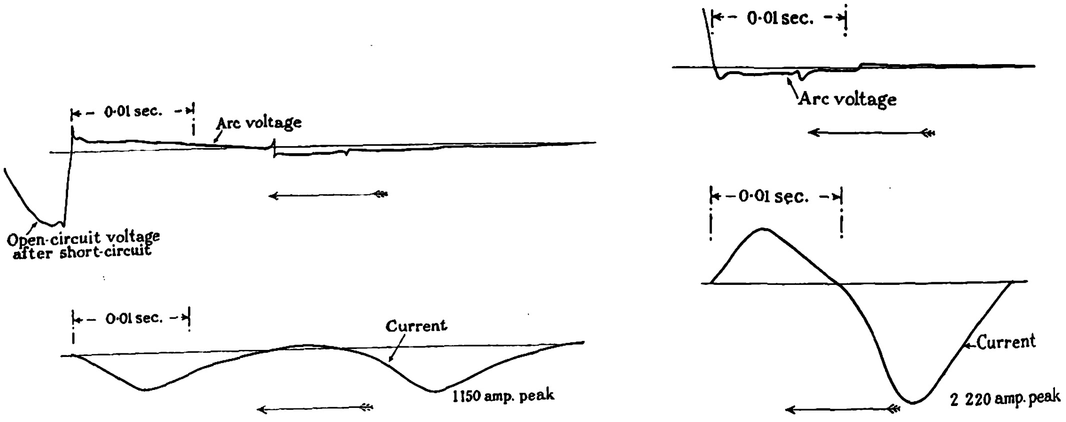

Fig. 4. Fig. 5.

Two oscillograms with break energy similar, but distress different.

The work subsequently carried out is now described, and it is prefaced by a short section submitted to show the influence of various factors on break energy and to indicate how far the latter is from being even an approximate measure of the distress.

(3) UNRELIABILITY OF BREAK ENERGY AS A MEASURE OF DISTRESS.

Voltage, Frequency and Current Constant; Break Energy Varied.—Figs. 2 and 3 show oscillograph records of two tests taken from a group wherein the voltage, frequency and current are of the same order. Particulars of three tests are given in Table 2. It will be noted that the break energy is not proportional to the variation of voltage, frequency and current, thus showing that break energy is not directly influenced by any of these factors.

Table 2.

Voltage	kVA	Current wave-form	Break energy
volts			kW-sec.
5 500	6 150	Symmetrical	4·64
5 500	5 180	Symmetrical	0·775 (Fig. 2)
5 500	4 870	Symmetrical	7·35 (Fig. 3)

Break Energy Similar, Distress Dissimilar.—Figs. 4 and 5 show two records wherein the break energy is substantially the same but the distress is different. These results are shown in tabular form in Table 3. This comparison shows that distress does not vary with break energy, as has frequently been assumed.

Break Energy Dissimilar, Distress Similar.—Figs. 6 and 7 and Table 4 show two records wherein the distress is substantially the same but wherein the break energy is not the same. In one test it is twice that obtained in the other.

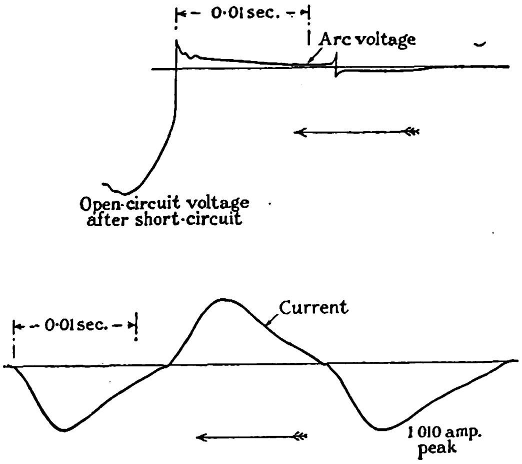

FIG. 6.

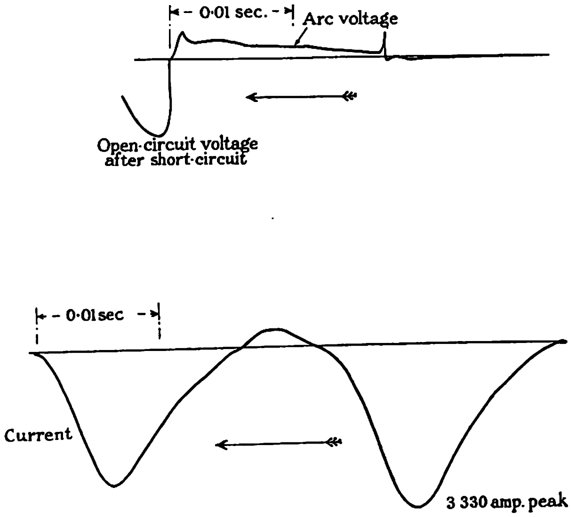

FIG. 7.

Two records with break energy dissimilar, but distress similar.

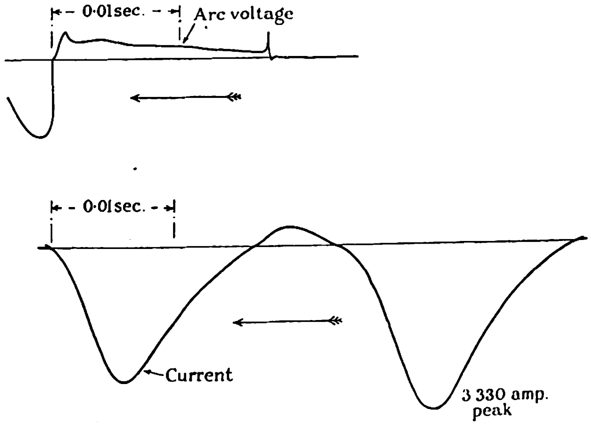

FIG. 8.

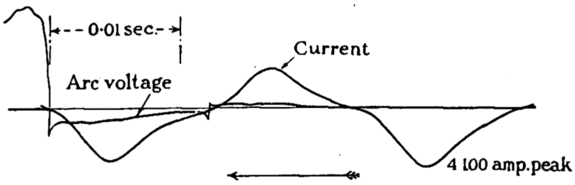

FIG. 9.

Two oscillograms showing similar pre-arcing conditions and similar break energy and wave-form but dissimilar distress.

Break Energy, Arc Characteristics and Wave-form Similar, Distress Dissimilar.—Figs. 8 and 9 show not only similar pre-arcing conditions but similar break energy and similar wave-form during the arcing period, yet the distress in the two tests is dissimilar (see Table 5). Thus, in addition to the broad comparison, this result disposes of the assertion sometimes made that variations of arcing voltage wave-form are responsible for the variations of distress.

It is considered to be unnecessary to quote any further tests to illustrate the foregoing, although many more are available. The existence of the extreme conditions alone would appear to indicate that the unreliability of break energy as an indication of distress has been proved.

TABLE 3.

Voltage	kVA	Break energy	Distress as gauged by deformation
		kW-sec.	
5 500	3 720	5·15	2·3 (Fig. 4)
5 500	6 150	4·64	1·3 (Fig. 5)

TABLE 4.

Voltage	Break energy	Distress as gauged by deformation
volts	kW-sec.	
5 500	9·2	2·6 (Fig. 6)
5 500	17·35	2·6 (Fig. 7)

In these tests and in similar ones which were carried out and in which the same inconsistency was displayed, the phase angle and other electrical conditions were similar in comparative groups. In addition, all the tests were carried out on similar switching apparatus to ensure that no possible source of error should creep in.

The results can be epitomized in the following. A given voltage, current amplitude or symmetry, wave-form, break energy or arc-voltage characteristic will produce switch distress of varying magnitude, the variation being of a considerable order. This does not imply that distress or even break energy is entirely independent of such factors. There would, of course, be greater average distress and break energy with 500 000 kVA than with 50 000 kVA.

(4) Investigation of Existing Switching Conditions.

Preliminary.—This section deals with the work which was carried out to determine the effect on oil-switch performance of circuit conditions such as voltage, current and phase angle, and of that separate group of factors which form an inherent part of switch design, such as oil head, class of enclosure and speed of break. This work was necessary to determine the best working conditions and to assess the risk.

The same type of switch was employed in all comparable tests carried out and described in this section. The switches were usually of such dimensions that with the power available they could be subjected to considerable stress; in many of the tests they were worked at what was believed to be the maximum breaking capacity, without any factor of safety.

In view of the widely varying nature of the phenomena involved, each test was repeated many times.

Comparison of Single-break and Multi-break Switches of Normal Design.—The advantage of breaking a circuit at more than one point is well recognized, and considerable investigations have been carried out by Messrs. Brown, Boveri and Co., the American General Electric Co. and others, to determine the precise nature of the advantage. Curves have been published connecting the number of breaks in series with break energy, and other factors intended to represent distress, but, while the results show correctly the trend of the relationship of the factors, the standards used are open to criticism and such curves are probably no more than a rough guide. A series of fixed relationships has been obtained by the author, but it is recognized that accurate relationship must vary somewhat with each design and possibly also with variations in circuit conditions. The degree of variation, however, is not great.

The comparisons given herein deal with the most common commercial instances, namely a single break compared with two breaks, and a single break compared with four breaks. Tests at 3 300 volts carried out on a single-break switch are compared with similar tests carried out on an otherwise similar 2-break switch. Further tests are given at 5 500 volts on a single-break switch and are compared with tests at 5 500 volts on a 4-break switch. All tests were carried out on similar switches.

Single Break versus Double Break.—The single-break tests were carried out at 3 300 volts with the generator on dead short-circuit and an unsymmetrical current wave. The phase angle was 85°, and six units of distress were registered. The unit of distress used herein is based on the deformation of the renewable section of the switch tank. The oscillograph record of this test is shown in Fig. 10.

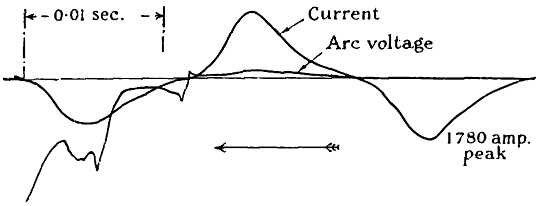

Fig. 10.

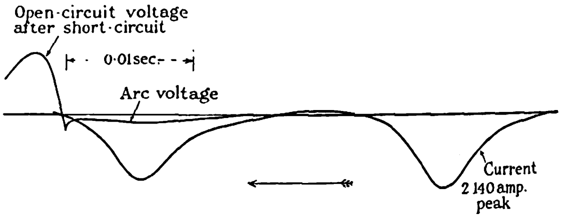

Fig. 11.

Single break versus two breaks on 3 000-volt short-circuit.

The 2-break tests were carried out, as in the single-break tests at 3 300 volts, with the machine on dead short-circuit, the current wave unsymmetrical and the phase angle 85° (see Fig. 11).

Single Break versus Four Breaks.—The single-break tests at 5 500 volts were on dead short-circuit at a phase angle of 84° with the current wave symmetrical (see Fig. 12). In this particular test the switch flashed over

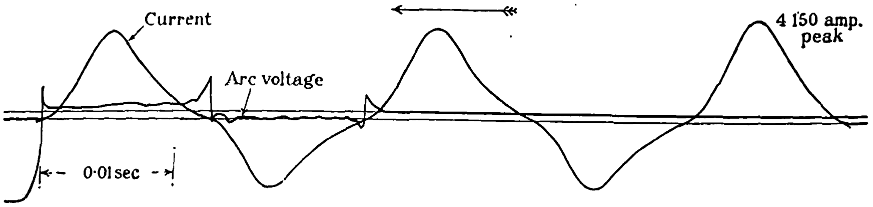

Fig. 12.—Single break versus four breaks on 5 500-volt short-circuit.

to earth internally and had to be cleared by other means.

The 4-break tests were carried out under similar conditions at 5 500 volts. In the first test illustrated the phase angle was 84° and the current wave symmetrical. The oscillograph record is shown in Fig. 13.

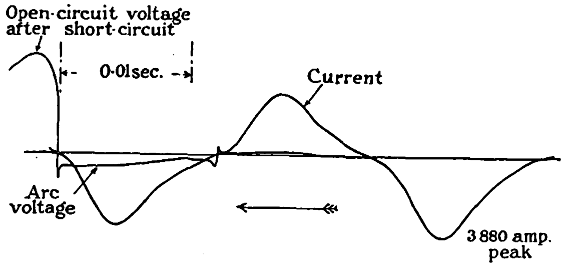

FIG. 13.—Single break versus four breaks on 5 500-volt short-circuit.

In the next tests the phase angle was again about 84° and the current wave totally symmetrical.

* Internal flash-over in this test.

It is not suggested that these results provide a precise comparison of breaking capacities, but rather that they provide evidence to enable a sufficiently close estimate of the relative performance to be made.

Conclusions.—In the comparison of single-break, 2-break, and 4-break tests, it can be accepted with fair accuracy that the breaking capacity gauged on the actual distress produced is in the ratio 100 : 62 : 50 for single, double, and 4-break switches respectively. Between four breaks and six breaks there appears to be less than 10 per cent improvement, but only a few tests were carried out and the results are not very definite.

Speed of Break, and Distress.—From the results of the tests carried out, the author reached the definite conclusion that, within limits, the speed of breaking has comparatively little effect on the distress. There is a range of speed which gives satisfactory operation, whilst operation becomes progressively more dangerous both above and below this band. The question of speed of break, however, is a more complicated matter than might appear at first sight, as it is involved with many other factors to an extent which makes it difficult to treat it adequately without becoming diffuse. Wilkins and Crellin have recently made some interesting observations * on the speeds attained on breakers installed in the United States, but the author is not entirely in agreement with them.

Very low breaking speeds produce excessive distress, but at about 10 ft. per sec. in the 3 000 V/20 000 V range the distress curve usually commences to flatten. The advantage of higher speeds is largely dependent upon the reactance of the system to which the switch is connected. It will readily be appreciated that if a switch were to open at an extremely rapid rate there would be danger of an induced voltage-rise owing to the current being forced down more rapidly than the rate which corresponds to the normal decrement for the inductance/resistance ratio of the circuit. This immediately introduces the very broad question of the working voltage of the system, since the impedance of, say, a 6 000-volt system will be greater than that of a 440-volt system and correspondingly less than that of, say, a 132 000-volt system. For instance, a 6 000-volt system is characteristically a distribution system; in a given instance which was investigated the short-circuit impedance was found to be 0·12 ohm. A voltage of 132 000 is essentially a transmission voltage; in a given instance the short-circuit impedance was found to be 150 ohms. Furthermore, the ratio of inductance to resistance is probably greater in the higher-voltage system. Therefore, to avoid voltage-rise, the interrupting speed should, if anything, be lower for the higher voltage, whereas the contrary is the usual practice. The high-voltage system, however, is capable of withstanding rather a higher opening speed than would be thus indicated, because the resistance of an arc for a given power is greater than on the low-voltage system, owing to the smaller current at the higher voltage. (The resistance of an arc, of course, decreases as the current increases.) The two factors are unlikely to balance one another and, furthermore, their respective numerical values are not in fixed ratio. Therefore the breaking speed should be fixed with due reference to both these factors.

The actual average linear speed of the main contacts, however, is, in the author's opinion, of small importance compared with the maximum speed of these contacts and with the effect produced by arcing contacts or other special devices which may introduce a very high momentary increase in speed with consequent disturbance of the arc. Certain contact arrangements tend to break circuit more rapidly than others, and the use of snap or other high-speed contacts is in fact more common at high than at low voltages, so that, apart from the simple question of cross-bar or main contact speed, special features of design may cause effects similar to those produced by a high average cross-bar speed. For instance, Fig. 14 shows an oscillograph record of a comparatively slow-moving oil switch which was fitted with snap contacts. All goes well until the snap contacts are released, when the voltage suddenly rises, producing not only increased energy at the break but actual re-establishment of the arc just at the moment when it is extinguished. Fig. 15 shows a record of a similar effect produced by a powerful magnetic loop formed by the arrangement of the internal connections, while Fig. 16 is another example produced by the action of explosion pots. These effects have been noticed at various voltages and seem liable to occur, irrespective of the circuit conditions, thus indicating the great influence which contact design has on this important problem. Therefore high-speed spring contacts, explosion pots (which have a similar effect in accelerating the speed of break), magnetic blow-out and anything which may tend to produce sudden speed-changes should be adopted only after careful consideration. It may be of some significance that one of the first troubles to develop in the past in explosion-pot switches has been insulation or mechanical breakdown of the pots, while the author is aware of several instances of flash-over and insulation breakdown on magnetic blow-out (air) breakers which could be attributed only to incorrect design of the blow-out field.

---

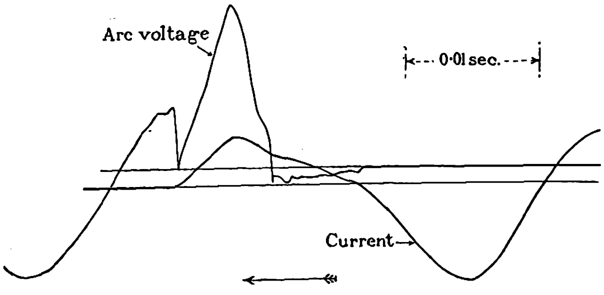

FIG. 16.—Oscillogram of voltage-rise obtained on oil switch with explosion pot.

Ratio of Air Cushion to Oil Head.—When the contacts of an oil switch separate, an arc is drawn which immediately commences to heat and crack the oil in its vicinity. A pressure is set up by the displacement of the oil by the growing arc, but a greater pressure results from the gas formed by the action of the arc on the oil. The gas bubble continues to grow, even after the arc is extinguished. The final size of the bubble depends upon the ratio of air cushion to oil volume, because the expanding gas bubble reaches a state of equilibrium only when the air cushion is compressed to an appropriate reactionary pressure; therefore, the larger the air cushion the larger will be the gas bubble and the lower the resultant pressure. It might be concluded, therefore, that it is necessary only to increase the air cushion to a large enough extent to reduce the gas pressure to a safe value, but a limit is reached when the gas bubble, which is of a conducting character, tends to bridge the contacts or form a path to earth and so introduce the danger of an internal short-circuit. During the early stages of growth the gas bubble does not move far from the point of formation—it may elongate from its originally roughly spherical form to a pear shape. At this stage the gas bubble somewhat resembles the core of a peach with the oil forming the flesh of the fruit and accordingly pressed into contact with the skin or container on all sides, including the top, the air cushion having nearly disappeared through compression and absorption, as illustrated in Fig. 17.

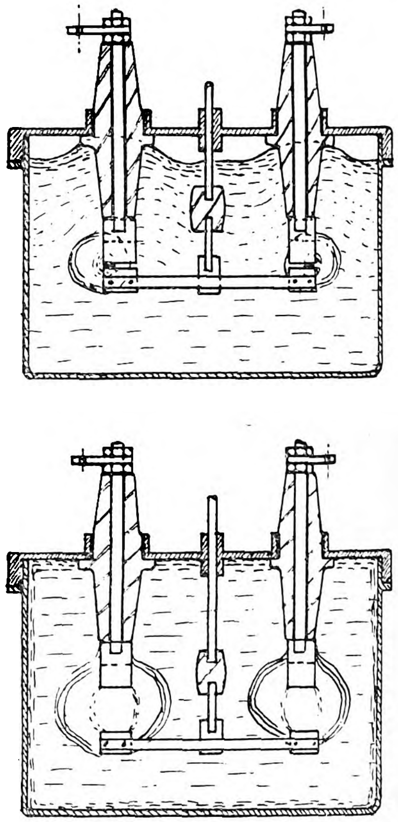

FIG. 17.—Disposition of oil during arcing period.

It might be helpful to consider an actual instance of what occurs in practice. An oil switch undergoing test had a tank measuring 20 in. × 20 in. × 20 in. with an air cushion of 10 per cent of the total tank volume. On a 150 000-kVA short-circuit the gas bubble, during an arcing time of 0·06 sec., was found to expand to approximately 11 inches in diameter and it set up a pressure of about 160 lb. per sq. in.; thus the air cushion would be reduced in the ratio of the two pressures, i.e. to 15/(160 + 15) = 0·086 of its original volume. The diameter of the gas bubble at the volume taken in the example is already about as large as is consistent with safety, so that an increase or decrease of the air cushion results respectively in either a larger gas bubble or a higher pressure. Furthermore, if the gas bubble be allowed to grow to a larger size, or if the oil head be not great enough, the gas bubble may break through to the surface in an incandescent state, so introducing the danger of a surface flash-over.

Safety is obtainable over a fairly wide range without sharply defined limits; the one extreme, that of no air cushion whatever, is dangerous, while operation with a large air cushion again becomes dangerous. Tests on commercial and experimental switches without any air cushion showed that successive operation under short-circuit conditions resulted in oil being forcibly ejected, even through bolted flanges, until a reasonably safe air cushion was obtained. Hermetically sealing the container with no air cushion will produce bulging or bursting of the tank and top plate. In general, tests indicate that, over the range of tank sizes in general use, the air-cushion volume should be at least 5 per cent, but not more than 15 per cent, of that of the tank.

Variation of Distress with Power Broken.—The term "power broken" is used herein as meaning the product of the open-circuit voltage and the R.M.S. value of the short-circuit current (during the first cycle). It will be shown that the average distress on a given switch varies roughly with the power broken, as might be expected. Repeated tests under similar conditions, it is true, do not give the same results, but the average of groups of repeated tests gives distress values which do vary roughly with the power broken. Two groups of tests are given as a partial illustration of this.

Tests.—The figures given in Table 7 and Fig. 18 were obtained in tests carried out at 5 500 volts at a phase angle of about 85°.

Symmetry of Current, and Distress.—When an alternator is short-circuited, the currents in the three phases assume varying degrees of asymmetry, depending upon the point of the voltage wave at which the short-circuit commences. The unsymmetrical condition persists for a few cycles to a progressively decreasing extent, and it is sometimes assumed that this condition is responsible for the distress variation when breaking the circuit. Results have been obtained, however, which show that such an assumption is largely untenable. There is certainly a small variation in average distress between the symmetrical and unsymmetrical conditions, but there is no doubt that this variation is relatively small and it is hardly of such magnitude as to render it worth while to modify the design of switching apparatus to provide for it, while relatively greater causes of variation remain unchecked and quite unprovided for. In a 3-phase single-tank switch the compensatory effect of the three phases is such that the degree of symmetry can usually be neglected as a factor in total distress production. It is in the 3-tank design only that any consideration of the effect of the degrees of symmetry may possibly be warranted. It has been the author's experience that the greatest result of current asymmetry is the effect it produces on subsequent phenomena such as arc growth, arc formation and arc fluctuations, rather than the smaller variations in distress produced by the current value *per se*.

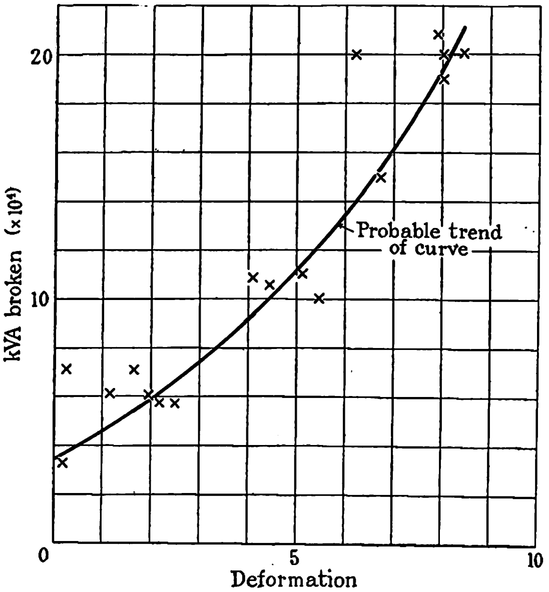

FIG. 18.—Curve showing relation between kVA broken and deformation (see also Table 7).

Table 8 shows a few selected tests from which it will be seen that the symmetrical and unsymmetrical conditions are almost swamped by other variable factors.

Phase Angle and Distress.—Consideration of the question of phase angle is allied with other matters, e.g. the influence of the arc phase-angle. The arc during the circuit-breaking process acts as an ohmic resistance which commences at a low value when the arc is short and the current heavy, so that the effect on the total phase angle is small. As the arc is lengthened, the resistance increases, but, as the current is now small, the relatively large effect on the phase angle is of small importance. In the subsequent paragraphs, therefore, arc phase-angle has been ignored, although its effect is, of course, contributory to the test-results given and all further references are to circuit phase-angle. A considerable number of tests were carried out in order to find the critical zones, and the figures given below were selected to represent roughly the maximum and minimum angles met with in practice, the third figure being approximately in the centre of the range and selected to correspond to maximum distress as shown by test.

TABLE 8.

Symmetry	Voltage (nominal)	Current	Break energy	Deformation
	volts	amps.	kW-sec.	
Sym. ..	5 500	1 250	3·1	3
Sym. ..	5 500	1 200	4·96	1·8
Sym. ..	5 500	1 150	2·2	1·3
Unsym...	5 500	700	5·15	2·3
Unsym...	5 500	800	5·0	2·3
Unsym...	5 500	767	0·5	0·1
Unsym...	5 500	750	7·1	3
Unsym...	5 500	650	4·9	2

At a phase angle of about 36°, current symmetrical, a group of tests produced deformations between 2·3 and 3·0. The general performance in these tests was fair; there was a fair amount of noise, oil throwing and gas. Fig. 19 is a characteristic oscillograph record of one of these tests. Between 54° and 57° phase angle, corresponding to 0·6 power factor, current again totally symmetrical, the deformation varied between 2·6 and 4·4. The general performance was poor. Fig. 20 is a typical oscillograph record. At 85° phase angle, with the current totally symmetrical and other conditions unchanged, the deformation varied from 0·1 to 3·3. Fig. 21 is an oscillograph record characteristic of these tests. (See also Fig. 1, which shows burning of contacts when switching a similar load at 60° and 36°.)

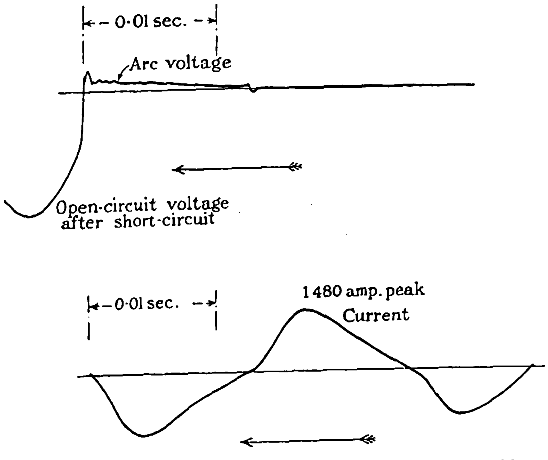

FIG. 19.—Reactance tests at a phase angle of 36°.

Conclusions.—These results are shown graphically in Fig. 22.

A phase angle of 36° is the smallest ever likely to be met with under short-circuit conditions; it is unlikely that this value will be reached except under extreme conditions. In practice, such a small phase angle indicates that the current cannot attain great proportions, as a considerable amount of resistance would necessarily have to be in circuit to change the low phase angle of the generating plant, alone, to the higher value. Therefore 36° is considered to be the extreme limit. At such a phase angle the author's tests show that the average distress is about two-thirds of that in the 55° zone, while the maximum distress is also about two-thirds. A phase angle in the 55° zone would be likely to be produced on a short-circuit at a short distance from the power source. At this phase angle the greatest average distress is produced,

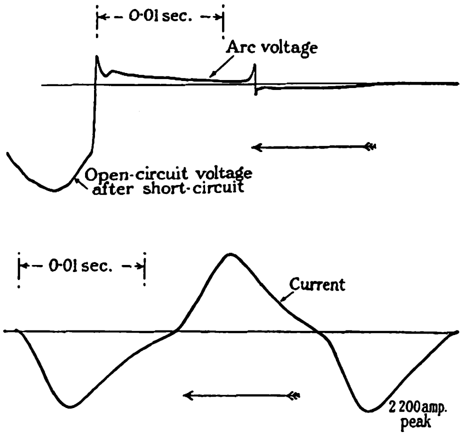

FIG. 20.—Reactance tests at a phase angle of 55°.

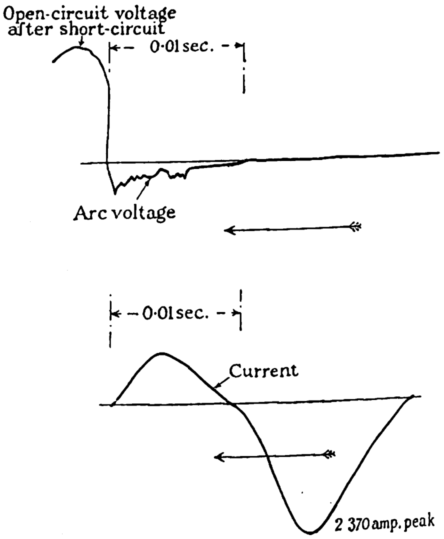

FIG. 21.—Reactance tests at a phase angle of 85°.

the actual range of distress being 2·6 to 4·4, while the range of variability is smallest at this value. At a phase angle of 85° the range of distress is 0·1 to 3·5, thus producing a low average and consequently indicating a lower frequency of occurrence of the maximum distress as compared with that at 56°, but the maximum is high at both 55° and 85°. Thus the switchgear is likely to be subject to about the same maximum distress, but the chances of such distress being produced are smaller. Therefore the switchgear user has to decide whether the apparatus is required to stand up under all circumstances, in view of the decreased expenditure or whether the lower frequency of distress occurrence can be taken advantage of and faced as a legitimate commercial risk.

The Effect of Resistance and Inductance.—The resistance of the cables or overhead lines has usually the most influence on the phase angle. Where the transmission-line resistance has not to be considered (as in the case of a busbar short-circuit), the addition of current-limiting reactors would reduce the current on short-circuit without affecting the phase angle to any material extent, as on a dead short-circuit of this character the phase angle is very large without the reactors, and the addition of the reactors makes but little difference. Therefore, the initially large generator phase-angle is not greatly augmented by the inductive effect of the reactors, so that the effect of the small phase-angle variation would usually be negligible.

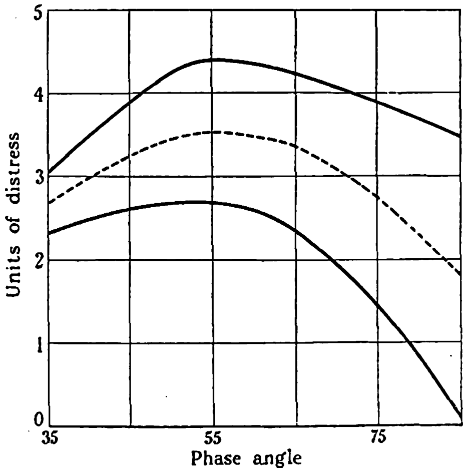

FIG. 22.—Curves showing mean distress for a group of tests at various phase angles.

Relatively heavy feeder short-circuits may be divided into near-by faults, within a radius of a few hundred yards from the power station, and those of greater radius up to about 2 miles; with a near-by fault the phase angle is already of the order of 55° to 60°, so that the addition of reactors would probably be helpful.

Beyond this area, as the radius increases, the phase angle would normally decrease owing to the resistance of the transmission system; the addition of reactors then has a progressively greater effect in bringing the phase angle back into the region of maximum distress. On a 6-kV system within a radius of about 2 miles from the power station a considerable proportion of large substations are normally placed, and their capital cost is largely dependent upon the class of switchgear installed. It is, therefore, in such circuits that reactance has frequently been provided, either at the substation or at the power station, usually with the intention of reducing switchgear costs. In the production of switchgear stresses, the current reduction may in some such situations have been more than offset by the increase in the phase angle.

In a transmission system consisting chiefly of radial feeders not interconnected, the phase angle would change into the middle zone at a shorter distance from the power source. For instance, at the end of a 1-mile length of 0·1 sq. in. cable, the conditions may be roughly equivalent to those obtained at a radius of about 2 miles on an interconnected network. The phase angle on short-circuit would in both instances be of the order of 45°, and the addition of current-limiting reactance with too great a proportion of inductance would increase the phase angle to the 55° zone.

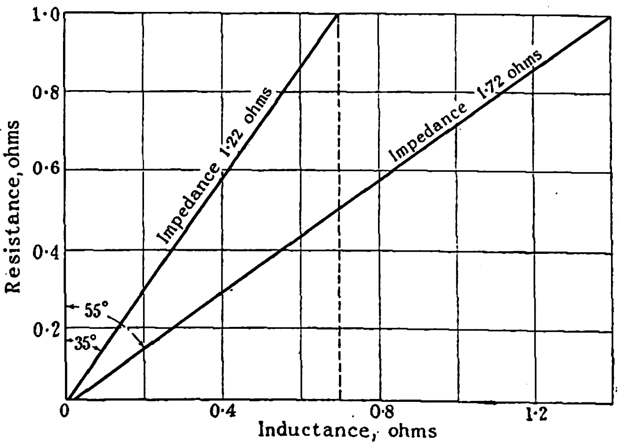

FIG. 23.—Vectorial relationships of current and voltage on increasing inductance by 100 per cent.

The curves in Fig. 22 show that the distress can increase approximately 46 per cent for a given current by the simple increase of the phase angle from 36° to 56°. The phase-angle conditions corresponding to these values are shown vectorially in Fig. 23, which also shows that to bring about a current reduction of 29 per cent on a given circuit composed of 1 ohm resistance and 0·7 ohm inductance, it is necessary to double the inductive component, thus making it 1·4 ohms, with a corresponding phase angle of 55°. At 36° the total impedance corresponds to 1·22 ohms and at 56° to 1·72 ohms, an increase in impedance of approximately 40 per cent, which results in a current reduction of 29 per cent.

The phase-angle variation during this change, after making allowance for the current reduction, thus causes an increase in distress of about 15 per cent in the instance considered.

Fig. 24 shows how the reactance of an alternator alters at various overloads and indicates that this variation may also contribute to alterations in the current phase angle.

Transmission-line transformers at a power source may bring about switching conditions of the same sort.

Two instances of this happening in practice are as follows:—In one, a 2 000-kVA transformer bank was connected to a 6 000-kVA, 6 000-volt alternator, with the result that, on short-circuit, the distress on the 6 000-volt generator switch was considerably greater than with the transformer not in circuit. The other instance happened with a 6 000-kVA step-up transformer bank, where the switchgear operated satisfactorily when dealing with a given load fed direct at 6 000 volts, but ejected oil when breaking a load of similar magnitude consisting of a step-up transformer bank.

Phase-angle variations have an important bearing on the use of step-switches employing resistance on the intermediate step or steps, for such a switch on a large-phase-angle short-circuit is liable to pull the phase angle into the 60° zone. Two commercial switches of this type were tested and, somewhat to the astonishment of the manufacturers concerned, the switching performance was considerably improved by the removal of the resistances. This does not mean that resistance step-switches are to be wholly condemned, but is intended to show that the haphazard introduction of resistance may be the reverse of helpful.

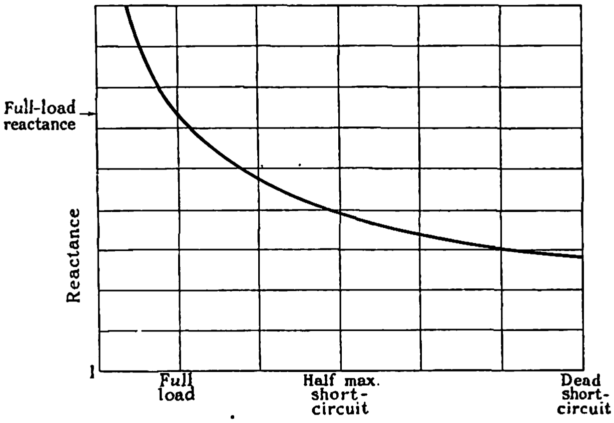

FIG. 24.—Alternator reactance at various overloads.

(5) CONCLUSIONS TO BE DRAWN FROM THESE TESTS.

Variability of Circuit-breaker Performance.—Switchgear designs tend to reach a stage of equilibrium owing to the experience gained from successive breakdowns on the one hand and the restraining demands of economics on the other, with the result that present-day apparatus appears to have gradually evolved to a condition suitable for average distress conditions.

This would indicate that the present commercial breaking-capacity ratings are similarly average ratings and, as such, are liable to a percentage of breakdowns of varying degree. The relative proportions of safe operations and unsafe operations depend upon the ratio of stress produced under the average and the maximum conditions. Having found this ratio, the maximum safe breaking capacity under all conditions can be determined. Using the ratio given below, i.e. 2·5 : 1, and assuming the largest commercial breaking capacity at present economically possible to be 2 million kVA, the true breaking capacity (i.e. that which will ensure 100 per cent service) will be 800 000 kVA.

Switchgear can generally be considered as falling into two groups. The first group includes the heavy-tank switch, usually of the ironclad form, which is so much used in this country and which is capable of withstanding a sustained pressure of 150 lb. per sq. in. and upwards, and the largest of which will, in the author's opinion, give satisfactory service on a short-circuit power of 800 000 kVA. The second group, although intended for the same duty as the heavy type, is of the light-tank design, largely adopted abroad and perhaps to a smaller extent in this country. Comparative tests indicate that the lighter type is likely to fail at about one-third the stress which the first group can withstand, both as regards the maximum power for which such switches can commercially be built and also with respect to the comparative performance of a given pair of switches from the two classes, assuming, of course, that switches of similar overall dimensions and nominal rating be compared. It has therefore been assumed that 300 000 kVA is the maximum power for which such switches can be relied upon under all conditions. These conclusions are roughly confirmed by an examination of records of switch failures under extreme working conditions and by comparative tests on smaller switches of both the light and the heavy pattern. The maximum safe rupturing capacity is assumed to be rather below the point at which permanent distortion of the container would be set up. This limit was decided upon by deformation experiments upon oil containers manufactured specially for various test-switches, and it was noticed that it was possible for failure (distortion) to occur at something less than half the commercial rating, or, more precisely, at two-fifths of this rating.

In the first (or heavy switchgear) group the ratio of maximum to average distress in all the tests carried out, of which those described in this paper are a representative selection, is approximately 2·5 : 1, whilst the ratio of maximum to minimum distress is 77 : 1.

If the previous paragraphs be accepted, this 800 000-kVA rating corresponds to the manufacturers' rating for a circuit breaker of 800 000 × 2·5, i.e. 2 000 000 kVA, since designs are based on average experience. Actually, a short-circuit breaking capacity of at least 2 000 000 kVA is required if service free from chance of breakdown is to be obtained, so that such a breaker would have a rating corresponding to 2·5 times that of the present-day 2 000 000-kVA breaker, or 5 000 000 kVA, and would be very costly.

An adequate source of testing power will soon become a *sine qua non* in the production of reliable circuit breakers. The possession of such a plant would enable circuit breakers to be tested at their rated breaking capacity, and would greatly assist in the evolution of designs without having to wait for operation experience, with its attendant risks to both user and manufacturer.

Mechanical Strength.—Arising out of the necessity for great mechanical strength, a comparison of rectangular and round tanks discloses the fact that, for a given volume and thickness of material, the round-tank switch is usually capable of withstanding 50 to 100 per cent greater hydraulic pressure than the square-tank type.

This is confirmed by an examination of manufacturers' test figures. It would thus appear that round tanks should be used wherever the space available and other factors permit this to be done.

There seems to be a tendency on the part of manufacturers to attribute quite low test pressures to tanks which should be capable of withstanding considerably higher pressures. For instance, one manufacturer tests to 50 lb. per sq. in. on a tank little greater than 1 cub. ft. in volume and constructed of stiffened $\frac{5}{16}$-in. steel. Such a pressure is very low for a tank of this class of construction, and one is left wondering whether it indicates lack of faith in the workmanship put into the welding and riveting, or whether there is some weak spot which, by comparatively minor modifications, could be improved sufficiently to make the whole apparatus of consistent strength. There is no doubt that a considerable increase in pressure could be applied to a tank of these dimensions if it were soundly constructed, and without adding materially to the cost, and, as it seems clear that breaking capacity is proportional to some function of the pressure-withstanding capability of the switch tank, it seems but logical to ask for a test pressure which indicates that the materials from which the tank is constructed are being reasonably well utilized.

TABLE 9.

Switch No.	Breaking capacity	Test pressure	Vol. of tank
	kVA	lb. per sq. in.	cub. ft.
1	75 000	150	3·0
2	100 000	150	3·3
3	150 000	200	4·4
4	250 000	200	7·1
5	350 000	250	12·7
6	500 000	350	16·1
7	750 000	350	30·5
8	1 000 000	500	56·2
9	1 500 000	800	88·0

In a given range of switches the rated breaking capacities and corresponding test pressures shown in Table 9 have been standardized, while Fig. 25 includes a number of other switches.

After making due allowance for size of tank or enclosure and after certain adjustments to some of the designs, the test pressure and mechanical strength in the above range of switches were found to be, in general, proportional to breaking capacity and, as it is found convenient in the manufacture of all except super-voltage high-power switches to increase both size and strength as the rated breaking capacity is increased (rather than to keep, say, size constant and to increase strength to a greater and disproportionate amount, or vice versa), it is evident that the breaking capacity is to some extent proportional to the product of tank volume and mechanical strength as indicated by test pressure.

If, in conjunction with the foregoing, the requirements of breaking speed and other factors are duly observed, it should be possible to specify breaking capacities with a fair degree of confidence.

Breaking-capacity Formula.—It will perhaps be agreed that any attempt to devise a breaking-capacity formula from a theoretical standpoint is doomed to failure because of the variability of the arcing phenomena. It seems, furthermore, somewhat futile to attempt to tie into a formula such factors as speed of break and air cushion, which, in a given design, must either be right or wrong, and, if wrong, should be remediable with little difficulty.

The factors which mainly determine the breaking capacity are volume and strength of oil container, and number of breaks in series per pole. That the number of breaks has a definite influence on the breaking performance is shown on pages 1094 and 1095. Using the 2-break switch as a standard it has been found possible to correlate strength, volume and breaking capacity in a formula based on practice and on test data. The work done in compiling figures similar to those in Table 9 has had a considerable bearing on the results.

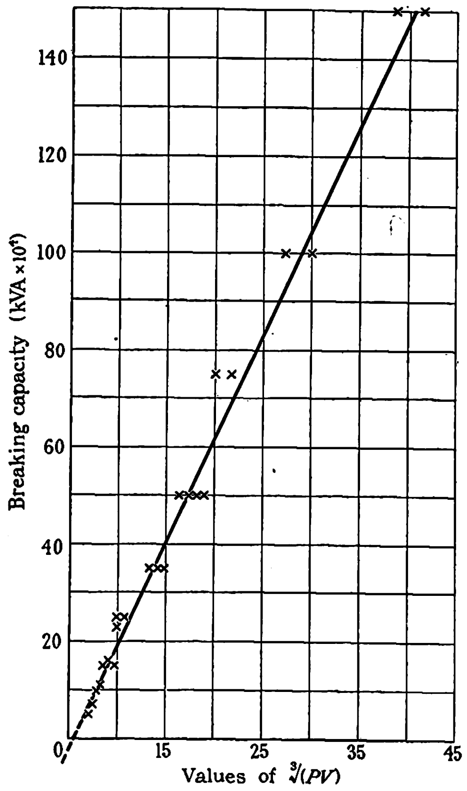

FIG. 25.—Curve showing connection between breaking capacity and the value of $\sqrt[3]{(PV)}$ of oil switches by various manufacturers.

The breaking capacity has been found to be not directly proportional to the strength and volume but proportional to the cube root of the product of these factors. It was found to be possible to plot breaking capacity to the cube root of this product down to quite low values; but values below about 50 000 kVA have had to be excluded by the introduction of a minus factor into the equation. At the other end of the scale the formula applies to switches up to about 100-cub. ft. tank capacity and, if care has been taken to ensure that switches lying off the line conform in the same manner as the range shown in Table 9, it will be found that the formula

Breaking capacity (average or commercial)

$$= 4\cdot26\left\{\sqrt[3]{(PV)} - 5\cdot7\right\} \times 10^4$$

applies consistently and that, given any two of the three factors, breaking capacity, test pressure and volume, the third can be found. The breaking capacity thus found is that corresponding to the average rating referred to on page 1100. To obtain the 100 per cent breaking capacity under all conditions it is necessary to divide the result by 2·5. In other words, the first result is the breaking capacity of a switch which under the usual load and running conditions on a large system (see pages 1101 and 1102) would break the power indicated by the formula in 96·75 per cent of the total times of operation. The second result, introducing the constant 2·5, gives the safe breaking capacity under all conditions, and is thus:—

Breaking capacity (true or 100 per cent value)

$$= 4\cdot26\left\{\sqrt[3]{(PV)} - 5\cdot7\right\} \times 10^4 \times \frac{1}{2\cdot5}$$

The results so obtained give the breaking capacity of a switch having two breaks per pole. With four breaks per pole the commercial breaking capacity would be greater by the fraction $\frac{5}{4}$, so that the formula would become $4\cdot26\left\{\sqrt[3]{(PV)} - 5\cdot7\right\} \times 10^4 \times \frac{5}{4}$, and the true breaking capacity would be

$$4\cdot26\left\{\sqrt[3]{(PV)} - 5\cdot7\right\} \times 10^4 \times \frac{5}{4} \times \frac{1}{2\cdot5}$$

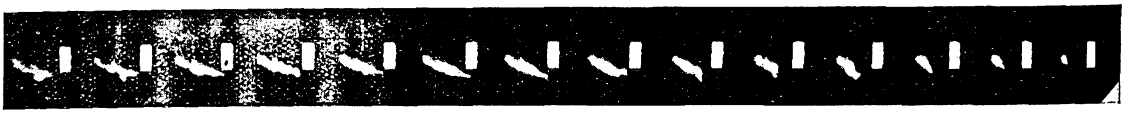

FIG. 26.—Photograph showing 6 000-volt 100-ampere arc, under fixed circuit conditions, fluctuating and breaking up.

Approximate distance between two arc roots under worst conditions = 30 in.
Approximate distance between two arc roots under best conditions = 2 in.

When considering extra-high-voltage high-power circuit breakers, voltage clearances necessitate a large tank volume and in consequence it is usually found that the mechanical strength is rather below the standard upon which the formula is based, and that the ratio of volume to strength is greater than in the former class of apparatus. Although the formula has been found correct in all instances where it has been so far applied, irrespective of the volume/strength ratios, in the large-volume range of switchgear it should be used with caution.

Existing Switching Conditions Analysed.—Existing switching conditions should apparently be regarded from the point of view of engineering risk, since it would appear that the short-circuit powers which now have to be dealt with cannot be broken with certainty by any existing oil switch. The question is: What is the maximum risk and what risk can or should be undertaken? To answer this involves an analysis of faults, first in the power station itself where the maximum short-circuit power occurs, and secondly on the distribution or transmission system where the short-circuit power does not attain such a high value. In such an analysis on three different power systems taken together, it was found that the annual total number of faults was 170. Of these, 11 were major faults; that is to say, they were either power station short-circuits or were in a part of the system where the short-circuit power could reach a greater value than the maximum certain rupturing capacity of the largest switching unit installed. Therefore, the switchgear would be called upon to operate under conditions exceeding its rating in 11 out of 170 times, or 6·5 per cent of the total.

It will, of course, be appreciated that on smaller systems where, especially during the slack hours, a maximum short-circuit kVA of less than 800 000 is available, the above percentage must be correspondingly reduced.

Still dealing with the larger type of power system, it is now possible to correlate these figures with the test figures showing the rates of variability in distress produced under various circuit conditions. The actual numbers of tests in the two groups (over-stress and maximum safe stress) were found for all practical purposes to be equal; therefore, taking 800 000 kVA as the greatest breaking capacity obtainable and the over-stressed condition as happening in 50 per cent of the total times of operation, the chances against the switchgear having to deal with more power than that equivalent to its true maximum breaking capacity become the product of the percentage already obtained and the ratio of over-stressed tests to total tests, i.e. 1 : 2, thus giving 3·25 per cent of the total. In other words, a high-power heavy-construction oil switch under the usual operating conditions in a power system having a short-circuit capacity greater than 800 000 kVA, but not much greater than this, will give a 96·75 per cent service.

(6) CAUSE OF DISTRESS VARIATION.

Switch Oil and its Effects.—The fortuitous variations in distress to which attention has been drawn in this paper undoubtedly depend on effects inherent in the electric arc and on the behaviour of the switch oil under its influence. The author considers that only a very crude smothering process takes place in an oil switch on breaking, and that the resultant action on the oil is complicated and largely uncontrollable. The function of the oil has become somewhat obscured in the evolutionary process. Oil was originally used in switchgear because it was found that, without it, the arc and the arc gases spread and burnt surrounding apparatus, but there seems little doubt that there has never been a true condition of arcing in the oil, and that actually the arc has been a gaseous one wherein the arc is surrounded by a gas skin which intervenes between it and the oil.

Oil has the advantage of reducing the hot zone of the arc gases, but unfortunately it localizes the pressure effects and, as a result of gasification of the oil, produces much higher pressures than those which can be caused by the arc alone. Prof. Thornton's work on this subject is of fundamental importance.

Arc Form and Ion Mobility.—Contributing to the complication are the variations in the arc, which is extremely unstable and takes infinite forms (see Fig. 26). It varies in the path it takes, in the length of the path, in its shape and in many other ways, and its thermal effects must vary in a similar erratic manner. A considerable amount of work on the theory of the arc has been carried out by Prof. Compton. One of the things he has demonstrated is that with an electric arc in oil the ion mobility is so small that the ions remain in sufficient concentration to re-strike the arc after the voltage has fallen to zero or has reversed. Slepian demonstrated that a 20 000-ampere arc, when moved rapidly across its source, could be maintained without any sign of the copper melting; there were only the merest traces of oxidation even with the greatest current used. Herr Solt (*Zeitschrift für Physik*) describes further experiments using smaller currents than Slepian. A somewhat similar effect seems to be embodied in the British Electrical and Allied Industries Research Association's British Patent No. 242318/25.

(7) New Designs of Switching Apparatus.

Preliminary.—In 1912 the author carried out tests which were probably similar to those of Slepian and Solt, and succeeded in obtaining improved results. In a paper* read before this Institution in 1926 a partial reference was made to the results of these tests in a brief description of a fusible cut-out with a stabilized arc which had given very consistent and favourable results. This, however, was really a side issue to the 1912 work which is embodied in the new switch described on page 1105.

Stabilized Arc.—In the stabilized-arc device as made, the cut-out is surrounded by a magnetic field which assists the tendency of the arc to keep in a straight line in the shortest path between the electrodes. Since that date, further tests have been carried out both on cut-outs and on switches designed in this way; oil immersion was used in most of the tests, but is not essential. Fig. 27 shows the arrangement of a single-phase switch of this form which was constructed for test purposes and which embodies a simple way of obtaining the required field, while Fig. 28 shows a convenient form of oil fuse embodying the same principle. The two oscillograph records in Fig. 29 show a comparison between the new form of switch and an oil switch of the usual form when breaking a 5 500-volt short-circuit. The comparison shows that in the ordinary oil switch the arc is unstable, whilst in the new arrangement the arc is stable and the voltage wave-form is smooth and flat, and the distress is substantially less than in the ordinary oil switch under corresponding circuit conditions. The flat wave-form of the stable-arc switch is very striking, as there is not even the normal double-peak wave-form which is generally associated with the electric arc.

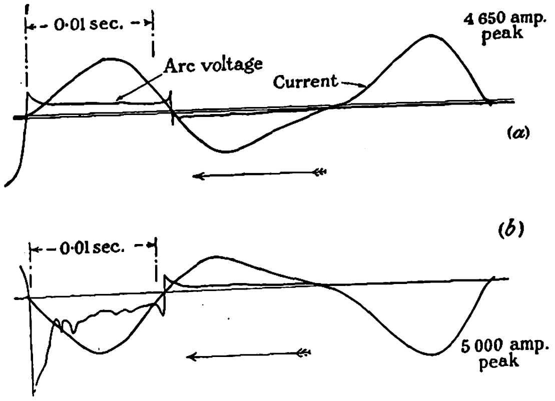

Fig. 29.—Oscillograms of stabilized and ordinary oil-switch wave-forms.

(a) Oil switch fitted with arc stabilizers.
(b) Oil switch without arc stabilizers.

The advantage of this stabilizing principle is generally similar when applied to multi-break switches. So long as the number of breaks is the same, the comparison between the operation of the ordinary type and the stabilized type shows to the advantage of the latter for any number of breaks. Mechanical and electrical forms of stabilization give somewhat similar results. Fig. 29 is a typical example of the results obtained. In a short-circuit at 5 500 volts with a phase angle of 85°, 49·2 kW-sec. of arc energy and 9 units of deformation were obtained on a non-stabilized switch. With the same switch fitted with stabilizers, and on a similar short-circuit at 85°, 29·2 kW-sec. of arc energy was registered and only 3 units of deformation. The switch employed had 4 breaks per phase.

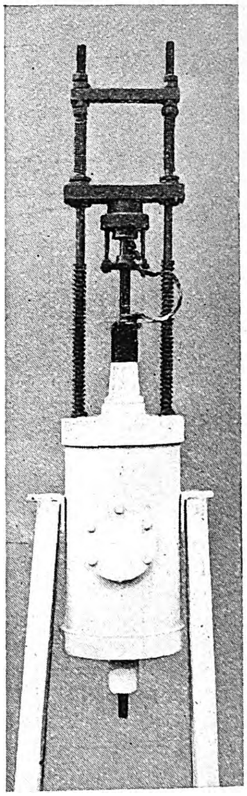

Fig. 30.—Single-pole quenched-arc circuit breaker in the "open" position.

Prolonged testing, however, showed that it was not possible to obtain the complete consistency of performance which was required.

This type of switch, although successful in stabilizing the arc, made no attempt to control the heat production and further tests were therefore carried out, from which was evolved the quenched-arc switch, which combines the features of arc stabilization and heat control.

A New "Quenched Arc" Switch.

Preliminary.—The evolution of good switching apparatus depends upon the observance of a number of factors, some of which have been dealt with in this paper. It has been shown that arc stability produces greater consistency of distress symptoms than is possible with an oil switch of ordinary form. The new step is to reduce the amount of energy appearing at the arc under given circuit conditions. This reduction can take two forms, one, of magnitude, by reduction of the voltage which appears across the arc, and the other, of time, by reduction of the arcing period. The first can be achieved in practice with an arc of low resistance per unit of cross-sectional area, and the second by rapid abstraction of the heat of the arc and consequent reduction of ion generation, upon which depends the ability of the arc to continue. The control of ion production is really at the root of the matter, but the majority of the existing designs of circuit breakers, although excellent in other respects, bear but little evidence of this principle having been recognized. Much good work in other directions has thereby been stultified.

* *Journal I.E.E.*, 1926, vol. 64, p. 920.

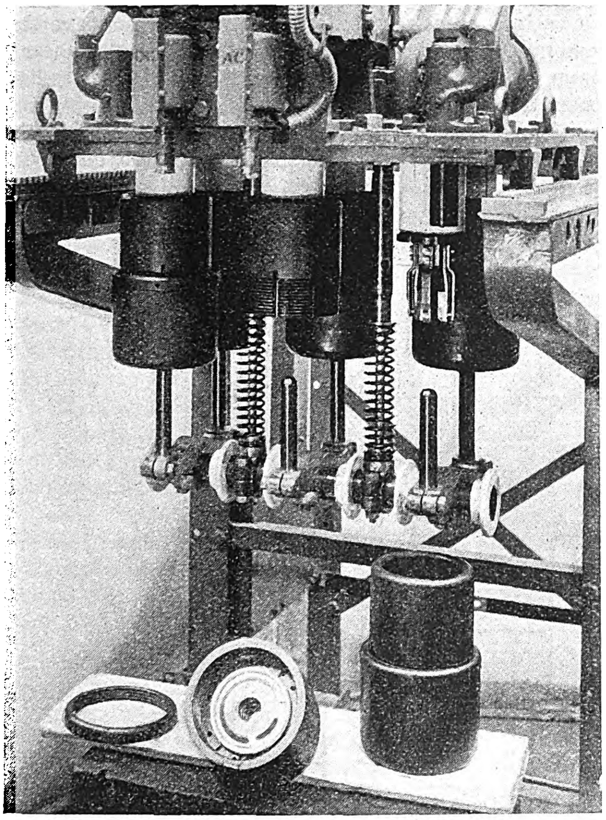

FIG. 31.—An 11 000-volt 350-ampere quenched-arc circuit breaker with two arcing contacts removed.

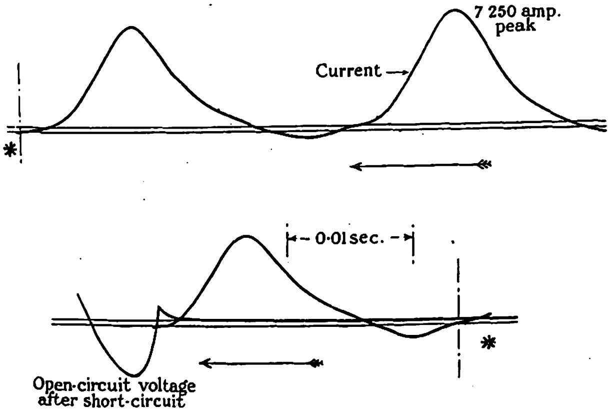

FIG. 32.—Oscillogram of quenched-arc switch clearing dead short-circuit on 6 000-kVA alternator.

The quenched-arc switch is designed to embody the above principles. The energy dissipated at the contacts is reduced to a low value and abstracted in the form of low-grade heat, thus preventing it being passed to the surrounding air, gas or oil, in any other form than that of low-grade heat.

Construction.—The switch * is arranged with a central orifice with lateral discoid openings between heavy metal plates between which a powerful quenching action is set up. This portion of the switch can be under oil, thus preventing the formation of gaseous conducting paths, but a large head of oil is unnecessary, a large air cushion being frequently beneficial. The arc is opened by withdrawing a central contact rod from a circuit contact under the oil; the rod then passes the discs (or other surfaces) successively, the arc being forced by magnetic and thermal action into the radial extinguishing openings. The extinguishing process takes place at a comparatively small radial distance from the central rod when medium amounts of power are being handled, while with greater amounts of power the path of

---

* British Patent No. 29714/1927.

travel becomes longer and broader, finally emerging into an annular extinguishing chamber near the outer edge of the discs where the heaviest power can be quietly broken. Arc stability is produced mainly by the metal discs which constitute guiding contacts, and partly also by the concentric iron container.

When passing through the radial openings the arc is formed into a series of annular sections which are kept constantly in motion, expanding radially under conditions of gas pressure and temperature which produce a low arc voltage and assist in the rapid extinction process. These are the factors which determine the fundamental voltage basis for a given design of switch. The correct pressure and temperatures are automatically provided under all conditions of breaking, and the moving parts are simple and strong. There are no valves, pipes or delicate parts, and the construction can be more robust, both mechanically and electrically, than the oil switch of conventional form. The current-carrying and arcing conductors are heavy and the insulation clearances considerable. Although strong construction is an inherent feature of the design, this ranks only as an additional safeguard, as in practice the pressure set up during the breaking process is negligible.

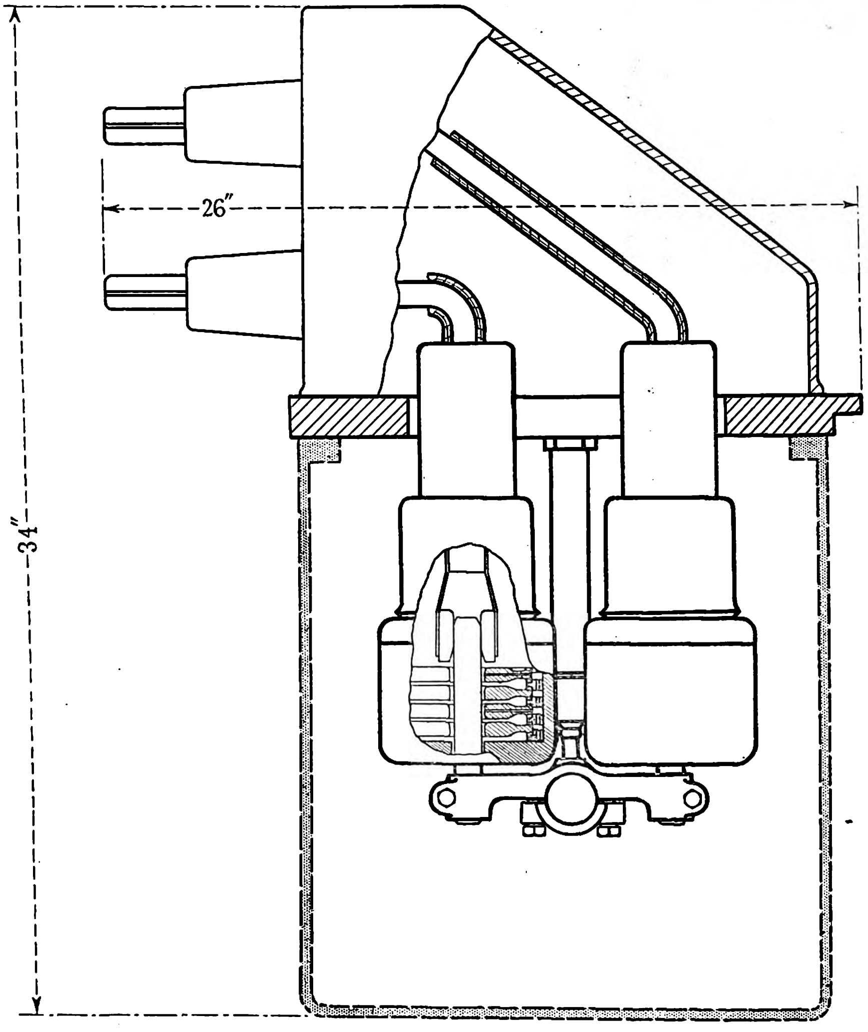

Fig. 35.—Quenched-arc circuit breaker for 1 million kVA (true rating).

Arrangements of baffles, metal and other cooling discs and similar arrangements have been previously proposed on various occasions, but these arrangements have been generally more or less haphazard and do not appear to have followed a logical scheme. Such of these as have been tested have not shown any radical improvement in performance distinguishable from existing forms of switchgear, and sometimes they are actually dangerous.

Fig. 30 shows a single-pole quenched-arc circuit breaker in the "open" position. The pressure disc can be seen in front of the container, the total length of the latter being 9 in. and its overall diameter 5 in. Fig. 31 is a view of an 11 000-volt 350-ampere quenched-arc circuit breaker with two of the arcing contacts removed to show the construction. The contacts can be changed in a few seconds. In the development of the quenched-arc breaker, special care has to be taken to depart as little as possible from well-tried constructional forms; and Fig. 31 shows a breaker of this pattern built into a standard ironclad draw-out pedestal.

B.E.S.A. clearances and tolerances have been observed throughout.

Object of the Oil.—Oil is introduced with the object of reducing insulation clearances. This is important, since a switch operating in a gaseous medium must necessarily have considerable clearances to prevent the arc and arc gases forming a conducting path; the oil enables the clearances between live parts and earth to be cut down to about 25 per cent of those necessary in an air design. During operation, the oil is forced automatically from the arcing area, but not from the region where it is required to maintain the insulation. When the arc is extinguished, the oil passes back into and scavenges the cells.

Performance.—A switch measuring 6 inches in diameter by 6 inches long, and weighing less than 28 lb., interrupted on numerous occasions 50 000 kVA at 6 000 volts without any external sign of its operation. There were none of the symptoms usually obtained with an oil switch, such as noise and gas, oil or flame, and, most important of all, no measurable pressure was set up in the container. Another switch unit, 6 inches in diameter and 3 inches long, interrupted the same amount of power, again without any distress. Attempts to measure the duty on the container by the deformation method used for the other tests described in this paper gave no indication of pressure.

TABLE 10.

Voltage	kVA	Size of unit	Performance
volts		in. in.	
6 000	50 000	6 × 6	Not near limit
6 000	50 000	6 × 3	No sign of distress
5 500	8 250	6 × 4	No sign of distress
3 100	2 800	6 × 4	No sign of distress
4 520	7 200	6 × 4	No sign of distress
5 240	10 600	6 × 4	No sign of distress
11 000	230 000	6 × 4 (6 units, 3-phase, 2 per phase)	Operated quietly. No distress

Test-records.—Fig. 32 is an oscillograph record taken during a test on a switch of this pattern when clearing a dead short-circuit on a 6 000-kVA alternator. The voltage was 5 500 (R.M.S.) across phases, and the switching element was subject to the full line voltage, i.e. $\sqrt{3}$ times that to which it would be subject in service; its maximum rupturing capacity was not nearly reached in this test. The switch measured 6 in. in diameter by 10 in. long and the container enclosed 1 500 cm^3 of ordinary switch oil. The clearance to earth between the switching element and the earthed container was about 1 in. The resultant short-circuits at 85° phase angle were cleared quickly and silently.

Examination of the oscillograph record rarely shows any perceptible voltage during the arcing period, the arc being extinguished very rapidly and without any sign of instability. As no appreciable voltage is set up across the switch, there can obviously be no material amount of power expended in it and consequently no generation of pressure inside it. Actually, of course, there must be some voltage, but it is a small percentage of that which would be set up across the contacts of an ordinary oil switch under similar circuit conditions. Prolonged arcing is effectively and safely prevented, and secondary effects on the oil are found by observation to be reduced to a negligibly low value.

In one of several series of tests, a group of 12 short-circuits at 5 500 volts was applied at intervals of 30 seconds. The switch was not opened out, and received no attention whatever between tests—the same oil being used throughout—and it operated perfectly in all these tests. No arc voltage was indicated and no deformation of the pressure-indicating apparatus was recorded.

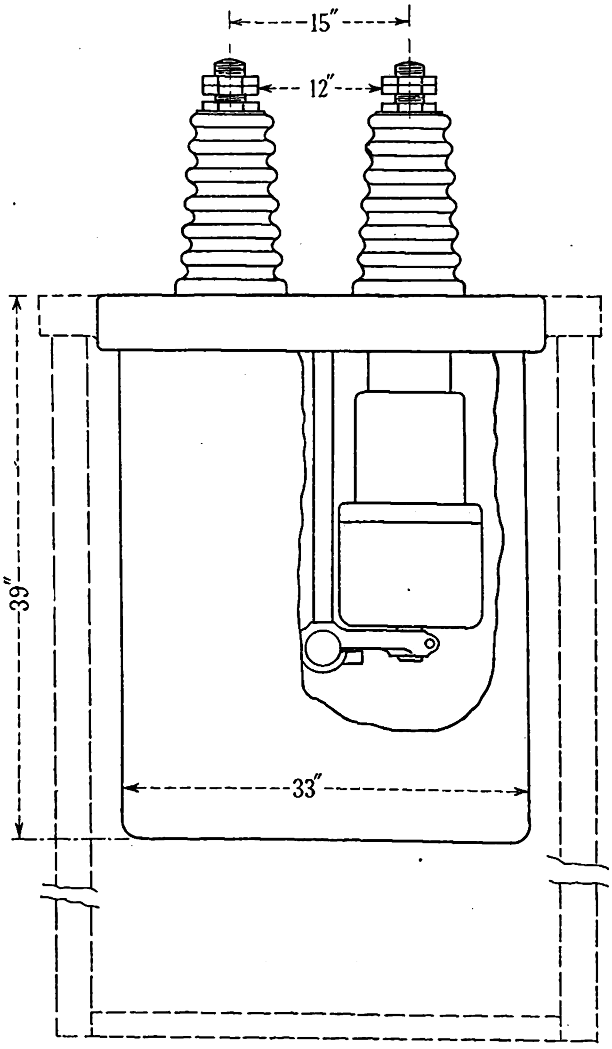

FIG. 36.—Quenched-arc circuit breaker for 2 million kVA (true rating) and 33 000 volts.

A number of tests were carried out at reduced power (examples being 4 520 volts, 1 590 amperes; and 3 750 volts, 1 475 amperes) to investigate the working of the switch at reduced current and voltage. One test, at 3 000 volts, 900 amperes, is illustrated in Fig. 33.

Fig. 34 shows a test at 5 240 volts, 2 020 amperes, equivalent to 10 600 kVA. This test is representative of a number carried out in steps between the low and the high values. A few tests under different conditions are given in tabular form in Table 10. Fig. 35 shows the commercial form of an ironclad oil-immersed circuit breaker of the quenched-arc type, with a breaking capacity of about 1 million kVA (true, not commercial, rating). Fig. 36 shows an enclosed 2 million kVA, 33 kV breaker. The highest power so far broken by a quenched-arc breaker in any test is 230 000 kVA: the breaker used for these tests is shown in Figs. 31 and 35. In all approximately 100 full-scale short-circuit tests have been carried out. By "full scale" is meant short-circuits involving 50 000 kVA and over.

It is interesting to consider what the development of this switch may mean for high powers. The present limitation of the oil switch is mechanical and it is this factor which is responsible for the economic difficulty in the way of further developments. The new device has apparently no such limitations. When breaking a 50 000-kVA short-circuit it has been proved that a unit measuring about 6 in. × 6 in. can meet all demands with perfect ease. To do this with an oil switch embodying the various important features discussed in this paper, i.e. massive mechanical construction, multi-break, correct speed of break, correct air cushion, etc., would necessitate a unit much greater in size than the new switch. There would, moreover, be this important difference: when the ordinary oil switch was breaking under short-circuit conditions considerable mechanical stress would result, whereas the quenched-arc switch of smaller size would break the same power with no appreciable mechanical stress. It would appear that there is no great difficulty in designing a circuit breaker of the quenched-arc type to deal with 2 or 3 million kVA, on the 100 per cent service basis.

The author is very grateful to all those who have helped him to carry out the work on which this paper is based. He is especially sensible of the assistance accorded by Messrs. C. A. Parsons & Co., the Newcastle-upon-Tyne Electric Supply Co., Mr. H. W. Clothier and Messrs. A. Reyrolle & Co., the British Electrical and Allied Industries Research Association, Prof. W. M. Thornton, Mr. Vernon Hope, Mr. R. W. Gregory, Mr. H. B. Poynder and Mr. D. Adam.

APPENDIX.

Limitation of Short-Circuit Current.

It would seem probable from this paper that the 100 per cent rupturing capacity of any oil switch commercially available is about 800 000 kVA. It has been stated that to reduce the short-circuit power of a large system to a value of this order may introduce power-factor conditions which, even taking into account the reduced current, could produce greater oil-switch distress at the lower current owing to the power factor passing into the heavy 55° to 60° zone.

In view of this the author has carried out a few experiments with the object of improving the conditions by other means. This Appendix has been included as a résumé of the results of these tests and to deal with other possibilities of achieving the same object, namely the reduction of short-circuit current without the introduction of detrimental effects.

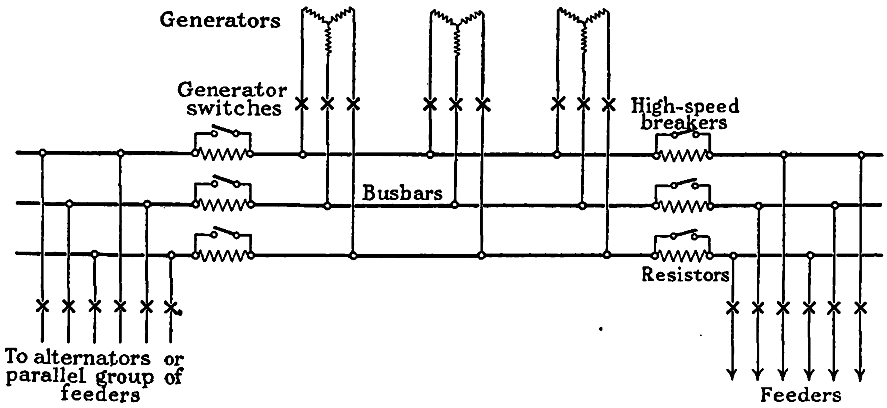

Fig. 37.—Busbar lay-out, showing oil circuit-breakers backed by high-speed breakers.

The new switch described in the paper appears to be one solution of the problem of breaking high short-circuit powers satisfactorily and, as this has been dealt with fairly fully in the body of the paper, nothing further need be said about it here. Other methods of tackling the problem all appear to take the form of current limitation, and to the author there seem to be two possibilities in this direction, (1) to limit the short-circuit current by means of resistance or high-inductance coils which, under load conditions, are cut out of the circuit and which under short-circuit conditions are sufficiently high to keep the phase angle out of the 50°–60° zone; and (2) to regulate the short-circuit current by manipulation of the excitation of the generating plant.

Current Limitation by means of Resistance (or Inductance).—Even if the effect of reactance were quite above suspicion and its influence on switchgear performance purely beneficial, there would yet remain the disadvantages attendant upon its being connected in the circuit at all times, chief amongst these being the permanent voltage-drop set up and the somewhat reduced security with such apparatus. With resistors in the place of inductance coils it becomes essential to devise a means of keeping them out of circuit until actually required.

A considerable amount of development has been carried out during the last few years on high-speed circuit breakers for direct-current work. At first, such circuit breakers were used in parallel with current-limiting resistors, but latterly improvements have resulted in their being used to break the circuit directly. The improved breaking capacity thus obtained is, on direct current, of the order of 100 000 kVA, whilst tests indicate that on alternating current considerably greater power could be broken. With a reasonable amount of development work, a circuit breaker could be devised for the control of the short-circuit current of a high-power alternating-current system. Asssuming, for example, a plant capacity capable of giving $1\frac{1}{2}$ million kVA on short-circuit, the output could be controlled by one circuit breaker per phase, as in Fig. 37, which indicates a usual arrangement of switching equipment with the oil circuit-breakers backed by means of high-speed breakers and current-limiting resistors. The high-speed breakers would, of course, open long before the oil switches and would reclose again immediately the oil switches controlling the fault had cleared it.

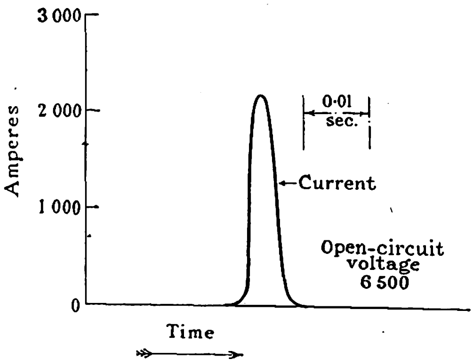

Fig. 38.—Oscillogram of high-speed breaker on 50 000 kVA (a.c.).

The maximum power to be interrupted by each high-speed breaker would be the earth-fault current of each phase multiplied by the drop across the series resistance. Assuming a system working at 11 000 volts, the kVA to earth per phase will be approximately 500 000. The high-speed circuit breakers should each be capable of handling 200 000 kVA (a.c.), so that the series resistances should be designed to reduce the short-circuit current from 79 000 amperes to 31 500 amperes, which would necessitate a resistance of $\sqrt{[(0\cdot 2)^2 - (0\cdot 08)^2]} = 0\cdot 183$ ohm. This breaking capacity under the unregulated condition is greater than the assumed maximum obtainable with oil circuit-breakers (of the order of 400 000 kVA per phase) but is lower than the regulated short-circuit power calculated above.

The assumed breaking capacity for the high-speed breaker could possibly be increased even when working on present lines with an air break, but a great improvement could be made by using an oil-break high-speed circuit breaker, with which very high operating speeds can be obtained and with which a neater lay-out can be made than with an air-break circuit breaker. Metal-covered connections could be used throughout and the apparatus completely enclosed, thus eliminating the bare connections which would be necessary with the air high-speed breaker. Fig. 38 shows an oscillograph record of the high-speed interruption of a 50 000-kVA alternating-current circuit, which demonstrates the feasibility of the foregoing contentions.

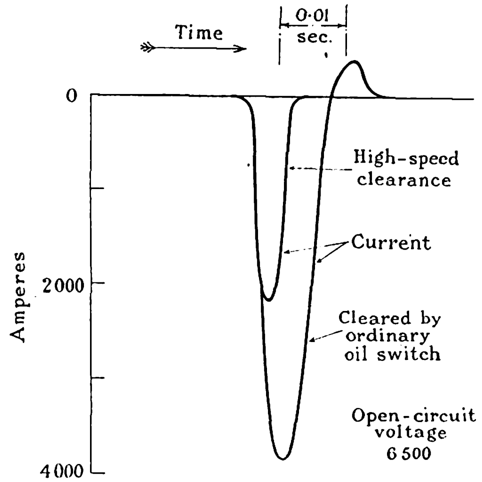

Fig. 39.—Oscillograms of power obtained on 50 000-kVA short-circuit when cleared by means of an ordinary oil switch and when limited by high-speed circuit breakers.

Alternatively, fusible cut-outs could be used either to sectionalize the power-generating plant or to insert limiting resistors, both arrangements producing the required reduction in current and so enabling the ordinary oil switches to operate safely at the reduced power. Fig. 39 shows an oscillogram of the power obtained when clearing a 50 000-kVA short-circuit by means of an oil switch of the usual form and, for comparison, a record of a high-speed fusible cut-out inserted in series to show the current reduction obtained.

Manipulation of the Excitation.—For some time past, Messrs. Brown, Boveri and Co. have sponsored a system of current regulation whereby the high-tension current on short-circuit is reduced by the insertion of resistance in the field circuits of the alternators concerned. With a method of this sort, an appreciable time must elapse before the excitation and consequently the short-circuit current can be reduced to a sufficient extent to permit the oil switches to operate. Moreover, a time interval must be allowed between the commencement of the short-circuit current and the opening of the field circuit breaker, or there will be set up across the field circuit-breaker terminals a voltage sufficiently high to damage the field winding. Nevertheless, this method has been adopted with some success on the French and Swiss power networks, particularly in systems wherein "loose linking" is adopted—usually from necessity owing to the spacing of the generating stations and the small amount of intervening copper—and where consequently the maintenance of synchronism of rotating plant under fault conditions is not part of the problem.

With an interconnected system the time interval necessary with the Brown, Boveri system is usually not permissible and rapid operation is essential. This is still more important on a system employing rapidly acting feeder protective gear such as the Merz-Price system, with which a fault can be completely cleared in 0·1 sec. to 0·3 sec. (depending upon the design of the circuit breaker) of its commencement. Therefore, much higher speed of field manipulation is necessary and some system becomes necessary* which employs a high-speed breaker in the field circuit, arranged in such a way that it opens and inserts resistance before the fault has actually grown and consequently before the armature reaction and excitation have been forced up (see Fig. 40). An operating time of the order of 0·01 sec. is required to obtain full benefit from the system. In this way the short-circuit current could be reduced to about one-half or one-third of the unregulated value. At the same time the power system protective equipment commences to operate and the switchgear will then have to clear the fault at the reduced value only.

Fig. 40.—Diagram of alternator field control system for limitation of short-circuit power in main circuit.

Immediately the fault is cleared the high-speed breakers reclose and restore the excitation to normal. Actually, the high-speed breakers would be open for only about 0·1 sec., i.e. from the start of growth of the fault to the moment of clearance of the fault, the exact time depending upon the speed of working of the ordinary oil switches.

* British Patent No. 21593/28.

DISCUSSION BEFORE THE INSTITUTION, 23RD JANUARY, 1930.

Mr. E. B. Wedmore: Circuit-breaking by the separation of two contacts under oil was first commercially exploited by Mr. Partridge, and the oil circuit-breaker was so effective that for a generation there was no substantial change; the typical large high-tension breaker of to-day differs from the original circuit-breaking device only in its bushings and other subsidiary features. There has been but little new development; the magnetic blow-out and the explosion pot have been exploited and some features of the former will be of permanent value. With the growth of plant capacity in recent years some disadvantages of the oil circuit-breaker and the inadequacy of information in connection with the subject have provoked further research. Circuit breakers must be judged primarily by a commercial criterion. If two circuit breakers have equal performance and reliability, no matter what the relative values of the arc energy or of the "distress ' may be, the cheaper circuit breaker will capture the market. The author's distress factor is not of universal application. What he has said, however, about 100 per cent performance is important. Circuit-breaking devices should not be regarded as satisfactory merely because they do not throw out excessive amounts of oil, smoke and flame. In other branches of electrical engineering something approximating to 100 per cent performance is expected and attained; I believe that within a few years circuit breakers will approach the same standard of efficiency. The author asserts that mistakes have been made in using arc energy as a criterion of performance. This is not the case so far as the Electrical Research Association is concerned. Our views have already been expressed in the *Journal* (1929, vol. 67, p. 591, col. 1, par. 2). The conclusions which the author reaches as to the complexity of the phenomena of circuit-breaking under oil and variations obtained in successive tests are in agreement with ours. The particular type of circuit breaker with which the paper deals undoubtedly shows a wide range of performance arising from numerous causes, one of which is the fortuitous action of the arc. The author uses the empirical method, a favourite tool of the engineer but one which has many disadvantages, one of which is that the results which it yields will apply only to the design which has been tested. If this is slightly altered the effect upon the action of the apparatus cannot be predicted. Despite its limitations, the method is one which many engineers have been forced to follow; in all civilized countries it is now giving place to scientific investigation in connection with the development of the subject of circuit breaking. Many more of the physical quantities involved in the problem of oil circuit-breaking have recently become known and evaluated. I wish the author had dealt in more detail with a narrower range of subjects. His published evidence does not adequately support his conclusions. He has, however, undoubtedly a mass of experimental data which might be of value to the industry if it were placed at the disposal of those who are able to apply more recent scientific knowledge to its analysis. The experimental measurement of distress appears to have been effected by observing the distortion of a metal disc (not prescribed) placed in the oil at a distance (not prescribed) from an arcing device (not fully prescribed). The force developed depends in part upon the test design. An irresistible force should not be opposed by an immovable body, but by one capable of moving easily. The effect of the force will then not be felt. I was for many years connected with the design and application of certain circuit breakers of the type dealt with, which fulfilled few of the conditions laid down in the paper and yet gave uniformly successful service. A flexible wall was provided and the size of the air cushion was much in excess of the limits suggested. It is clear, therefore, that the author's criteria are not suitable for universal application. Fig. 22, dealing with the effects of reactance in circuit, shows greater distress in the circuit breaker at 55° than at 90° phase angle. I see no theoretical justification for this and am disposed to attribute it to some peculiarity of his testing circuit. No doubt the author obtained greater deformation of his discs under the conditions indicated, but that is not sufficient evidence for the general conclusion that with all designs a phase angle of 55° or 60° puts greater strain upon the switch than a phase angle of 85°. Further, there is no inevitable relation between the ability to withstand certain stresses on the circuit-breaker wall and the preventing of the arc from re-establishing itself after the current has passed the zero value. Many factors, other than the possibility of distorting a well-designed tank wall, affect the performance of the switch. These cannot be observed with distress as the sole criterion. The author refers, for example, to speed of breaking as a feature of the oil circuit-breakers appropriate for experimental investigation by his methods. To begin with, there is no such thing as *the* oil circuit-breaker which may be taken for the purpose of establishing a law governing the variation of this quantity. Any figures for speed of breaking can only apply to the design tested or to other very similar designs. I do not follow the argument in which the author visualizes speeds so high as to force the current down and to increase the voltage on the system. The latter process might be dangerous; it is in any case unnecessary and lies outside the range of possibilities with any other than fresh designs. Illustrations are given to show that with higher speeds of breaking there would be a greater voltage, not on the system itself but across the circuit breaker; this would result from a longer arc. As to whether there is a real objection to either of the designs of which oscillograms are shown, I am not clear, partly because no scale is given. In Fig. 14 I cannot trace re-establishment of the arc as described, and in Fig. 16 the indications are that the arc has gone to earth. From the very nature of the phenomenon there must, however, be an optimum speed. An attempt to open a large circuit by slowly separating the contacts must result in the burning of the latter; ultra-rapid separation must increase the voltage across the arc by forcing up the resistance of the arc before the current has reached its normal zero value in the ordinary course of the cycle, thus resulting at least in the liberation of excessive energy to no purpose. Between these two extremes there must be, for a given design, an optimum speed at which excessive energy is not released and there is no excessive burning. That speed will depend upon many other factors which enter into the design. I am interested in the features which the author describes as having a stabilizing effect upon the arc, for I realized some years ago that it was undesirable to allow the action of the latter to become wholly fortuitous.* The author has devised means for preventing this accidental lengthening of the arc, although I am not quite clear as to the method adopted; it seems that the arc in the centre of the magnetic cylinder is essentially unstable and must be attracted towards the wall. The lengthening may be fairly uniform and may repeat itself satisfactorily. In my own work the aim has been to minimize the tendency to lengthening, and this can be accomplished by suitable devices in a particular design. I believe that future circuit breakers will have an arc length so small in comparison with the diameter of the arc that very little bowing will take place. The author shows an interesting multiple-plate " quenched-arc " switch, but he does not point out what are the new features incorporated in it. His contribution to the arc surely lies in these and not merely in the use of the multiple-plate design. Little information is given about the action, and without further information it is difficult to understand the formation of an annular form of arc. I cannot conceive of any magnetic device which would produce an annular or partially-annular arc. The E.R.A. carried out several years ago some experiments with certain multiple-disc devices under the same short-circuit power as the author has been using, when results similar to those which he has shown were obtained. We deferred this development mainly because we believed we had more promising lines to pursue.

Mr. H. W. Clothier : I have the greatest admiration for the free-lance manner in which the author has tackled the problems of breaking alternating-current circuits. He has had only moderate facilities in size of testing plant, but he has made the best of these small powers by trying out breaking capacities on models made to one-quarter full size or 1/64th the cubic contents. It is remarkable how much comparative information he has been able to collect and record from these and other contemporary researches. The world's practice to-day in oil circuit-breaker contacts is divided, but he contributes his experiences on these divergencies. For example, he finds that such devices as snap contacts, magnetic blow-outs and explosion pots all produce unsatisfactory recovery-voltage characteristics, but he demonstrates a large increase in breaking capacity for multi-break devices. He abandons the elusive method of judging the quality of performance on the " arc energy " or " break energy." Instead, he adopts the very practical method of comparing effective pressures by measuring the distortion of a disc fixed in the tank wall. Fig. 18 shows a reasonable relationship between the power broken and the pressure set up on the sides of the tank. The curve might just as truly be drawn as a straight line. The upward trend shown implies lower tank pressure per unit of power broken with increasing power, which is unnatural. In a broad way the author justifies the claim of strength of tank enclosure as a leading factor of breaking-capacity quality, which hitherto some experts have been loath to admit. For instance, Mr. Wedmore has just spoken of the design of tanks which yield to the pressure. It depends upon the accepted theory of circuit-breaking in oil. As I understand it, the main function is to prevent the restoration of the arc immediately after passing through zero. This is best effected in the gas bubble at maximum density. If the tank is allowed to yield, the bubble expands correspondingly and its pressure is reduced. I therefore prefer a tank which will not yield, with an air cushion above the oil, limited to about 5 per cent of the tank capacity. This seems to be confirmed by the author. I should be glad if he would say what the unit of deformation represents in lb. per sq. in. Has he correlated the pressures on the model to the actual full-size circuit breaker? Without knowing the tank stress the breaking-capacity limits on a full-size circuit breaker cannot be theoretically anticipated. Fig. 22, which shows variation in stress with phase angle, affecting the use of reactances, is another good step in research work, but again the conclusions are formed from a wide range of divergent results and may be misleading. Some differences must be narrowed down by more research with larger power before the conclusions can be taken as final. Fig. 25 and Table 9 have been ascertained from manufacturers' data, and so the formula at the top of page 1102 is actually derived from practical evolution in tank dimensions up to date, and includes recent innovations. The author is to be congratulated upon his investigations and derivations, which will be helpful in lining up manufacturing practice. The data now published for the first time so fully, however, must not be confused with the experiments on the small scale model. The latter are to the good so far as safe comparisons can be drawn, but I contend that there is insufficient evidence to warrant the author's sweeping assumption that ratings established by modern British practice must be divided by 2·5 to be what he calls " true " ratings. Some of the very early designs of circuit breakers were over-rated in the absence of power sufficient to obtain experience, but this does not warrant a wholesale writing-down of all ratings or of large modern breakers. On the contrary, some of the designs have been repeatedly tested, and in my opinion and experience they actually carry a safety factor. I do not agree that the designs are based on average experience. I have always held that manufacturers' designs are, or should be, based upon the maximum experience. The author expresses his opinion that the largest circuit breaker is capable of breaking 800 000 kVA. This opinion is based upon experience of designs in long use, the largest of which in this country has been rated at 1 500 000 kVA. The ratio of 1 500 000 to 800 000 is not $2\frac{1}{2}$ to 1 but only $1\frac{7}{8}$ to 1. One particular 1 500 000-kVA circuit breaker design known to me 10 years ago had originally a single break with conductors specially arranged for an increased magnetic field across the arcing space; but they are now of the 4-break type, and on the author's figures this would result in an improvement of 50 to 100. This design correction should therefore raise the true rating from 800 000 to something above its declared rating. The selection of a suitable rating for a circuit breaker in regard to the generator-plant capacity is important, and this is an occasion to ventilate standardization of demand. A circuit breaker is given a rating signifying its ability to make and break circuit, and to obtain a 100 per cent service it should be so selected that its rating exceeds the maximum possible short-circuit kVA that can occur at its terminals in service. If a smaller rating is selected, it is such use that brings about the risk of overstressing the circuit breaker. I consider that, as a general practice, circuit breakers should be so selected that their rating corresponds to the maximum symmetrical short-circuit kVA that can occur across their terminals in service. In this case the only risk of overstress is the very rare occasion of a break on a maximum unsymmetrical short-circuit. I welcome the search for what might be termed the "peaceful" method of arc extinction, aimed at in such devices as shown in Fig. 35, but, as in making other concessions for peace, one must be ever on the look-out for the effects of a breach. This particular form of sparking contact appeals to me, because it fits in with existing metal-clad practice. Although it acts so well up to a certain rating, the author's so-called "true" rating of 1 000 000 kVA must to a considerable extent be based upon empirical data and may therefore be wide of the mark. However, my company have had the privilege of making this apparatus to the author's designs, and in due course such long outstanding factors relating to large and small circuit breakers will be investigated by practical full-value tests on a large short-circuit testing plant which is now installed at Hebburn.

---

* See British Patent No. 236293.

Mr. W. A. Coates: The author has devoted some three-quarters of the paper to the results of a series of experiments carried out on plant of limited power and voltage. A wider practical knowledge would probably have shown him the inaccuracy of some of his conclusions. A great deal of misunderstanding would be avoided in papers of this nature if results checked by tests were clearly distinguished from theories and extrapolations. The author proposes to take as his basis the first cycle of current of a short-circuit, whereas it has already been internationally agreed to calculate the breaking capacity on the current during the first half-cycle of the arc. The first half-cycle of the current does not have any direct effect upon the phenomena of arcing. Although I have carefully studied Table 6 I cannot see how the author's conclusions have been reached. The ratios which he has given in his conclusions regarding the table are not applied to the empirical formula given on page 1102. Most investigators are prepared to concede that for given circuit breakers under given conditions there exists an optimum speed of break; they would not agree to the suggestion that as the voltage rises the speed of break should decrease. During the last year further experiments have proved conclusively that it is beyond the present skill of designers to provide a circuit breaker which will work at a sufficient speed when the voltage is so high that the arc recurs several times. It is only at or about generating voltage that, with a good circuit breaker, there is a reasonable prospect of rupture during the period of one half-cycle. The speed of break of high-voltage circuit breakers is not very important because, at the higher pressures, the design of a circuit breaker is controlled by considerations other than those of gas volume and pressure on the tank. The theory of surging to which reference is made on pages 1096 and 1097 and which is illustrated in Fig. 17 is not a novel one. It was referred to in the paper* by Messrs. Wedmore, Whitney and Bruce which was read before the Institution last year. In the ensuing discussion I made the suggestion that the real merit of the explosion pot lay in the fact that it held the gas bubble in position at the maximum possible pressure. It seems to me not improbable that the slight advantage which has been found with the author's stabilized design really arises from the fact that the magnetic hood holds the gas under some control. On low voltages it is probable that the arc would be extinguished so rapidly that the gas would have no chance of escaping from under the hood. With regard to the author's pessimistic remarks about the modern circuit breaker, purchasers, including the firm of consulting engineers with which he is associated, expect manufacturers to stand behind their scorned "commercial" ratings, and in practice are justified in doing so. A large number of circuit-breaker failures are directly attributable to causes which have no connection with the design; this fact is ignored by the author. My own experience of the last 20 years has frequently proved that failure results from omitting to insert a tank packing or hanger bolt, from failing to clean the oil sufficiently often, or perhaps from choked vent-pipes. The author suggests that circuit breakers are designed for average and not maximum conditions. I can only state in reply that no designer or manufacturer would dare to risk his reputation by gambling in rating figures which could not be borne out in practice. It is totally unreasonable to apply the author's factor of 2·5 to commercial ratings. A few years ago I participated in an elaborate series of tests on a complete range of circuit breakers manufactured by a well-known firm. The plant gave a maximum of slightly more than 600 000 kVA in the arc. Throughout the tests not a single circuit breaker showed distress, in the sense of throwing oil or of emitting an undue amount of gas or smoke, at less than 110 per cent of its rating; and the majority had reached well over 125 per cent before distress occurred. The author's comparison between round and rectangular tanks is unfair to the round tank because, for a given strength, the rectangular tank would have to have walls of from 3 to 7 times the thickness (depending upon the use of 3 separate or 1 single tank) of those used for the round tank. The curve in Fig. 25 and the formula given on page 1102 are empirical; this requires special emphasis in view of the fact that many attempts have been made to evolve formulæ of this kind. As soon as any departure from the particular type of circuit breaker is made, such formulæ are of no use. On checking the values given by the author's equation I find that at high voltages the points lie well away from the straight line. The new design of contact shown in Figs. 35 and 36 is extremely interesting. Although thermal and magnetic effects are said to force the arc between the surfaces of the metal discs, I cannot see that this is possible. The gas will pass between the discs as it expands, but there is nothing to induce the arc to take the same path and it is manifest that there can be no magnetic effect, since the tests were made with a single-break switch. I conclude that the success obtained was due to the fact that the discs act as de-ionizing agents. The fact that adjacent metallic discs de-ionize the arc stream is well known. The master patents covering the application of this effect are held by the firm with which I am associated. Papers relating to it have been read before another Institution during the last two or three years; they indicate that such contacts as these have ruptured powers of the order of 300 000 kVA. I agree with Mr. Clothier that the author shows great confidence when, having tested a small switch capable of breaking 50 000 kVA and 6 000 volts, he submits a design which would presumably have a commercial rating of 50 000 000 kVA.

---

* "An Introduction to Researches on Circuit Breaking," *Journal I.E.E.*, 1929, vol. 67, p. 557.

Mr. H. Trencham: In general the paper appears to be a wholesale condemnation of manufacturers' present breaking ratings and, apparently to avoid hurting the feelings of designers, the author refers to them as "commercial ratings." It is admitted that circuit breakers must be designed for a widely fluctuating duty, and an empirical method of design has been referred to by earlier speakers. Such a method of design, however, need not fall short of giving 100 per cent correct duty. If we assume that satisfactory breaking distance, speed of cross-bar, air cushions, etc., can be settled by test, correct empirical design necessitates that tests be made to cover the whole field of variation and, having defined its limits, to design for the worst possible condition. The breaker so designed takes into account the whole of the author's uncertainty factor. Breakers have been so designed from data obtained by numerous tests carried to very much higher breaking values than those mentioned as used by the author. It is contended, therefore, that the author is unfair when on page 1102 he states that "it would appear that the short-circuit powers which now have to be dealt with cannot be broken with certainty by any existing oil switch." There is probably some ground for belief that, especially in small sizes, commercial optimism has resulted in overrating, particularly where testing facilities have not been available, but for the heaviest class of oil circuit-breakers I believe that these can be, and are, designed to operate up to their maximum rating. In considering breaking devices in general, it must be remembered that they have also a current-carrying function and the modern plain circuit breaker, particularly for fairly heavy current, utilizes practically 100 per cent of the space occupied. Up to about 500 000 kVA, therefore, the standard type of breaker appears to be the best economical proposition for meeting requirements, notwithstanding the interesting breaking devices which have been investigated from time to time, because their introduction involves occupying more space and incurring greater cost. In reference to the author's quenched-arc switch, this is, as indicated by him, an application of an idea which is not new, though he claims to have made the first logical application of sound design principles to the idea in question. The breaker is, in fact, the third form of breaking device for which it is claimed that the fundamental conditions governing arc formation and extinction are attacked—the others being the Deion and gas-blast breakers. Contrasting this new application with the other two, I cannot see ground for expecting from it as good performance as from the others. It is clear that, to limit the emanations from the hot cathode which may be held to act as a feeding-point for the arc, some quick and positive smothering effect is required. The intensity of the effort to do this effectively must be of an order similar to the tenacity of the arc to its root. I do not know of any information which can be recorded as a reliable quantitative indication of this particular effort, but I fear it may be decidedly underestimated. The point of origin of the arc is probably small in area, whether the amount of current being interrupted is large or small and whether the contacts themselves are also large or small, and the tenacity above referred to may be expected to appear as some function of the melting temperature of the metal, and of the current—possibly as the square of the current or even as the square of the current density. It is in this respect that, in my opinion, scale models of circuit breakers have failed in the past and must continue to fail in the future. However that may be, it is clear that in the Deion breaker two strong magnetic fields are necessary—one to direct the arc into the cooling spaces and one to keep it moving quickly enough along a long path therein. In the gas-blast breaker a considerable expenditure of energy is directed towards the same end, by the liberation of compressed gas, and whereas when breaking small currents (of the order of 50 000 kVA) the contacts of the gas-blast breaker, though small, show only a slight etching due to the arc, when larger powers are involved (approximately 500 000 kVA), certain tests have shown the removal of 1 in. to $1\frac{1}{2}$ in. of material from the end of a heavy copper rod in a single shot. If I understand the illustration in the paper correctly, each of the cooling paths appears to be an annular space of short radial length leading to a *cul de sac.* Pressure behind the arc may have a tendency to drive it into the spaces provided, but this tendency will be strictly limited and magnetic forces are not likely to assist, because, as stated on page 1103, they tend to keep the arc in the centre of the pot. In any event, the cooling arrangements appear to be entirely inadequate for heavy short-circuits, in view of experience on other designs. Within the range of tests covered by the author there is almost nothing to be distinguished between the results obtained by him and the records of operation of a "properly" designed explosion pot on which much higher tests have been carried out. The word "properly" is advisedly used as many investigators have contented themselves by the use of any kind of an enclosure on the contacts and called it an explosion pot, whereas its correct design is the result of specialized study. I should expect the author's breaker to fail at short-circuit values much below those at which he rates his heavy design, owing to the inner walls of his cooling rings developing incandescent surfaces linked by a cascading arc. I can only admire the courage that enables him to extrapolate through a range of 10 to 1 in breaking capacity as between guarantee and tests carried out; I fear that his results might be found subject to errors even as great as those of which he accuses present-day manufacturers. Referring to the Appendix, it does not appear that much is to be gained by an endeavour to predetermine the power factor of faults. It seems to savour of a challenge to fate, and a better course is to look the situation straight in the face and undertake to cater, in the circuit breaker, for the worst conditions liable to arise.

Dr. W. B. Whitney: While I find it difficult to agree as to the validity of some of the author's conclusions on the evidence he has so far published, the paper serves the useful purpose of throwing into bold relief a number of questions of first-rate importance. These are bound to challenge discussion, careful examination and further experiment in the future, thus being of service in clarifying a subject which the author agrees to be exceedingly complex. The question of measurement of distress is one of great interest and is an important feature in the paper. There is, as is pointed out, a big variation in the internal behaviour of an oil circuit-breaker, but a question of major importance would seem to be the determination of the effect of this variation upon the final break-down condition of the apparatus. The device adopted by the author for indicating distress is simple and robust, but what physical quantity does it actually measure? It would seem, as explained below, that the mere distortion of a disc or small specially weakened area of a strong tank may have little or no relationship to the general pressure set up as measured, for example, in the cushion, excess of this latter type of pressure being, in my experience, a frequent cause of tank failures when these occur in experimental work. The author appears to base his conclusions as to the relative merits of various designs on the distress as measured by the above-mentioned renewable discs. In Section (5) he also uses this basis in connection with his estimate of volume and pressure-resisting quality of tanks to give 100 per cent breaking capacity. The value of much of the paper, from the point of view of its contribution to knowledge, thus seems to depend upon whether the criterion of distress (namely the distortion of a renewable disc) does actually give a correct measure of the bursting pressure set up within the tank in the process of arc rupture, and a weakness of the paper seems to lie in the fact that it contains no experimental or mathematical demonstration of a correlation between degree of pressure and disc distortion, existence of which seems to have been tacitly assumed by the author. Assuming, for the moment, that the author is able to demonstrate such a correlation, can he demonstrate that the discs are only distorted by rise of static pressure and are unaffected by the high-frequency pressure pulsation which, he agrees, also accompanies arcing, and one type of which is known to exert less and less pressure per unit area as the wave-front spreads out from the source? Unless he can show that the disc does not respond to this latter type of pressure it may be assumed that it will owe some of its distortion to the above-mentioned localized effect, which varies in strength according to whether the energy source happens to be nearer to or farther away from the disc surface, being greater when nearer and smaller when farther away. In the case of single-break tests such variation may take place owing to movement of the arc path away from the direct line of contact separation under the effects of magnetic field or surging oil, and in multiple-break switches owing to the same effect and to the geometric position of the breaks in relation to the measuring disc, and is likely to result in one arc exerting on the disc a force out of all proportion to the others. In addition it would seem, for the same reason, to be very unsafe to make comparison between distortion results with renewable discs in tanks of different sizes of geometrical shapes, and I hope the author will give us much fuller information on this subject in his reply. What precautions were taken, when bolting the discs to the tank, against distortion of the disc by uneven or excessive pressure of one or more nuts? Was the cushion volume kept exactly the same in all tests compared and were the switch tanks tightly sealed, or was there a vent or venting between top plate and tank? If there was such venting, a further uncertainty is introduced by the fact that the surging oil will at times fortuitously block the vent, thus causing higher pressure for the same gas output than at other times. The question of venting raises an interesting question as to the dangers that have to be avoided in extrapolating from the results of tests on small scale models. In most commercial designs, when the oil-level rises during arcing, some of the air in the cushion is forced out through the joint between the tank and top plate, unless special precautions have been taken to ensure accurately faced flanges. It will be seen, however, that, given a fixed ratio between initial cushion volume and tank volume, the ratio (vent area at the flanges)/(cushion volume) and assuming constant gap thickness, will decrease as tank volume increases, thus allowing relatively less and less pressure relief. Thus, unless allowance is made, for example for this factor, conclusions drawn as to the rating of large breakers from the results of tests on small ones are likely to be misleading. It would be useful to know the actual number of deformation records used by the author in arriving at the ratio of 2·5 : 1, between observed maximum and average distress used on page 1102, and to what extent he has established that the above ratio is independent of the number of tests. Section (3) is devoted to an attempt to show that break energy is unreliable as a measure of distortion of the pressure discs (i.e. " distress number "). In this connection I would mention that in a certain series of E.R.A. experiments on closed tanks, in which piezo-electric and other high-frequency pressure-recording instruments have been used, a good correlation has been found between total break energy and maxi-

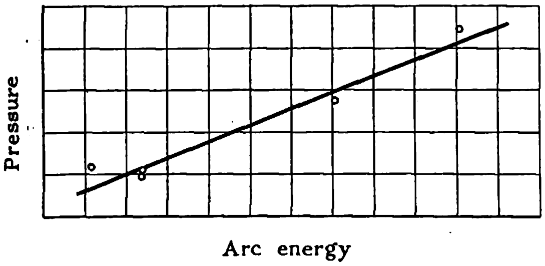

FIG. A.—Variation of pressure with arc energy in a closed circuit-breaker (E.R.A.).

mum cushion pressure tending to burst the tank (see, for example, my Fig. A). It thus seems fair to conclude that, where the author's results fail to show such correlation between break energy and disc distortion, such failure is due to the causes mentioned above or to the unreliability of disc distortion as a measure of pressure, and from the scientific point of view it would appear to be sounder to measure a quantity like break energy, which in general is related to gas volume and can be interpreted in terms of cushion pressure, than to measure one which, like the author's "deformation number," may have no simple physical meaning. Apart altogether from the meaning to be attached to the "distress numbers" in the paper as discussed above, Section (3) (in which much of the oscillograph data in the paper is concentrated) leaves the feeling that there is a rather uncritical handling of material. In Table 3, for example, which, it is stated, "shows that distress does not vary with break energy, as has frequently been assumed," the reverse conclusion would apparently be reached when the figure 5·15 for kW-sec. in the top line of the table is increased as the result of correcting for the error in fixing the zero line too high in the top oscillogram in Fig. 4. Also the results in Table 8, with the exception of one point, show quite a good correlation between break energy and "distress" (see Fig. B). Referring to Table 6, in which comparison is made between different numbers of breaks, are single, double and quadruple breaks being compared at the same speed of cross-bar separation, i.e. at increasing total velocity of contact separation, or is the cross-bar speed halved with each doubling of the number of breaks, thus keeping the total velocity constant, as should be the case if the tests are to be truly comparable? I ask the question as records similar to the quadruple-break test in Fig. 13 can at times be obtained with a *single* plain break in oil by using an appropriate high speed of contact separation at the same voltage and current as in Fig. 13 (see Fig. C). Does the figure of 15·4 kW-sec. for arc energy (Fig. 12 in Table 6) include the arc energy released within the tank in the arc to earth, which would have contributed to the distress recorded on the disc? Also, was the cushion volume in all the tests in Table 6 exactly the same? On page 1104 oscillograms 29(*a*) and 29(*b*) are given in comparing quadruple breaks with and without arc stabilizers. These records show approximately 30 and 50 kW-sec. of arc energy and 3 and 9 units of distress respectively. Can the author tell us what feature in design caused this 4-break switch (both with stabilized and unstabilized arcs) to give so much more break energy and distress than the quadruple-break switches shown in Table 6, seeing that the applied voltage and also the average current during arcing were practically the same? In regard to the quenched-arc switch, what steps were taken to control the velocity of contact separation? The oscillograms in Figs. D and C * show almost identical records obtained with the same circuit conditions by means of a single plain break in free oil at a sufficiently high speed of break, and it seems possible that pressure set up in the confined space in which the moving contact operates in the quenched-arc switch might have the effect of blowing the contact outwards at a speed of the

order of that used in Figs. D and C. Are the kVA in Table 10, single-phase kVA in all cases except the last, and to which results does the note at the foot of the third column apply? I wish that more space in the paper could have been devoted to data from "repeat tests" under identical conditions of speed, number of breaks and cushion volume, such as are given in Fig. 18. In the section dealing with phase angle and distress, the author shows some interesting curves in Fig. 22 which indicate that, on the generator and with the circuit breaker he was using, distress reached a maximum at about 55° phase angle instead of at 90°, as might have been expected from theoretical considerations, with a given wave of voltage. Our own results * seem to indicate a similar effect (see point 10, Fig. 11*a*). From investigations which the E.R.A. have carried out at different phase angles, on the voltage wave-form of the machine used by us, I am inclined to think that under certain conditions a rather higher voltage may be available in the neighbourhood of zero current with this machine on single-phase tests when the phase angle is between 50° and 60° than at larger or smaller phase angles. It is curious, however, that the effect, if any, of such higher voltage in lengthening the arc does not seem to be so apparent in Fig. 11 of our paper, though the tests were carried out on the same machine as those in Fig. 11(*a*). While the author has drawn attention to a phenomenon which may have important practical bearings, a fuller investigation into the available voltage at zero current and different phase angles (both on single-phase and 3-phase operation) seems to be called for on machines of other design than that used by him. Until this has been done, it seems unsafe to conclude that the peculiarity to which he has drawn attention, and regarding which no explanatory theory is advanced, is common to all power circuits and affects the use of reactors in the interesting manner he suggests.

Prof. J. T. MacGregor-Morris (*communicated*): On page 1104 the author refers to the stabilized-arc device, and he gives in Fig. 27 its application to an oil switch, and in Fig. 28 to a fusible cut-out. In common with a number of others, I should be glad if the author would give a scientific explanation of the action which he describes as "the cut-out being surrounded by a magnetic field which assists the tendency of the arc to keep in a straight line in the shortest path between the electrodes." In Figs. 27 and 28 he shows the cylinder as a magnetic cylinder, and therefore I presume that there is some magnetic action assisting. Has he tried replacing the magnetic cylinder with a cylinder of the same resistance but of unity magnetic permeability?

Mr. P. D. Morgan (*communicated*): The aspect of the paper with which I wish to deal is the author's method of estimating the distress of a switch. He estimates this distress from the amount of deformation of a lead disc inserted in the tank wall, i.e. he attempts to link up the deformation of the disc with the stresses in the tank material. It is evident that, so long as the tank itself is not strained beyond its elastic limit, the stress in its material is related to the internal pressure, so that the author's method of estimating distress really involves the correlation of the internal pressure in the tank with the deformation of the inserted disc. It is well known that, for a disc supported at the edges and loaded with a uniform intensity of pressure, the deflection at the centre is directly proportional to the intensity of pressure, *provided the maximum stress in the material does not exceed the elastic limit.* If, however, this limit is exceeded—and the author has indicated in his remarks that this was the case (as the deformation was a "permanent set" which could be measured after the tests)—the above-mentioned proportionality ceases, and the deflection becomes a function not only of the pressure but also of the time of application of the load. Bauschinger * has shown that this is especially the case for lead and tin. Therefore to correlate the stress in the tank (which is the assumed criterion of distress) with the deformation of the disc by the author's method, one of two alternative methods must be followed, viz.: (*a*) The duration of the pressure impulse due to arcing must be measured and the effect of the time of application of the load on the deformation produced also determined, or (*b*) the disc must be calibrated with impulses of the same duration as will be caused by arcing. The author, however, does not mention having adopted either of these methods. The first alternative, that of measuring the duration of the pressure impulse, is practically as difficult as measuring both the duration and the magnitude and this has been done successfully, as I will show later. The second alternative is practically impossible either with hydraulic pressure or by detonation of explosives in the tank, as neither of these gives a pressure impulse similar to that set up by arcing in the tank, which is a succession of impulses, the number, magnitude and duration of which depend on the arcing period and various other factors. These considerations lead to the conclusion that, to estimate the distress of the switch from the standpoint of the stresses in the tank wall, a pressure recorder must be employed which fulfils two conditions, viz.: (*a*) It will faithfully respond to impulses of relatively high frequency (above about 50 per second), and (*b*) the deformation produced must be within the elastic range of the recording material. Both these conditions are fulfilled by piezo-electric pressure recorders in which the pressure incident on a quartz crystal produces a potential difference across its faces. The Bureau of Standards have shown that the pressure and p.d. are directly proportional up to many tons per square inch. By means of a suitable amplifier the p.d. generated can be made to operate an oscillograph, and the E.R.A. have a number of records taken in this way, in which the instantaneous pressure due to arcing, the current through the arc and the p.d. across it are recorded on the same film by three separate oscillographs. To attempt to estimate a stress which is within the elastic limit of the tank material from a measurement of the inelastic distortion of a lead disc, seems to me unsound in principle.

[The author's reply to this discussion will be found on page 1126.]

EAST MIDLAND CENTRE, AT LOUGHBOROUGH, 21ST JANUARY, 1930.

Mr. L. M. Jockel: I am interested to find that the author has cast some doubt upon the use of reactors. I have myself had considerable doubt as to the efficacy of reactors, and the conditions are such that the reactor may or may not have a beneficial effect upon the rupture of a short-circuit. I had an experience some years ago of a dead short-circuit on a 6 600-volt network. The short-circuit occurred approximately 1 mile away from one of the main power stations. The switch on this particular feeder had been installed 15 years prior to the time of the accident and it was of excellent design, whilst reactors were used on the busbars. It was an oil-immersed switch and had phase-separation tanks. The calculated short-circuit current was 14 000 amperes and 163 000 kVA had to be broken by the switch. I assumed in these calculations that the reactance of the cable was comparatively small compared with its resistance. Happily, the switch broke the circuit, but we afterwards noticed that every window had disappeared from our switch house, all of them having been blown into the street. This is all that happened, and although there was no oil left in the switch the latter had broken circuit and saved the situation. I think this shows that switches designed in those early days were intended to deal with a total capacity of less than, say, one-third of the final plant capacity. If the quenched-arc switch described at the end of the paper proves to be a success—and these experiments suggest that it will—I think we shall be approaching a time when a first-class switch of comparatively small size will be available. This fact should be of great importance, as modern switch rooms are large and expensive and add greatly to the capital cost of a station.

Mr. J. F. Driver: The paper deals with *oil* switches, but I am interested to know whether, after all, oil is the most suitable material for the purpose. I am old enough to remember the performance of switchgear in the days when the switch was broken under water. The most serious trouble was that overheating boiled away the water. Will the author tell us how much has been done in the way of trying other liquids? The next question which is rightly stressed in the paper is that of the size of contacts. It seems to me that there is a tendency to use contacts which are far too small and have little heat capacity. I am interested in the remarks regarding speed of break, and feel that pressure-rises occur in many cases through the breaker operating too fast. When a rotary convertor flashes over, a high-speed breaker does not necessarily make such a big difference as we like to ascribe to it. With regard to the type of switch described by the author is there not a tendency for the switch to be forced open due to the fact that an electric circuit always tends to enlarge itself? In view of this additional force it would seem to be rather difficult to measure the speed of break. It would be interesting to know whether, under short-circuit conditions, the breaker really opens at the calculated speed. With regard to the question of measuring distress, the system adopted is simple and ingenious. It measures the "summation" of the distress, but it does not show how the distress takes place. Indicators are now being developed, particularly for use when testing Diesel engines, designed to reveal the various changes in pressure inside the cylinder and also to record time, giving such information as the exact times of valve opening, fuel admission, etc. I suggest that such apparatus could be adapted for use on an oil switch, so that we could ascertain how the oil pressure changes, and also the relation of the pressure variations to the position of the contacts. If used in conjunction with an oscillograph, some interesting information should be made available.

Mr. A. D. Phillips: Mr. Driver suggests that we try to clear troubles too quickly. My experience is that if troubles are not cleared quickly they are apt to give rise to something more serious. I think he also questions the possibility of accurately timing switch-operations. It is quite possible, with ordinary commercial instruments, to take time records accurate to 0·01 sec. I gather that the author claims that the most important thing is to control the arc, and that variation of the arc accounts for variable operation of a switch under conditions which otherwise appear to be similar. The experiments referred to in the paper are apparently designed to prove that variable operation is due to a different formation of the arc. The difference in switch design as suggested is of interest, but it would also be interesting to have some idea of relative costs.

Mr. S. H. Fowles: I should like to ask the author whether the factors given on page 1102 of the paper could be applied to typical switches to find out what such switches are capable of dealing with. I take it that they were calculated on the basis of typical switches. Referring to the quenched-arc switch, I think this is a device which will get us out of our difficulties.

[The author's reply to this discussion will be found on page 1126.]

NORTH-EASTERN CENTRE, AT NEWCASTLE, 27TH JANUARY, 1930.

Mr. B. H. Leeson: Towards the end of 1922, Mr. Clothier suggested that short-circuit tests should be carried out upon specially selected oil-immersed circuit breakers of various constructions in order to determine their relative behaviour. At that time few facilities existed for carrying out short-circuit tests commensurate with the kVA ratings of large modern circuit breakers, and the wisdom of the suggestion for testing at reduced scale has been justified by the interesting points which have arisen, and the developments which have taken place as the result of the investigations carried out by the author. In certain instances, however, I think that the results obtained may be capable of interpretations different from those recorded in the paper, and in view of this I think that some of the explanations and conclusions require further consideration. The author uses the term "nominal short-circuit power" to describe the product of short-circuit current and open-circuit voltage, and I suggest that the term is misleading unless power factor is also included in it. Why is the term "distress" used in the paper to describe the capability of a circuit breaker to withstand stress? A circuit breaker which has performed satisfactorily is no more distressed than is a boiler at its working pressure, and for this reason it is customary, and, I think, justifiable, to rate both of these in terms of the stress, in pounds per square inch, for example, which they will withstand with safety. The author finds that his "nominal short-circuit power" expressed in kVA, the break energy expressed in kW-seconds and the so-called distress in the tank apparently have chance relationships, but I think that this may be explained by considering Fig. E, which shows, in a general way, the manner in which a circuit breaker can dissipate the energy imparted to it by the circuit to which it is connected. It will be seen that the break energy can be dissipated in a large number of ways, and I suggest that it may be illogical to expect it to have a definite relationship to any one mode of dissipation, such as the stress upon the tank wall measured at one location, which only represents a percentage of the total energy dissipated. In connection with this question of energy balance, I should like to know whether the energy dissipated in the form of low-grade heat was considered. If so, was the temperature of the circuit breaker constant at the commencement of each test, was its temperature-rise measured after the test, and was the condition of the contacts, etc., identical in all the tests compared for the purpose of drawing the conclusions given in the paper? The author calculates the short-circuit kVA broken by a circuit breaker from the maximum or initial value of the short-circuit transient, whereas the break energy measured will have been caused by a smaller value of current, due to the decrement of the latter during the time when the circuit breaker was preparing to open its contacts. Why has he ignored the standard and, I think, better method of taking the R.M.S. current value at the instant when the contacts of the circuit breaker separate, that is, the value of the current in the arc at its inception? Thus, unless the decrement of the current transient, the inherent opening time of each circuit breaker and the condition of the arcing contacts, etc., are identical in every test, it seems illogical to expect any useful proportionality to exist between the short-circuit kVA broken, and the break energy in kW-seconds in the arc. I suggest that the author's conclusions on existing switching conditions might profit by consideration in the light of the foregoing comments, and I do not agree with the views expressed in the paper upon speeds of break, which ignore the need for a short arc duration; the upward trend of the curve in Fig. 18, which makes the kVA infinite for an appropriate distress; and the shape of the curve in Fig. 22, which is contrary to my experience, because I have not found that making the power factor worse reduces the stress in a circuit breaker. I think that the author attaches too much importance to the variability of the particular factors which he has selected for comparison, and to the distress factor, whilst more attention should have been given to making circuit and other equally im-

Fig. E.—Diagram illustrating principle of energy balance for a circuit breaker. The three principal items compared by the author are shown enclosed.

portant factors which enter into the design, construction and application of circuit breakers. Thus, referring to the sixth test in Table 6, and assuming the tank to be satisfactory, the vital point is that a flash-over occurred to earth, and this is more important than that the distress was 10. Any mechanical device is subject to varying stresses when in action, and the criterion of its satisfactory behaviour in service is that its components have been designed and manufactured to withstand with a factor of safety the maximum stress to which they are likely to be subjected. Circuit breakers designed and constructed in this way are giving satisfactory performance in service, and I do not agree with the author in his generalized statement that the largest circuit breaker manufactured to-day should only be rated at 800 000 kVA. Applying his de-rating factor of 2·5 to a circuit breaker of smaller size, a breaking-capacity rating of 150 000 kVA would become a rating of only 60 000 kVA, yet such circuit breakers have performed satisfactorily when tested to well in excess of 150 000 kVA. They have for years proved equally satisfactory in practical operation in locations where the short-circuit kVA has at least been equal to their rating. Such practical experience, combined with tests conducted on companies' systems and special machines at least up to the author's maximum rating figure, have resulted in the curve of Fig. 25, which represents, broadly speaking, manufacturers' practice in respect to the dimensions of modern lower-voltage circuit breakers and their kVA ratings. Is all this collective experience, gained over many years, to be ignored entirely? Are breaking-capacity ratings to be arbitrarily reduced in the ratio of 2·5 : 1 in order to gain, according to the author, the comparatively small benefit of 3·5 per cent better efficiency? I suggest that the benefit to be gained by such a step is out of all proportion to the cost which it entails, and, apart from the question of improved technical performance, such de-rating is impracticable from the economic point of view. I agree with the author that all circuit breakers should be tested for breaking capacity and, incidentally, for making capacity as well. Mr. Clothier has indicated how this is being put into practice in this country. Unlike the author, I do not think that such tests will result in the need for de-rating, but instead I believe that they will result in improved details of construction and improved factors of safety over the present standard ratings, which will be retained. This latter, and preferable, policy is the one underlying the usefulness of the author's quenched-arc device. I hesitate, however, before being satisfied that it will effect so great an improvement as is indicated by the dimensions and ratings given in Fig. 35, namely, that a circuit breaker whose rating (I take it) complies with the 150 000-kVA standard (or 60 000 kVA as de-rated by the author) can be re-rated at 1 million kVA. The British Standard Specification for Oil-Immersed Circuit Breakers requires that the standard kVA rating assigned shall be based upon an operating duty which consists of making and breaking short-circuits successively, and I should like to know whether the 1 million kVA rating of the circuit breaker shown in Fig. 35 is assigned on this basis. Why is a circuit breaker of the dimensions shown in Fig. 36, which (I take it) complies with a 1 million kVA standard rating, credited only with a 2 : 1 improvement instead of the 6·6 : 1 improvement applying to Fig. 35? I suggest that the arc in the quenched-arc circuit breaker is not stabilized in the sense that the paper implies, i.e. that it is centralized, because the magnetic field causes, and is required to cause, the arc and its root to travel rapidly and laterally between the metal electrodes surrounded by gas at high pressure. These are the essential characteristics governing the satisfactory behaviour of the device. I have been privileged to witness some tests upon the quenched-arc circuit breaker and to inspect the resultant records, and, subject to the qualifications in the foregoing, I am of the opinion that the author's device shows great promise as a means of improving breaking capacity. I think that it functions upon the right lines, because it keeps the length of the arc down to a minimum and assists in dissipating the liberated energy in the form of low-grade heat rather than in stresses. For these reasons I consider that there is a future for its practical application.

Mr. R. W. Gregory: The limits which in practice have settled the breaking capabilities of commercial oil circuit-breakers have in the main been mechanical. The author has investigated, using direct and simple methods, the effects of variation in switching conditions and design by measurement of mechanical distress—the latter being gauged by the deformation of a renewable part of the switch tank. Many of his results confirm practical experience in the behaviour of circuit breakers. As an example from my own experience, a certain design of single-break switch has shown itself to be distressed more often and more seriously than a 4-break switch. Both the single-break and the 4-break switches were in tank structures of similar design and had rupturing duties of the same order. The author's results also confirm my experience that it is much more difficult to break a fault with reactance in the circuit, than to break the same kVA without reactance in the circuit. The breaking-capacity formula on page 1102 apparently represents the law according to which reputable British manufacturers design their switch tanks. The basis of the formula is $\sqrt[3]{(PV)}$, which appears to have given a satisfactory mechanical test for circuit breakers of the standard plunger type. The author's ratio of 2·5 : 1, for comparing the commercial breaking-capacity rating with the actual 100 per cent service rating, appears to be misunderstood by manufacturers. This ratio does not appear to me to imply that the service given by commercially rated circuit breakers is unsatisfactory on circuits where the breaking duty may reach the commercial rated breaking capacity, but it means that commercial circuit breakers cannot be expected always to break their rated fault kVA under service conditions. I take it that manufacturers do not claim this of their circuit breakers—at any rate they have never yet been able to prove that the rating of the circuit breakers which they sell for the highest rupturing duties meets the requirements of the B.E.S.A. definition of breaking capacity. There is a general feeling that the present design of oil circuit-breaker is by no means the final one, and the effect of research both in

Europe and in America is showing itself by the production of designs the main objects of which are to reduce, or even to eliminate, explosive switching. The air-blast circuit breaker of the B.E.S.A. and the A.E.G., and the American Deion switches are examples which show the trend of modern circuit-breaker design. The quenched-arc switch described in the paper is another attempt at the production of non-explosive switching. I was privileged to see the author's experimental circuit breaker under test at Carville, and its behaviour was most impressive. Power to the value of 50 000 kVA was broken time after time in a small container not much larger than a domestic coffee tin, without the least sign of distress; there was no oil-throwing and no smoke. These tests show that there is reason to expect a 2 million kVA circuit breaker within the dimensions given in Fig. 36.

Mr. H. W. Clothier : It has occurred to me that it would be of interest to recall the beginnings of the use of oil in connection with circuit-breaking devices, and I should like, therefore, to show lantern slides of the original Deptford air-break switches, the addition of an auxiliary oil-break by Mr. Partridge, and the first power-station switch designed specifically for oil-break, due to the late Dr. Ferranti and installed at Bankside power station. I would also draw attention to some actual examples which I have here of the last-mentioned switch, together with the oil-break fuse which was at that time the circuit breaker. Prior to the use of oil, a sort of air-blast was obtained by means of a spade-like portable insulator, which was manipulated by hand to chop through an over-persistent arc across the switch contacts.

Prof. W. M. Thornton : The measurement of distress when a structure is subjected to suddenly applied forces has long engaged the attention of engineers. It came to a head, perhaps, in the consideration of questions of damage to ships by explosion of mines in water. The point at issue was whether the damage was proportional to the pressure developed by the explosion, or whether it also involved time. The view which met with most acceptance at the time was that the destructive effect varied as $\int P dt$, the actual distress depending upon the strains produced, such as those indicated by a crusher gauge, to which the author's lead-plate deformation is closely analogous. There can be little doubt that an arc changes type during the period of break. The cinematograph records show this clearly, and they are similar to the photographs obtained by Mr. Harle in my laboratory some years ago, when investigating the properties of short transient arcs in reference to the ignition of gases. At a critical arc-length and current the volume of the arc increases suddenly, most likely as a result of the conductivity of the metal vapour coming into action. The suppression of this latter effect is the explanation of the success of the high-speed break. To extinguish the arc before the metal vapour takes charge would seem to be the right thing to do. This is borne out by the remarkable success of the author's divided-plate breaker, and in any case large contacts have a striking influence upon the properties of arcs. When sparks are made between thin or light contacts in highly explosive gaseous mixtures, and the current is adjusted so that there is ignition every time, the mere changing from light to heavy contacts (everything else remaining the same) entirely prevents ignition. A real change in the properties of an arc is therefore brought about by using heavy contacts. The question of an arc re-striking concerns both the voltage and the conductivity of the gas in the bubble. If the metal-vapour stage can be suppressed it becomes a question of electric strength alone, and the problem can be investigated by static experiments. The introduction of metal vapour complicates matters, however, for the ionization of a mixture of metal vapour and the vapours from "cracked" oil is different and less well known. Fig. 25 is interesting and valuable. If we may assume that the test pressure P has been chosen by experience to be proportional to the actual pressures which the tank has to carry when breaking a circuit of the given kVA, and that the volumes of the tanks are those necessary for safety, the reason for the relation would seem to be as follows. Consider a spherical enclosure of radius r containing a liquid, at the centre of which a pressure P_0 is suddenly set up. The pressure at any point in the fluid varies as the inverse cube of the distance from the centre. Thus the pressure at the boundary is kP_0/r^3, where k is a constant. The volume V of the enclosure is $\frac{4}{3}\pi r^3$, and for these conditions $\sqrt[3]{(PV)} = (\sqrt[3]{\frac{4}{3}\pi r^3})(kP_0/r^3) = c\sqrt[3]{P_0}$, depending only upon the pressure at the centre. If in Fig. 25 we replace $\sqrt[3]{(PV)}$ by $\sqrt[3]{P_0}$ we find that the values of distress kVA are proportional to this quantity. The pressure P_0 is proportional to the volume of gas generated by the arc and to its time of formation. Assuming the latter to be much the same for all oil-break switches, P_0 is proportional to V_0, the volume of gas generated, and $\sqrt[3]{V_0}$ is the radius of the bubble. It would therefore seem that the radius of the gas cavity around the arc should be proportional to the kVA broken, in the case of a single-break switch in a spherical tank. That $\sqrt[3]{(PV)}$ is so closely proportional to the kVA in the figure is an indication that manufacturers have found by experience that such a relation holds for the more complex oil-break switches. The forces set up in the oil by the expansion of the walls of the gas cavity, through the pressure of the gas generated to its maximum radius before the burst into the air space, are the cause of the tank distress which determines the breaking capacity of the switch. That this distress limit is proportional to the radius of the equivalent single gas cavity formed is the simple rule behind Fig. 25, though for practical purposes the curve gives the desired information.

Mr. T. Carter : I will refer first to what the author terms the "stabilized" arc. A switch fitted with this device is shown in Fig. 27 and a fuse in Fig. 28. So far as I can gather from both theory and practice, an arc in a container such as that illustrated in Fig. 28 will stay accurately in the centre if it is there initially; but in the more likely event of its being even slightly displaced from the centre it will tend to approach the side of the container because of the unsymmetrical magnetic pull set up by its eccentricity. This being so, there must be some cause, other than automatic centralizing by the magnetic field, for the difference between the two oscillograms shown in Fig. 29. I suggest that in the switch of Fig. 27 [Fig. 29 (*a*) was presumably obtained from a device similar to this] the container on each pole acts as a shield for the other pole from the effect of the presence of a loop in the circuit (see Fig. 15). No oscillograms like those of Fig. 29 are given for the fuse shown in Fig. 28; but again, if the general effect of the magnetic field is as I have suggested, and if the author intends it to be understood that results like those of Fig. 29 (*a*) and Fig. 29 (*b*) are actually obtained from the fuse, with and without the container respectively, must it not be the case that the arc is stabilized because the container shields it from draughts or other mechanical disturbances, and not because of the magnetic field? There is no loop in the circuit of Fig. 28, and even without the container one would think that the arc would tend to be more stable than in the switch of Fig. 27, where a definite loop exists. Has the author investigated the possible differences in behaviour to which I have referred between the switch and the fuse? Secondly, I will turn to the quenched-arc circuit breaker. On page 1105 the author refers to a forcing of the arc by magnetic and thermal action into the radial extinguishing openings, and apparently the greater the amount of power the greater is the force. The magnetic action referred to is not explained, and it would be very useful to have some further particulars. Superficially, indeed, there seems to be almost a contradiction; for at the end of the same paragraph it is stated that arc stability is produced partly by the concentric iron container. Judged by the author's statements in regard to stabilized arcs, this must mean that, in his opinion, the iron container tends to centralize the arc. But it is not desired that the arc should remain central: arc instability would rather appear to be what is desired. This whole matter is so important that I hope the author will amplify the statement in his reply, with a view to indicating how it is that one magnetic action forces the arc outwards, while another, set up by the iron container, stabilizes it. Is the word "stabilize" perhaps used in two different senses? Lastly, I will say that I have read section (5) of the paper a good many times, but I cannot altogether follow the reasoning that leads to the author's adoption of the "safety" figures which he proposes. In any case, I have not much confidence in such wide deductions when they are drawn, for example, from data representing so comparatively small a number of faults as 170 in all, and when a much smaller number like 11 is the final guide to the difference between certainty and uncertainty. Further, the origin of the divisor 2·5 is not at all clear. This question also is so serious that it deserves more ample treatment, and I hope that the author will give fuller details in his reply.

Mr. J. A. Harle: The variability of the phenomena of arcing in oil has been emphasized by the recent papers read by members of the Electrical Research Association, and I therefore welcome the author's efforts to overcome this variability by suitable circuit-breaker designs. I agree with the statement regarding contact sizes on page 1091, but I would point out that there is a limit in size beyond which improvements by such means cannot be found, as for each arc current a certain crater size will occur and the contact dimensions can only be increased to some function of this if the material is to be used efficiently. The author's method of measuring pressure stress by the use of diaphragms appears to be an ingenious and practical scheme, but such devices indicate a pressure which includes the static pressure as well as some component of the dynamic pressure waves set up in the oil, and consequently the readings obtained by such a diaphragm are only reliable as to the stress if a number of results are taken and averaged. How many such discs were used in the tank during each test, and where were they fitted to the tank walls? Unless a number were used in each test the stress indication would only apply to one point and it would not be a reliable indication of the total stress on the tank, especially in view of the effect of the pressure waves upon the results. The accuracy of the devices as reliable stress recorders is questionable, and I would point out that they do not indicate the distress of the switch in any way, as the author suggests. With regard to the conclusions as to break energy, the variability appears to confirm the Research Association's published work and, wherever possible, designers must allow for the worst conditions. I agree that the arc energy of any individual test is no guide to the stress, but I think that from a group of tests an average value and a maximum value could be obtained. I consider that a similar group of tests is desirable if the stress results obtained by the author's method are to be compared with any other results, and unless this is done misleading conclusions may be drawn. The oscillogram of Fig. 4 is interesting in that the voltage wave appears to have a displaced zero line, which would have the effect of decreasing the arc energy. If this were not so, the first half-cycle of the current wave would apparently be accompanied by negative arc energy: this would be rather a phenomenon in view of the fact that no arc energy would have so far been delivered to the arc. I should like to ask whether the arc-energy value given in Table 3 was based on this line, or whether it was calculated upon some other basis. I am interested in the author's conclusions regarding the number of breaks, and I should like to know whether the distress value indicated was obtained from a single diaphragm. Where was this located relative to the arcs, in each case? I do not entirely agree with the statement on page 1096 that the final size of the bubble depends upon the ratio of air cushion to oil volume. I consider that it is purely a function of the air cushion and of the arc energy, and that in the end, after the arc energy has reached a certain value, it becomes practically a function of the air cushion alone, unless oil is vented from the tank. No absolute empirical rule exists as to the best value of air cushion, as this is a function of arc energy, ultimate tank strength, clearances, etc. Each design has its own best value of air cushion, and this enables a balanced performance to be obtained. I agree with the author regarding the necessity for an adequate head of oil, so as to prevent the gas bubble from breaking through in an incandescent state. Are the conclusions regarding symmetry (page 1095) based upon the data in Table 8? If so, it would appear that the author is comparing an unsymmetrical current of about 750 amperes with a symmetrical current of about 1 200 amperes, whereas on the same circuit a symmetrical fault-current value would be associated with a higher unsymmetrical current value. Also, if he averages the break energy for the symmetrical conditions and compares it with the average for the unsymmetrical condition, ignoring the freak case therein, he is comparing an average of 3·42 kW-sec. with 5·23 kW-sec., and a deformation of 2·03 with one of 2·4. If he allows for an unsymmetrical current of approximately 1·5 times the symmetrical value and corrects the unsymmetrical values for this, there appears to be an increase in arc energy to 12·6, and in deformation to 5·4, based on an increase of arc energy and stress proportional to the kVA involved. This would indicate that a switch opening a symmetrical short-circuit would produce less arc energy and stress than one opening an unsymmetrical short-circuit on the same circuit. I should welcome the author's views on this, as the figures do not appear to support his conclusions. The switch shown in Fig. 35 is interesting and sound, but I consider that the author's conclusions in this connection are optimistic. I think that the device will be very critical in action, being perfectly satisfactory up to a certain kVA value even for a number of operations, but on breaking any faults above this value the switch will be destroyed due to complete breakdown. I consider it unsafe, therefore, to assume that, because a switch of this type has opened 230 000 kVA successfully and quietly, its ultimate rating is 1 million kVA. The policy adopted by the author is sound in that he sets out to improve the circuit breaker and not to de-rate it. With regard to Fig. 37, I should like to know the author's opinion as to the effect of suddenly switching on a power load across the machines, as he suggests. This would appear to mean suddenly switching over three times full load on to the machines, judging from the value of resistance suggested on page 1110. In the case of Fig. 40, his proposal would not, I think, reduce the peak value of the initial current rush to any extent, as this is mainly governed by the stator reactance, but it might reduce the decrement to some extent. I fear that this reduction, however, would only be of the second order on a modern solid-rotor machine. Preliminary experiments carried out by switching an inductance into the rotor circuit on a small machine appear to confirm this.

Mr. R. H. Brierly: It is of considerable interest to note the conclusions drawn by the author from his comparative tests on circuit breakers fitted with single, two or four breaks. Generally speaking, it may be stated that the behaviour of a 4-break switch is twice as good as that of one fitted with a single break; this improvement compares favourably with the results obtained by other investigators, in particular Messrs. Brown, Boveri and Co., who published results of similar tests in the *Brown Boveri Review* of March 1923. The improved behaviour of the multi-break switch is probably due to the splitting-up of the arc into a number of smaller arcs, each of which is less stable than one large one. The gas bubbles produced by these multi-arcs have a total cooling surface much in excess of that produced by a single arc, and the switch may be so designed that they are distributed throughout the available space in the tank. As a result of this extra large cooling surface and the better disposition of the bubbles, the quenching limit of the oil is not exceeded and excessive carbonization is reduced. It was found in practice that when an old type single-break switch operated on severe faults the oil was so badly carbonized that it was essential to take the switch out of commission, filter the oil and clean all horizontal insulators. On the other hand, multi-break switches operating on the same value of fault kVA have been replaced in service immediately, with the oil hardly discoloured. In addition to this important point in favour of multi-breaks, their construction is particularly suitable for obtaining the long length and high speed of break required for high voltages. The author states that in his opinion a lower speed of break should be used for the higher voltages than for the lower ones, and he gives a value of about 10 ft. per sec. for a voltage range of 3–20kV. I agree that such a figure may be approximately correct for this range, but not that a lower figure should be used for higher voltages. The primary object of a circuit breaker is to disconnect a faulty section from the system as rapidly as possible and, since experience shows that the arc length is much greater on high than on lower voltages, it follows that with the same speed of break a high-voltage switch would take considerably longer than a low-voltage switch to clear the fault. The break energy produced would in all probability be excessive, producing pressures in the tanks that would strain them unnecessarily. In connection with the author's tests, it would have been interesting if the values for the speeds of break used for the single-break and multi-break switches had been given. It would appear essential, when comparing relative performances, that the switches should be identical with regard to speed of break, head of oil, etc., the only difference being that of the number of breaks. The principle of the stabilized-arc switch and stabilized-arc fuse is interesting, but I should like to ask how the stabilization effect is obtained. It would appear that the satisfactory performance of this type of gear is due more to the high pressure developed in the stabilizing pot, than to any centralizing of the arc due to the metal screen. This being so, it is probable that this type will suffer from the same disability as the explosion pot, i.e. although it may behave well on a limited range of fault currents, if this range is exceeded the container may burst; if the upper limit of the range is not reached, a pressure sufficiently high to ensure satisfactory operation is not obtained. Again, although from the results of extensive researches it is now possible to predetermine the behaviour of an open-arc type of circuit breaker with a certain degree of accuracy, it is still quite impossible to obtain any idea of the performance of an explosion-pot breaker without making tests. The author's decision to take the first cycle of the short-circuit current as the value broken by the switches during his tests is somewhat unusual. Unless particulars are given of the reactance and decrement of the test generator, and of the times between the commencement of the short-circuit and the separation of the contacts, it is impossible to obtain the current or kVA value broken by the switch. A delay of at least 4 or 5 cycles is usual between the commencement of the short-circuit and the separation of the contacts, and during this period the value may be expected to fall away rapidly. It would be of considerable interest if the author could show an oscillogram of the 230 000-kVA test mentioned in Table 10.

[The author's reply to this discussion will be found on page 1126.]

WESTERN CENTRE, AT CARDIFF, 10TH MARCH, 1930.

Mr. S. B. Haslam: I think that the paper is extremely important, and the somewhat revolutionary design with which it deals will undoubtedly play a great part in the future development of high-tension switchgear. Hitherto the chief efforts of the designers of switchgear to meet the enormously increased rupturing strains have been concerned with enlarging and strengthening the tank, and it must be agreed that the strength of the tank plays an important part. The main function of the break in oil is to make it difficult for the arc to be re-established after passing through a zero, and this is best effected by keeping the pressure of the gas bubble at maximum. Any yielding of the tank causes a corresponding expansion in the bubble, with a subsequent reduction in pressure. A tank, therefore, which will not yield, and which at the same time will provide only a limited air cushion above the oil, seems to be the best practice, and in all probability the author will confirm this. I am glad that the author refers to the ratings of rupturing capacity. I do not think that he is quite justified in stating that the ratings established by present-day practice must be divided by 2·5 in order to obtain the true rating. No doubt this may have been so in earlier designs, due probably to lack of sufficient experience, but I have no hesitation in stating that in a great many of the best designs a safety factor will actually be found. That much may depend upon whether the designs are based on average experience is a point on which I cannot agree with him. Design should be based on maximum experience, and the responsibility for accepting anything less than this should be put upon the user. With regard to the question of the quenched-arc circuit breaker, according to the paper the arc is " forced by magnetic and thermal action into the radial extinguishing openings," but I cannot quite understand how the magnetic action operates. In the first place, it is stated that the stability of the arc is partly produced by the concentric iron container—a remark which appears to imply that this container tends to centralize the arc. On the other hand, it is specially desired that the arc should not remain central, and I should be glad of further explanation on this point. It appears that one magnetic action tends to force the arc outwards while another one tends to stabilize it in the centre.

Mr. T. C. Christianson: Referring to page 1092—with regard to power broken, break energy and distress—other investigators' test-results have shown that in a given breaker the break energy and the signs of distress vary over wide limits for given powers broken. The general opinion, however, is that break energy and distress vary in proportion to the power broken. Such test-results have also shown that, for a given power broken, the average break energy and distress vary in different designs of breaker. Were these not the facts, there would be no possibility of improved breaker designs. Referring to snap contacts, some explanation of the curves in Fig. 14 would be of interest. The arc voltage is shown to rise slightly and then suddenly shoot up to a peak. Is the initial rise due to badly designed shunts on the snap contacts? The curve in Fig. 14 is apparently not representative of the performance of the best designs of snap-contact breakers. The author's suggestion of a 2·5 : 1 ratio for commercial to true breaking capacity cannot be accepted in regard to present-day designs. His suggestion seems to be based on somewhat confused reasoning and matters of opinion. The summary on page 1089 refers to the fundamental limit of breaking capacity as the short-circuit power which can be broken time after time by a given breaker without breakdown. Commercial breaking capacities are based on B.S.S. No. 116, viz. a 2-shot cycle (i.e. B—2—MB—2, meaning, break the declared kVA—2 minutes' interval—make and break the declared kVA—2 minutes' interval), after which the breaker is to be fit to make and carry normal full-load current without dangerous temperature-rise. It is implied that the breaker will be examined at the first convenient opportunity thereafter, and, if necessary, will be fettled before breaking any further short-circuits. Referring to page 1100, the author starts off from the basis that present designs of breakers are suitable for average stress conditions; this is a matter of opinion and his assumption may be an understatement or an overstatement of the facts. I suggest that for properly maintained British breakers of reputable make it is definitely an understatement. On page 1101 the factors which mainly determine the breaking capacity of the conventional design of breaker are stated to be the volume and strength of oil container and the number of breaks in series per pole. Many further factors, however, are of considerable importance, e.g. the disposition and shape of the arcing contacts, the relative impedances of the main and shunting or arc-contact paths, the thermal capacity of the contacts and conductors, and the strength of the conductors, insulators and mechanism. Thus, while tank volume and strength alone form a convenient measure of breaking capacity, they are by no means the sole determinants. The breaker shown in Fig. 27 is practically the conventional explosion-pot breaker with an enlarged throat-opening. If Fig. 29 is representative of average performance with the Fig. 27 breaker, it is difficult to believe that the oscillogram of Fig. 16 is representative of the conventional explosion-pot type. With reference to the quenched-arc breaker, the author's theory of its action appears to be open to doubt where he says on page 1105 that the arc is " forced by magnetic and thermal action into the radial extinguishing openings." The more probable effect would appear to be that the hot gases are forced into the inter-plate spaces. Referring to Fig. 35, it would appear that the insulation of the metal plates to each other and to the " pot " would have to be of a particularly reliable nature—capable of standing up to high temperatures and possibly carbonized oil and volatilized metal deposits. It would be useful to know the amount of maintenance that breakers of this type would require. It is generally accepted that it is desirable to examine ordinary breakers after opening two or three short-circuits, and it is then frequently necessary to dress the arcing contacts and sometimes to renew the oil. With the quenched-arc breaker considerable risk of failure might exist if the insulation of the metal plates were not carefully maintained. Such maintenance might prove somewhat troublesome and costly as it might involve frequent renewal of the insulation. Insulation maintenance may prove to be the limiting feature in the breaker's ability to function within its rating. I have scaled the drawings in Figs. 35 and 36 and have thereby deduced the volumes of the two tanks, assuming 31-in. and 60-in. 3-phase tank lengths respectively for these two breakers. The volumes so deduced are 6·25 and 40·5 cub. ft. respectively, for what the author suggests would be breakers of 1 million and 2 million kVA (true rating) breaking capacity. I have neglected the fact that the author's dimensions would have to be increased to permit the accommodation of main contacts large enough to carry the normal load currents. Present conventional breakers of 1 million kVA declared breaking capacity would have a tank capacity of 35 to 55 cub. ft., and those of 2 million kVA declared breaking capacity would have a tank capacity between 100 and 150 cub. ft. Taking average figures of 45 and 125 cub. ft. respectively, for the above commercial ratings we get, say, 7 and 3 times the quenched-arc breaker tank-volumes deduced as above. It will thus be seen that if we can even approximate to the author's suggestions a considerable reduction in dimensions will be possible. It is not clear from the paper whether any of the tests carried out by the author on the quenched-arc breaker were made by " closing on the fault " or whether all were conducted merely by " opening on the fault." We have found that these two conditions can lead to greatly different effects and distresses. With the quenched-arc switch one can imagine a greater order of variation under these conditions, e.g. if the metal-plate insulation were low the " closing on the fault " effects might be disastrous. Another point of interest is that " other load " in parallel with the fault circuit can have considerable effect on the duty of the breaker in the fault circuit. Referring to the Appendix, page 1111, is the time of 0·1 sec. a misprint for 1·0 sec. or longer? In a paper * by Mr. J. A. Kuyser interesting figures on the rate of fall of alternator field current under different conditions of opening were given. These indicated that when opening the main field without discharge resistance a period of about 0·1 to 0·2 sec. is necessary for field-current reduction from the no-load value to 50 per cent thereof, and a greater time with discharge resistance.

Mr. G. E. Whitehead: I am convinced that the future will prove the author's effort to be an important forward move. In the switchgear of to-day there is a tendency for manufacturers blindly to copy those designs for which other makers have created a market, irrespective of whether the designs in question still meet the changed conditions. For many years I have not been able to understand why switchgear designers cannot get away from the earliest practice based on utilizing three knife switch-blades (later, V-bars) mounted on a common baseplate and placed in an oil container. This was to me particularly inexplicable during the period when it was found necessary, owing to the rapid increase in size of generating units, to concentrate on the question of rupturing capacity. It has always seemed to me that switchgear makers generally blundered during that period by developing on the earlier lines and concentrating merely upon length, speed of break and mechanical strength of baseplates and tanks. Surely, during the critical period when the various manufacturing firms were concentrating upon this problem, there was ample scope for initiative in other directions. From my own experience of the manufacture of switchgear, it seems as though the commercial side was always predominant and that the users contributed to the lack of real progress by their conservatism and their tendency to consider only the types in vogue. To confirm this point one has only to consider truck-type switchgear, which at one stage fulfilled a very useful purpose. There are now about 16 firms in this country manufacturing truck-type cubicle switchgear, and I think I can safely say that the majority of these set out to cater for a market which had been created by the pioneer firms, and that the maximum effort put forward by the former was merely to copy existing makes of trucks and to concentrate less on improvements than on cheapening. The usual procedure is to secure prices and designs of existing makes, permit their designers to inspect one or two installations supplied by other manufacturers and go ahead. The departure being entirely new to these particular firms and their salesmen, in their enthusiasm they were unable to appreciate the fact that the (to them) progressive venture (along the already well-beaten track) was a fiasco as, owing to the changed conditions, truck-type switchgear was not a good proposition for 100 000 kVA and upwards. I am convinced that in the near future switchgear will be designed on totally different lines. There are, to my mind, three alternative solutions to the switchgear problem and the author's has gone 80 per cent of the way in one direction. I believe that his claims as regards the increased efficiency of his breaker with the resultant far-reaching saving in size will be confirmed in due course. Any new departure of this description is fated to meet with a hostile reception from manufacturers generally, probably because of vested interests in existing plant and designs and the conservatism of the users. One of the real obstacles to progress in the past has been the time-lag or period of delay until some user, not waiting for others to make the first tests, took the initiative. If manufacturers had developed their designs without studying existing types overmuch there would have been no necessity for the monstrosities at present being manufactured, as there are wide fields for development in so many directions. I have not the least doubt that it is possible to design circuit breakers of, say, 350 000-kVA rupturing capacity which would be practically indestructible, accessible and safe to handle and which could be brought down to within 25 per cent of present-day dimensions and costs. There are three obvious solutions and a simple combination of these presents a simple, practicable, commercial proposition without the necessity of introducing compressed air or gas.

---

* " Protective Apparatus for Turbo-Generators," *Journal I.E.E.*, 1922, vol. 60, p. 761.

Mr. W. A. H. Parker: Several important points dealing with the operation of circuit breakers under fault conditions have been raised by previous speakers, and the question of breaking a circuit under these conditions has been gone into fully, but the making of the circuit after fault conditions have arisen seems to me to be of equal importance. In fact, it may be of greater importance, and I think that more time should be spent on so designing breakers that the contacts will close quickly, irrespective of the speed of operation of the reclosing mechanism. One can readily conceive what will happen when the handle is operated slowly with the standard type of reclosing mechanism, and in the paper several illustrations of contacts which show distress after opening the circuit are shown; I have seen contacts similarly marked after a switch has been closed on a faulty circuit. The author shows that the short-circuit impedance of the circuit should be calculated before the speed of break of the switch is determined, but it seems to me that from the practical point of view this would entail constant changes, as the circuit conditions vary from time to time, and unless we can vary the speed of break after the switch is installed we cannot take full advantage of his proposals. The number of tests which the author has made on the new switchgear has necessarily been limited, whereas the standard type of switch has been well tried out under actual working conditions. In America they are spending more and more time on actual field tests over periods of years instead of the usual factory and laboratory tests, and I believe that this is the only satisfactory way to arrive at a true estimate of the performance of this type of gear.

THE AUTHOR'S REPLY TO THE DISCUSSIONS AT LONDON, LOUGHBOROUGH, NEWCASTLE AND CARDIFF.

Mr. L. C. Grant (*in reply*): The disc method of distress indication has been severely criticized, but not always with justification or with complete understanding of it. Other devices such as the piezo crystal, the crusher gauge, the quartz crystal and even the microphone were considered. These all have their limitations. For example, the piezo crystal is hygroscopic and its calibration is thereby affected. The crusher method masks results because of inertia effects. Quartz crystals are susceptible to electrical and other influences and have highly resonant characteristics. The microphone, although used in America, has undoubtedly very serious and well-known limitations. Moreover, the actual measurement of pressure (even if a completely accurate method could be devised) goes only part of the way. There are two further steps which must be taken: (*a*) the determination of the amount of energy passed to the tank walls, and (*b*) the effect which this combination of pressure and energy will produce on the tank. The object of the disc method is to indicate directly, and without an intermediate step, what would happen to the oil-switch tank; and this is, after all, what we want to know. The methods just enumerated were therefore abandoned in favour of the discs, which in my opinion give more direct and consistent results than any of the other methods.

A whole gamut of pressures may be set up with, at one extreme, waves of steep contour and, at the other, sustained pressures similar to those set up in a boiler. The measurement of pressure waves of varying steepness is in itself a baffling problem. What, then, is to determine the method in oil-switch work where any combination of kinetic and potential energy may exist? Surely it is better to use the disc method which shows what is happening to the switch container and thus indicates the vitally important condition of that container. That the disc method does indicate accurately the condition of the tank has been proved by detailed experiment and also, perhaps crudely but none the less fundamentally, by the consistent behaviour of two discs under similar testing conditions.

I do not agree with Dr. Whitney's contention that the various forms of pressure—in particular, the two extreme forms of pressure pulsation and sustained static pressure—need be separated. The switch tank has to withstand these two forms, and the pressure discs are affected by both forms. Why, then, separate them or employ indicating devices which attempt (very indifferently) to differentiate between them? What the switchgear user wants to know chiefly is whether his switch tank is strong enough mechanically: he is not so interested in what goes on in the arc or even in the body of the oil. The interesting problem is whether the switch is likely to remain a useful factor in his calculations; and the ground which is common both to the designer and to the user is the container.

It is interesting to note that Dr. Whitney's experience and the E.R.A. experiments show an agreement between break energy and bursting pressure, but Mr. Wedmore apparently does not agree with this. The measurement of break energy may be scientific intrinsically, but it fails to explain actual results. Where is there any connected science in the action of an oil circuit-breaker, and what is there that is scientific in properly applied empirical methods? The pre-arcing sequence is as dependable as any electrical phenomena, but immediately arcing commences the connectedness is broken, the arc takes charge and becomes the determining factor in what follows. In short the arc destroys the relationship of circuit conditions, and thermal and pressure effects, just as effectively as Lac Leman destroys the identity of the two parts of the Rhône. Mr. Wedmore's high opinion of flexible-wall circuit breakers does not seem to have been justified by results, and modern switch design tends in the opposite direction. It is perhaps superfluous to point out to him that an "irresistible force and an immovable mass" cannot have simultaneous existence. It is rather difficult to deal with some of Mr. Wedmore's statements owing to a lack of supporting evidence. He should not be discouraged because oil switches attract attention from all shades of technical opinion. Every day brings new light to bear on the problem, and even a streak of Apemantusian philosophy may in time prove to be not without its results.

Mr. Wedmore refers to *the* circuit breaker, whereas *several* circuit breakers of different designs were used in the experiments. I cannot find it stated in the paper that there is an inevitable relationship between the ability to withstand stress and the prevention of the arc from re-establishing itself after the current has passed through zero, and I did not imply that the distortion of the tank wall was the only factor which affected the performance of the switch. Mr. Wedmore apparently agrees that very rapid breaking must increase the voltage across the arc by forcing up its resistance, that slow breaking is equally bad, and that there must be an optimum value of speed. This is the main contention of Section 4 of the paper. I do not agree that excessive speed of break is unlikely in present designs; it is suggested in the paper that the actual linear speed of breaking of present-day switches is of small importance compared with the maximum speed at which the arc may be lengthened, for instance by arc distortion, which may give an excessive momentary speed super-imposed on the relatively low linear speed of the main contacts.

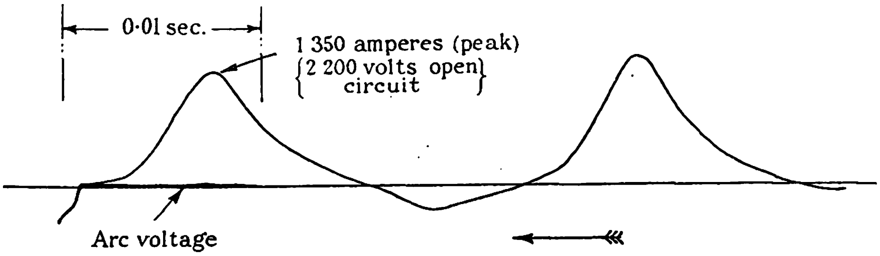

Fig. F.—Oscillogram of short-circuit at 2 200 volts (open circuit).

The quenched-arc circuit breaker and its action were discussed at some length in 1927 with Mr. Wedmore, with whom it was agreed that the Electrical Research Association's work was on different lines from mine. In the quenched-arc circuit breaker, the arc is rooted in the discs or plates, whereas the Association's work dealt with breaking methods employing discs to cool the *gases* from the arc. Mr. Wedmore is not quite correct in stating that the E.R.A. used the same short-circuit power as I did. In addition to this source of power, the quenched-arc switch was tested with 250 000 kVA. Several speakers, indeed, appear to have overlooked the fact that a power source of this magnitude was used in the tests. Part of the "mass of experimental data" was expeditiously analysed by the application of an extremely up-to-date method due to Mr. J. C. Preston, M.Eng., of Liverpool University, and brought to my notice by Prof. F. J. Teago. This is a much quicker method than that generally used by investigators and appears to be worthy of more extensive adoption.

The cross over the zero line in Fig. 4, referred to by Dr. Whitney, is due to the thick line used for reproduction, so that Dr. Whitney's argument in regard to Table 3 is inapplicable. With regard to Table 8 and Fig. B, surely Dr. Whitney does not seriously suggest plotting a curve from eight points when one of the eight is more than 100 per cent out of line and when Figs. 2, 3, 4, 5, 6, 7, 8 and 9 show the reverse effect. Dr. Whitney inquires what precautions were taken to guard against distortion of the pressure-indicating discs. The total thickness of the flanges between which the discs were bolted was 1 in., and the effective diameter of each disc was 3 in. The precautions to which Dr. Whitney refers were all observed, and where model switches were used the whole model was carefully scaled down. It does not seem to be generally realized that most of the "models" were quite as large as commercial breakers; some, indeed, *were* commercial breakers. They were described as models only because of my postulation of $1\frac{1}{2}$ million kVA as the normal short-circuit power of a full-scale system. Not at any time were the "models" or the testing conditions on a smaller scale than the work of the E.R.A.* Dr. Whitney and others should bear this in mind in comparing my results with other investigations. The speeds of cross-bar supports were the same in the single-break, double-break and 4-break tests so that the speed of arc drawing would be greater in the 4-break tests than in the single and 2-break tests. Fig. 12 includes the energy which flows to earth. The air cushion in all the tests in Table 6 was the same. Dr. Whitney should read the paragraph below Table 6. With regard to the tests on the stabilized-arc switches, the chief reason the stress is different is because the switches tested were of different design and size. I am rather surprised that Dr. Whitney should select *two* tests from his research work and compare them with a *group* of tests; his Figs. C and D can be obtained from any ordinary oil switches if selection is resorted to; for instance Fig. F shows the same effect in a test which I carried out. The oscillograph records and data given for the quenched-arc switch show its normal performance, whereas the oscillograph records of oil switches of normal design are exceptional; in fact they represent the lower end of the scale referred to in one of the E.R.A. Reports,† and they support my contention. No "principle of selection" was adopted for Fig. 18; the tests were taken at random. It is noted that the last point in Table 7 is not recorded. With this point included, the curve will become straighter and will obviously strengthen the argument; it will also reply to Mr. Leeson's question.

* For instance, see the E.R.A. Report in *Journal I.E.E.*, 1929, vol. 67, p. 557

† *Journal I.E.E.*, 1929, vol. 67, p. 557.

I am glad to have Dr. Whitney's confirmation that the E.R.A. investigation on the effect of phase angle and inductance shows a similar effect to that which I obtained.

Doubt has been expressed of the adequacy of the evidence supplied to support some of my statements. It is interesting, therefore, to compare this evidence with the published information emanating from the three bodies who have the facilities for carrying out similar tests. Let us call them A, B and C. Each has been responsible for sponsoring a new switching device which A and B have developed to a commercial stage and upon which A has carried out 82 tests, B 27 tests and C 33 tests. On the quenched-arc switch more than 100 tests have been carried out. C has carried out considerable detailed experimental work similar to mine. On three lines of research taken at random (they deal with number of breaks and effect of phase angle) C offers 12, 9 and 14 tests as supporting evidence, while I submit respectively 20, 10 and 25 tests and an equal number of "bracketing" tests. In the same tests C's average per point on given curves are 8·7, 3·2 and 2·3; in two instances two tests only are deemed sufficient to justify plotting a point and in two other cases one test suffices. The smallest number of tests per point in any of the work covered by my paper is 5.

It is gratifying to have the support of Mr. Clothier to the scope and extent of the paper. His choice of the word "illusive" in connection with the use of arc energy and break energy as standards of quality and performance seems apt. It has already been pointed out that the curve on page 1097 when redrawn to include the last point in Table 7 would tend to become a straight line. The pressures obtained have been noted with switches capable of breaking up to 250 000 kVA. I believe that with a sufficiently extended curve Fig. 18 would, in practice, become a straight line. The results shown on the curve in Fig. 22 have been confirmed to some extent by observations made with a source of power capable of giving 1 million kVA on short-circuit. The ratio of 2·5 : 1 was obtained from the experimental work described in Section 5, and it is the ratio of maximum distress and average distress set up under fixed circuit and power conditions. It was not obtained from a comparison of commercial switches. The arrangement of busbars in Fig. 37 is purely illustrative; it could be developed into a ring or a duplicate busbar system without modification to the principle. Mr. Clothier's suggested arrangement of resistances and short-circuiting switches on the star side of the generator windings appears to be sound. It would necessitate a larger number of switches and resistances, but would have the advantage that, if desired, insulation could be reduced. My extrapolation of the quenched-arc switch shown in Fig. 35 up to 1 million kVA represents an extrapolation ratio of only 4 : 1, not 10 : 1. A quenched-arc switch of the dimensions shown has broken 230 000 kVA, which is double the rating of the same switch without the quenched-arc arrangement.

Mr. Coates does not appear to have read the paper very carefully. He says that the ratios given in the conclusions from Table 6 are not embodied in the breaking capacity formulæ on page 1102; yet on that page this information is given at length. Again, it is the essence of Fig. 25 and the formulæ given on page 1102 that they are based on data obtained from commercial switches and are thus empirical. The formulæ are of practical value only because they *are* empirical. Mr. Coates will also find that attention is drawn in the paper to the need for caution when dealing with large high-voltage switches. The formulæ have been applied successfully in at least 95 per cent of the cases. What Mr. Coates calls "the theory of surging" is not novel. As he states, it is referred to in the E.R.A. Report in 1929, and it is also mentioned in my paper in 1926.* The magnetic ring used in the stabilized-arc switch is open at the top and bottom and, although there has been noticeable simplification of the explosion-pot circuit breaker lately, the latter is not yet entirely open at the top and bottom. I am unable to understand what Mr. Coates means by implying that manufacturers' breaking-capacity ratings can be proved in practice. The series of tests in which Mr. Coates participated on a 600 000-kVA plant go less than half way to prove present-day ratings. I have carefully followed the field and other tests carried out during the last few years, chiefly in the United States and on the Continent, and so far have found no tests which prove that any existing circuit breaker will break 1 500 000 kVA. My comparison of round and rectangular tanks was made from an examination of manufacturers' designs. Mr. Coates will find on referring to the paper that attention is directed to the anomaly of the apparent weakness of round tank switches and for the need of the physician to heal himself.

"De-ionizing" has been recognized since the earliest days of electrical engineering. The work of Prof. Thornton and of Prof. Compton is fundamental and of long standing, and there cannot be any master patents for the application of this effect. I have followed the development of the "de-ion" circuit breaker with great interest and have noted its good performance. Practical application, however, appears to lie with the so-called "de-ion grid" breaker, a device of quite different conception. Comparisons of the "de-ion," the "de-ion grid" and the "quenched arc" circuit breakers will be found at the end of my reply. Mr. Coates accuses me of not being practical enough, while Mr. Wedmore alleges the opposite; I aimed at a middle course.

Mr. Trençham rather refreshingly admits that circuit breakers are designed from practical experience, but I do not agree that the resultant circuit-breaker ratings take into account the "uncertainty factor" of 2·5 : 1. To Mr. Trencham's list of new types of circuit breakers should be added the de-ion grid breaker, which appears to have out-paced the de-ion breaker. Mr. Trencham is correct in assuming that the cooling paths of the quenched-arc breaker form a *cul de sac*, if by this he means that the arc does not travel beyond the annular enlargement; but this is true only so far as the arc is concerned, and oil and gas can pass and escape at the edges of the plates. I have compared the tests on the quenched-arc breaker with numerous tests on explosion-pot breakers, and I find that the arc voltage in the quenched-arc breaker is less than 1/100th of the arc voltage of the explosion-pot breaker, and that whereas the quenched-arc breaker is completely consistent in its action (the " uncertainty factor " does not exist), the explosion pot breaker still possesses the inconsistency of the conventional oil breaker. If these two fundamental differences are " almost nothing," the problem of designing a scientific and peacefully operating circuit breaker has never existed. Mr. Trencham appears to have the impression that the de-ion breaker has been tested on considerably larger amounts of power than the quenched-arc breaker, whereas both have been tested up to 250 000 kVA (see also my reply to Mr. Clothier).

---

* *Journal I.E.E.*, 1926, vol. 64, p. 920.

In reply to Prof. MacGregor-Morris, the magnetic cylinder of the stabilized-arc switch increases the permeability of the flux path round the arc which strengthens the field round the arc and increases its natural tendency to complete a straight line between the co-axial electrodes; it also forms a magnetic ring which screens the arcs from one another and from exterior unstabilizing influences. A non-magnetic cylinder of the same resistance has been tried, with quite different results.

In reply to Mr. Driver, few liquids other than oil have been tried in switches; water and carbon tetrachloride and "Excello fluid" are the chief ones. Not infrequently, switches are forced open electromagnetically, as Mr. Driver suggests. Undoubtedly, many circuit breakers open at a speed depending upon the current passing. The formulæ on page 1102 can be used on the generality of oil switches.

In reply to Mr. Leeson, power factor is taken into account in Section 4 of the paper. Mr. Leeson's analogy of a circuit breaker with a boiler must be a very limited one, as the latter works under fixed conditions of pressure. I do not agree that a circuit breaker is no more distressed than a boiler. If the boiler analogy is good, why does Mr. Leeson test his circuit breaker tanks by means of explosives? It is reasonable to rate the mechanical strength of an oil switch in pounds per square inch if the various pressures and rates of pressure-change can be referred to a common base. Mr. Leeson is not correct in stating that the remarks in the paper on breaking speeds ignore the need for a short arc. This requirement is constantly referred to in the paper. Mr. Leeson's Fig. E shows in an assimilative manner the relationship between the modes of dissipation, and while " arc energy " can be divided in the manner shown in the chart, there is little hope of it ever being a measure of stress (or distress). Mr. Leeson's comment on Fig. 22 is noted (see my reply to Dr. Whitney). Mr. Leeson apparently considers that while the factor 2·5 : 1 may exist, the comparatively small operating benefit of 3·5 per cent may not be worth the cost; then he paradoxically suggests that the resultant efficiency is low, but 96·5 per cent efficiency of service is not necessarily low. If, however, it is suggested that the " derating " factor of 2·5 is incorrect, the only logical course I can see is for manufacturers to demonstrate by full-scale tests what are their actual safe breaking-capacity ratings. I do not " ignore the collective experience gained over many years." On the contrary I have great respect for it, and devoted the best part of Section 5 of the paper to it.

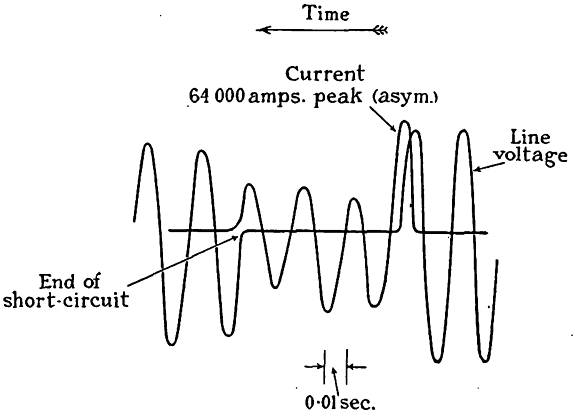
Mr. Leeson confirms the performance of the quenched-arc breaker on 230 000 kVA. In the switch shown in Fig. 35 stability is produced by drawing and maintaining a short arc of constant length. Examination of that figure will show that no matter how far the arc may be bowed out, the arc length will always be constant. This is a vital requirement of circuit breakers and it is possessed, as far as is known, only by the quenched-arc breaker. In some of the single-pole experimental switches a mechanical stabilizing system was used. Markings on some of the circular plates taken from quenched-arc switches suggest that the arc expands as a ring. The reason why the switch shown in Fig. 36 is credited with only 2 : 1 improvement (instead of 6 : 1 as in Fig. 35) is because Fig. 36 shows a higher-voltage circuit breaker which requires larger insulation clearance.

As Mr. Gregory assumes, the breaking-capacity formulæ on page 1102 represent the law according to which reputable British manufacturers design their switch enclosures, and the basis of the formula $\sqrt[3]{(PV)}$ is now used to formulate mechanical tests for circuit breakers of the standard type. There is undoubtedly a universal feeling that present-day oil circuit-breaker designs are not final; the introduction in recent years of several new switching devices is good evidence of this.

Prof. Thornton's authoritative support of my method of distress measurement, the properties of arcs and the ignition of gases is welcomed. His calculations of the relationship between pressure and distress is similar to calculations which I carried out some time ago. He also shows that the law demonstrated in Fig. 25 is that the stress limit is proportionately to the radius of the equivalent single gas cavity.

Mr. Carter is correct in his assumption that the ring in the stabilized arc switch acts as a magnetic shield; the ring probably also shields the arc from turbulence and other disturbances. Stabilization in the switches shown in Figs. 35 and 36 is carried out electrically, and by the method, referred to on page 1104, of using the metal discs as guiding contacts. British Patent No. 9714 referred to in Section 7 covers methods of stabilizing by magnetic, electrical and mechanical means. In the circuit breakers referred to by Mr. Carter, stabilizing is effected by keeping the arc of a constant fixed maximum length and of maximum cross-section. In the two switches illustrated in Figs. 35 and 36 the arc is similarly of constant length. Properly controlled, a moving arc is not an unstable arc: in the quenched-arc breaker the arc moves and is stable.

I agree with Mr. Harle that there is no advantage to be gained by increasing the contact size beyond certain limits. A very large number of tests would be necessary in order to obtain the average and maximum values of arc energy as Mr. Harle suggests; and, when obtained, the results still remain unrelated to the mechanically stressed condition of the tank walls. The pressure discs were arranged to be as near as possible to the arc, and they were always embedded in the tank walls. Table 8 is not a comparison but actually shows inconsistency of results. Not only the quenched-arc breaker, but any switching device, would be critical in its action at the point implied by Mr. Harle, that is when exceeding its maximum breaking capacity, and I anticipate no difficulty in so designing the quenched-arc switch that proper limits are not exceeded. The switch shown in Fig. 35 has been tested on short-circuit on considerably larger amounts of power than it would handle as a plain oil switch. Its breaking-capacity limit must therefore be greater than that of a conventional oil switch of the same general dimensions. The maximum breaking capacity will probably soon be determined by means of the testing plant referred to by Mr. Clothier. In the arrangement shown in Fig. 37, there is no intention of switching additional load on to the machines. Switching would take place only under fault conditions and the value of the power to be broken would be considerably less than with a short-circuit under ordinary (unregulated) conditions. I agree that the reduction in the peak value would probably only be of the second order on a solid-rotor machine, but such reduction is still of useful magnitude. The test carried out by Mr. Harle was valueless because of the small amount of inductance used.



Open-circuit voltage = 5 000 (R.M.S.)

FIG. G.

In reply to Mr. Brierly, I do not suggest that the designed speed of a high-voltage breaker should be lower than for a low-voltage breaker. I contend that there is a factor which points to the need for a lower speed: there are other factors which argue a higher speed (see page 1095). It has already been pointed out that pressure cannot accumulate inside the stabilizing ring of the stabilized-arc circuit breaker. In my investigation I adopted the first cycle of current in preference to the method advocated by the International Electrotechnical Commission, in order to avoid possible confusion in measuring the duration of the pre-breaking time. There should not be any difficulty in calculating the current at the moment of breaking; only the decrement is required and this can be obtained in a moment from an oscillograph record. Fig. G shows an oscillograph record of a test of the magnitude referred to by Mr. Brierly: it shows the quenched-arc breaker in Figs. 31 and 35 dealing with over ½ million kVA.

COMPARISON OF DE-ION GRID AND QUENCHED-ARC BREAKERS.

De-ion Grid.	*Quenched-Arc.*
(1) Employs plates of Fullerboard, which would appear to be liable to charring or burning by arc.	Employs thick metal plates: nothing to burn.
(2) Arc is lengthened and bowed out by magnetic field, which produces instability and a considerable amount of heat.	Arc is maintained of constant form and of limited fixed length; is a fraction of the length of the "de-ion grid" arc.
(3) Arc is drawn between two adjacent slots formed in Fullerboard strips. There would appear to be danger of arc and gas bubble spanning the gap and short-circuiting the breaker.	Arc is drawn in a symmetrical condition and is surrounded by metal plates. Is insulated all round, thus no danger of arcing across.
De-ion Grid.	*Quenched-Arc.*
(4) Operation depends upon gas bubble breaking through arc, and is thus explosive in action; moreover, the two arcs of a given pole may be blown together.	Action quiescent. Arcs are isolated from one another.
(5) Construction relatively delicate, embodying a pile of Fullerboard sheets and a similar pile of magnetic horseshoes.	No magnetic system required.
(6) Oscillograph records show an arcing voltage envelope of considerable area; comparable with, and having the characteristics of, an ordinary arc in oil or oil gas.	Arc wave-form is smooth and much smaller in area, about one-tenth.
It is stated that energy released in arc is 1/12th to 1/15th of that in an ordinary oil circuit-breaker, and this implies that breaking capacity is proportionately greater than in oil circuit-breaker.	Energy released by arc 1/100th of that in ordinary oil circuit-breaker.
(7) In consequence of foregoing, heat available for explosive effects is relatively large.	Non-explosive action.
(8) Oil has free access to arc.	Arc is almost completely shielded from oil and practically no cracking can take place.

It is debatable whether the expression "de-ion grid" is properly used to describe this circuit breaker. It implies a parallel to the " de-ion " air circuit-breaker, but the strips of laminated material in the 'de-ion grid " are Fullerboard (not metal) and are *necessarily* used to support the magnetic field system, which must be laminated otherwise it would short-circuit and bridge the main contacts.

COMPARISON OF DE-ION AND QUENCHED-ARC BREAKERS.

De-ion Breaker.	*Quenched-Arc Breaker.*
(1) Large number of plates to limit voltage to about 150 volts per gap.	Small number of discs at about 1 000 volts per gap.
(2) Thin metal is used for the plates and appears to be liable to severe burning.	Heavy discs or plates are used. (About 8 times as thick as the " de-ion " breaker plates.)
(3) Magnetic field is required to force arc into plates. The magnetic field is provided by coils which have to be excited from some outside source, or from the high-tension circuit, and which are near the arcing zone.	The arc travels automatically between the discs and no magnetic field or parallel assistance is required.
(4) Air break—probably greater chance of flash-over (out of 82 published tests there were 2 internal short-circuits in the breaker).	Break is surrounded by oil and out of 100 short-circuit tests no breakdowns have been experienced.
(5) Air insulation—consequently great space required for clearance.	Oil insulation which prevents hot gases short-circuiting conductors or forming a path to earth, and economizes in space.
(6) Arc is drawn in narrow slot between large numbers of thin metal edges.	Arc is drawn in a hole in the midst of the plates against metal faces approximately ½ in. thick.
(7) Construction is relatively complicated.	Construction relatively simple.
(8) Requires entire circuit-breaker structure to be re-designed, thus necessitating the commencement *de novo* of circuit-breaker design troubles.	Can be built into existing circuit-breaker structures, thus eliminating " teething " troubles.
(9) Maximum power interrupted on test is 300 000 kVA at 12 700 volts open circuit.	Maximum power interrupted on test is 250 000 kVA.

LOW POWER-FACTOR MEASUREMENTS AT HIGH VOLTAGES.

By E. H. RAYNER, M.A., Sc.D., Member, W. G. STANDRING, M.A., R. DAVIS, M.Sc., and G. W. BOWDLER, M.Sc.

[From the National Physical Laboratory.]

(*Paper first received* 1st *October, and in final form* 5th *December*, 1929; *read before the* METER AND INSTRUMENT SECTION 4*th April*, 1930.)

SUMMARY.

The paper describes a study of methods of measuring dielectric losses which has been carried out with the object of determining the nature and magnitude of the various errors to which different methods are liable. The most important errors are those due to stray capacitance currents, which affect especially the phase angle of the currents in resistors commonly used in wattmeter methods. A method is developed of shielding a simple resistor of flowing water, so that the current is in phase with the voltage within about 0·0001 radian. A resistor has been developed on these lines for 150 kV.

The standard of reference has been a specially designed air condenser of the parallel-plate type. The separation of the plates is variable; and at 10 cm separation, suitable for 100 kV, the capacitance is about 500 cm. The curvature of the edges and of the guard plates was decided as a result of studying the electric stress distribution by models in an electrolyte. The use of a condenser with the Schering bridge form of circuit has been found to be almost free from errors of importance which are difficult to allow for. The work has been carried out for the British Electrical and Allied Industries Research Association, more particularly with reference to the measurement of the power loss in cable dielectrics.

INTRODUCTION.

For some time past work has been in progress at the National Physical Laboratory on the study of methods of measurement of dielectric loss at power frequencies and high voltages, and satisfactory methods and apparatus have been evolved for use at voltages up to 150 000 or 200 000 volts.

The work has been directed chiefly to methods applicable to high-voltage cables. The power absorbed in the dielectric is one of the few physical properties of a cable which can conveniently be measured, and its variation with temperature, voltage and frequency is regarded as affording valuable information as to the quality and condition of the cable.

Measurements at high voltages, and apparatus suitable for high voltages, are liable to certain types of error due to interaction between different parts of the circuit. Owing to capacity effects, currents are introduced into the measuring apparatus which alter the phase relation between current and voltage and seriously affect the accuracy of the measurements.

The power factor of modern high-voltage cables is usually less than 0·01. It is important to be able to measure this quantity with some accuracy, and sensitivity and accuracy to a value of 0·0001 have been aimed at and achieved. Power factors, when small, if expressed as a fraction of unity denote, as a fraction of a radian, the amount short of a right-angle by which the current leads the voltage, and phase angles of resistors and other measuring apparatus expressed in the same unit can be directly added.

LINE OF INVESTIGATION.

By various methods, including those in general use, the power factor of a condenser load was measured, and the results obtained by the different methods were compared. For this purpose a load of constant power factor was desirable, and a mica condenser of 5 000 $\mu\mu$F capacity, designed for radio frequencies and 40 kV, was kindly lent by the Dubilier Condenser Co. This condenser was found to have a power factor of 0·0013, which proved to be a convenient value for the various methods. During the earlier part of the work the apparatus available—high-voltage wattmeter, resistor and air condenser—was only suitable for 20 000 or 30 000 volts.

Large discrepancies were observed between the results obtained by the different methods; but, partly through studying the variation of discrepancies with frequency and voltage, the various sources of error were eventually determined and agreement to 0·0001 power factor was reached by all the methods.

At this stage it was clear which methods were suitable for carrying on the work to higher voltages, and that an air condenser and some form of resistor were required. An air condenser and a water resistor for 150 kV were developed, were checked directly against each other as standards, and led to similar results when used to measure the power factor of a length of cable. Accounts of the condenser and resistor are given in the section dealing with standard apparatus.

METHODS OF MEASUREMENT.

The methods available may be divided into those which measure power, requiring also the measurement of voltage and current; and those which, measuring the phase angle, give the power factor directly. For the former some kind of wattmeter is required, while in the latter case a circuit adjustment is made to balance some type of bridge arrangement or to reduce to zero the deflection of a wattmeter.

The method least susceptible to error is that which uses a high-voltage electrostatic wattmeter,* the full voltage being applied to the needle and the quadrants being connected to the ends of a variable resistance in series with the capacity load, as shown in Fig. 1. Readings with different values of quadrant resistance are taken, and extrapolation to zero resistance gives the power loss required. Observations by this method proved of great value in indicating the errors in other measurements. On account of its dimensions, however, an instrument suitable for 20 kV has a long period of swing and is troublesome to use; several observations are necessary in order to obtain a value for the power factor, and the instrument has not the desired sensitivity. For these reasons the method was not developed for higher voltages.

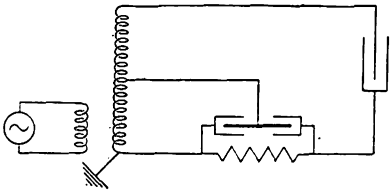

FIG. 2.—Electrostatic wattmeter. Half voltage on needle.

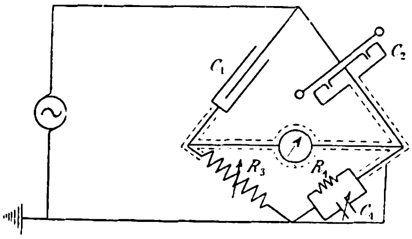

FIG. 3.—Schering bridge—shields earthed.

Low-voltage wattmeters, either electrostatic or electrodynamic, may be used with some arrangement for supplying a low voltage or current in phase with the high voltage. A step-down transformer, tertiary winding, or a tapping on the high-voltage winding of the transformer are frequently used for this purpose, but are liable to errors. The method is illustrated by Figs. 2 and 6. The low voltage can be more satisfactorily obtained by a resistance potential-divider of suitable design. Capacity effects introduce error into a very high resistance; but by shielding with screens maintained at suitable potentials the error may be reduced to zero or accurately calculated * (Fig. 5). With such a resistor a low-voltage wattmeter may be used either to measure power loss, or by a null method to measure the power factor direct. The resistor current flows to earth through one element of the wattmeter, and the condenser current flows to earth through the other element. Figs. 7 and 8 illustrate these methods. If, in the null method, the resistance of the wattmeter element is small compared with the total resistance to which the high voltage is applied, the magnitude of the high resistance does not enter appreciably into the expression for power factor. The wattmeter element, of resistance R, is shunted by a variable capacity C, or alternatively, in the Emanueli circuit, has a variable inductance L placed in series with it, a resistance S being connected across the two. When the value of these has been adjusted so that the deflection is reduced to zero, the power factor is given by the expression $RC\omega$ or $L\omega/(R + S)$, where ω

$= 2\pi \times$ frequency. The compensated methods are particularly convenient. The capacity compensation is the more sensitive, as a greater current passes through the wattmeter element. It is desirable to keep the resistance of the wattmeter elements low, and for this reason, and on account of its robustness, a dynamometer is a more suitable instrument than an electrostatic wattmeter. An advantage of the null method is that the magnitude of the high-voltage resistance, if sufficiently large, does not affect the balance adjustment. Flowing water, the resistivity of which varies with voltage and rate of flow, can therefore be used, and provides the only type of resistor feasible for use at high voltages without very great trouble and expense.

A resistor of uncertain magnitude would be practically useless, however, for bridge measurements requiring constancy of circuit quantities. The most suitable form of bridge is the Schering bridge arrangement, having condensers in the high-voltage arms and resistances in the low-voltage arms. For such methods a high-voltage condenser of known power factor is required as a standard. A loss-free condenser is a simpler problem than a resistance without inductance or capacity; and the Schering bridge is the most convenient of all the methods to use.

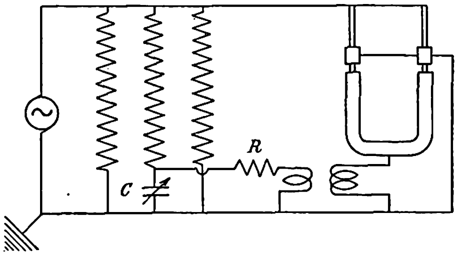

FIG. 8.—Compensated dynamometer. Capacity compensation.

Figs. 1 to 8 show the various methods tried.

SOURCES OF ERROR IN POWER-FACTOR MEASUREMENTS.

Errors in High-Voltage Apparatus.—With the exception of the high-voltage electrostatic wattmeter method, which is cumbersome and unsuitable for very high voltages, all the methods make use of, or must be calibrated by, a standard of phase angle—either a resistor or a condenser. The design of standards of known phase angle is considered in the section dealing with standard apparatus, and particulars are given of types which have proved satisfactory at 150 000 volts.

In methods using a low-voltage wattmeter the voltage element is sometimes excited by a step-down transformer, or by a tertiary winding or a tapping on the secondary winding of the high-voltage transformer. These devices may introduce large phase-angle errors; in the case of a transformer with a 1/200 tapping, errors between 0·005 and 0·01 radian were observed. Such phase angles naturally vary with transformer load and voltage, and equipments of this kind require calibration under actual conditions of use.

Errors in Low-Voltage Apparatus.—Errors may be inherent in the wattmeter used. The effect of self-inductance in the wattmeter elements in series with very large impedances is negligible, and so is the effect of mutual inductance, except in the case of a dynamometer if some of the turns are short-circuited. Self-capacity, however, may shunt part of the current in one element, causing a power-factor measurement to be high if the effect occurs in the current element. Self-capacity in the voltage element makes the measurement give too low a reading, so that this error can be detected by interchanging the current and voltage elements, if their current-carrying capacities permit. An instrument with very small values of inductance and capacity is desirable, and a sensitive dynamometer made by Messrs. H. Tinsley and Co. has proved of great use. The coils are all contained in a space about $1\frac{1}{4}$ in. square by $\frac{1}{2}$ in. The moving coil has a resistance of 40 ohms and is rated at 20 mA. The fixed coil is in 10 sections which can be connected in series-parallel arrangements for 0·02, 0·04, 0·1 and 0·2 ampere, the resistance of all sections in series being 450 ohms. At first no appreciable difference was observed between ranges, but later the lowest range developed an error of 0·0003 radian. By interchanging voltage and current coils and taking the average reading this error has been eliminated. It is thought to be due to increase of self-capacity of the fixed coils, due perhaps to softening of insulation through overloading. The effect would naturally be greatest on the range of highest resistance.

It may be necessary to make a correction for the loss in the coil carrying the condenser current. If this coil has a resistance r, and the condenser has a capacity c, the power-factor reading is too large by the amount $rc\omega$.

Low resistances of 1 ohm or less, used for large capacity currents in bridge measurements when considerable lengths of cable are tested at high voltages, may be slightly inductive. Their phase angles, of the order of 0·0001 or 0·0002 radian, can be easily measured at low voltage by audio-frequency bridge methods. When such resistances are used in a Schering bridge, care should be taken that the earth and galvanometer connections are made to the proper points, as the inductance added by using a foot or so of lead may appreciably alter the phase angle of a low resistance.

Errors due to capacity effects.—In high-voltage measurements there is often electrostatic interaction between different parts of the circuit, and errors may be caused by capacity between the low-voltage apparatus, or the leads connected to it, and high-voltage conductors. The magnitude of such errors depends on the equipment and set-up; but it is usually essential for the low-voltage lead from an air condenser or resistor to be protected from this source of error, though in the case of a load of high capacity (such as a cable coiled on a drum) protection may not be necessary. The simplest way of removing these errors is to shield the low-voltage leads and apparatus by metal screens connected to earth, as shown in Fig. 3. In Schering bridge equipment the leads and galvanometer can conveniently be shielded at their own potential by connecting their shields to the guard plates of the air condenser, placing a resistance between these and earth, and balancing against the other arms of the bridge, as indicated in Fig. 4. Sometimes, instead of earthing the transformer an earth connection is made to an auxiliary pair of balanced bridge-arms, for example, to the guard plates of the air condenser, a resistance being connected between these and the transformer. This device, termed a " Wagner earth," eliminates the effect of the earth capacity of the galvanometer and the leads. When leads are shielded by earthed screens one source of error is increased. If R be the resistance of the low-voltage arm of a bridge, or of a wattmeter element, and if the lead to it have a capacity C to earth, a phase error $RC\omega$ is introduced. If the error is on the side of the standard, a power-factor measurement gives too low a value; if the error is on the load side the value obtained is too high. These errors may be eliminated by shielding the leads by screens connected to auxiliary apparatus at the same potential; but this arrangement is not always convenient and requires a separate balance adjustment, as seen from Fig. 4. The magnitude of the errors may be observed by taking observations with different values of resistance. The error is proportional to the resistance, and extrapolation to zero resistance gives the value required. Alternatively, the capacity may be measured and the error calculated.

Electromagnetic Effects.—With a sensitive instrument like a vibration galvanometer of the type used in bridge measurements, electromagnetic as well as electrostatic shielding may be required. Near the high-voltage transformer it was found impossible to use a moving-iron instrument, except inside a case of magnetic material. Some distance away the effect was negligible.

Errors associated with the Load.—In the measurement of the properties of small lengths of cable two precautions are necessary. Owing to leakage and tangential electric stress in the paper insulating material, a considerable loss of power occurs at the ends. To eliminate this from the measurements guard rings should be placed over the paper beyond the lead, as shown in Fig. 8, otherwise the error may be as large as the quantity being measured. Even on a 200-yard length the effect may not be negligible, if the stripped ends are protected against flash-over, e.g. by semi-conducting paper,* for measurements at very high voltages. A few inches of guard-ring beginning 1 in. or ½ in. beyond the lead covering may suffice. In the case of some measurements on a 50-ft. length of 66-kV cable a gap of 1 in. was found to introduce an error of 0·0001.

The other possible source of error is connected with the capacity between a high-voltage line and its cable sheath. If ionization is present around the line, impure capacity current, which is in parallel with the cable under measurement, has a bad power factor and may introduce a serious error. On a 50-ft. length of cable an error of 0·001 was observed when using a high-voltage line of No. 18 S.W.G. wire at 100 000 volts. The capacitance between the line and cable sheath was only 1/200th of the cable capacitance, but its power factor was about 0·2. The error was removed by using a high-voltage line 1 in. in diameter, at which size ionization did not occur, or by shielding the cable sheath with an earthed screen of wire netting.

Effect of Wave-form.—A consideration of power factor and power-factor measurements with a voltage supply of bad wave-form is given in Appendix 3.

STANDARD APPARATUS.

In the absence of ionization, the loss in air under electric stress is so small that an air condenser having sufficiently small resistance in its plates and leads is practically a pure reactance, and forms the most reliable and easily constructed standard for measuring phase angles at high voltages. Care is necessary to ensure that the low-voltage plate is influenced by nothing but the high-voltage plate, and only through air dielectric. The errors due to incomplete shielding of the low-voltage plate are sometimes surprising, and some account of the magnitude of such errors, met with in the development of the N.P.L. condenser for 150 kV, may be of interest.

Design of Condenser.—Condensers for high voltages may be of the flat-plate or cylindrical form, but for research purposes of the type dealt with in this paper a plate condenser has advantages; and it was decided to use a high-voltage plate between two low-voltage plates. A capacity large enough for direct comparison with a resistor standard by a dynamometer method can conveniently be obtained with this design, and the two sides of the condenser can be compared under different conditions, which was found to be a most valuable feature.

TABLE 1.

Separation of plates	Flash-over voltage	
	Unpolished	Polished
cm	kV	kV
10	100	135
15	135	185
20	165	220
30	200	260

NOTE.—These figures are subject to considerable variation, and higher values have been observed.

The condenser is illustrated in Fig. 14, and is described in Appendix 1 with a consideration of the shape of the plates to avoid ionization at the edges.

Conditions affecting the Behaviour of the Air Condenser: Effect of Surface on Power Factor.—A few sharp protruding edges and points on the surface of the plates can introduce a power factor, depending on the voltage, through local ionization. Removal of the points, and the smoothing of scratches into hollows without sharp edges greatly reduces the trouble. An error of 0·0004 radian was removed in this way.

Effect of Surface on Flash-over.—The flash-over voltage was observed for various separations, in order to determine at what voltages the condenser could be used. Measurements made with one side polished and one unpolished are given in Table 1, and show a considerable increase due to polishing.

Effect of Time on the Surface.—About 10 weeks after the initial polishing, phase-angle measurements were made before and after repolishing. No change was detected. Hence the polishing process need not be frequently repeated.

Effect of the Wooden Framework carrying the Low-

---

* E. A. BEAVIS: "Some Developments in the Routine Pressure-Testing of High-Voltage Cables," *Journal I.E.E.*, 1928, vol. 66, p. 1086.

Tension Plates.—It is necessary to ensure that no insulation which can affect the low-voltage plate is subject to high-voltage electric fields. Such insulation must be surrounded by a conductor at a potential which cannot introduce error into the condenser. Referring to Fig. 14, the struts CC were found to introduce a power factor of 0·0006 for a separation of 40 cm. At this separation the wood is evidently to be regarded as part of the dielectric between the high-voltage plate and the surface (DD, Fig. 14) of the low-voltage plate, and it introduces loss. Covering the struts with tinfoil connected to the guard removed this error.

The horizontal members of the frames, the portion to which the porcelain supports were bolted and the concrete floor under the condenser, were found not to produce a measurable effect.

Effect due to Porcelain Insulators.—The low-voltage plate is supported by 10, and the guard plate by 12, porcelain insulators (EE, Fig. 14) which pass through holes 10 cm in diameter in the back of the guard plate. It was found necessary to cover the exposed porcelain and the holes with tinfoil connected to the guard plate, otherwise an error of 0·0007 negative power factor was introduced for a separation of 40 cm between plates.

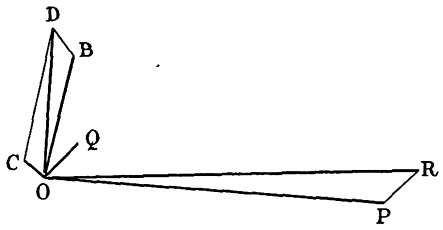

FIG. 9.—Vector diagram explaining apparent negative power factor.

OR = voltage on condenser.
OP = voltage between h.t. line and porcelain.
OQ (= PR) = voltage on porcelain.
OD = capacity current to porcelain.
OC = current from porcelain to low-tension plate.
OB = current from porcelain to guard.

The effect was only observed on that side of the condenser facing the high-voltage line, and the following explanation is suggested: The porcelain insulators have a small capacity to the high-voltage line and so receive a small current leading by 90° relatively to the voltage. This current goes partly to the guard plate and partly to the low-voltage plate. The exposed porcelain is quite close to the guard plate but relatively remote from the low-voltage plate. Thus the capacity between the porcelain and the low-voltage plate has a considerable air space as dielectric and will have small loss, while the capacity between the porcelain and the guard plate is likely to be larger and to have a bad power factor. Reference to the vector diagram (Fig. 9) will show that the current from the porcelain to the low-voltage plate may be in advance of the voltage on the condenser by considerably more than 90°; so that, although very small in magnitude, it may have an appreciable influence on the phase angle of the total current reaching the low-voltage plate. The total current at the low-voltage plate may thus be more than 90° in advance of the voltage, the condenser having, apparently, a negative power factor.

Effect of the High-Voltage Connection.—With a separation of 40 cm a connecting wire of No. 18 S.W.G. in the position FF (Fig. 14) increased the power factor of this side of the condenser at 90 kV by 0·0005 above that with the conductor vertical. The error was reduced by 0·0004 by using a conductor 1 in. in diameter. The effect is evidently due to some capacity between the conductor and the surface DD, combined with power loss due to ionization at the surface of the wire.

Potential of the Guard Plate.—By inserting a suitable impedance between the guard plates and earth and balancing the guard potential against that of the measuring plates, ideal shielding of the low-voltage plate may be effected. Usually, however, it is more convenient to earth the guard system. The capacity between the low-voltage plate and the guard system then shunts the low-voltage apparatus in series with the condenser and acts as an addition to C_4 (Fig. 3); such capacity must, in consequence, be allowed for.

The importance of a good connection between earth and the guard system may not be obvious; but serious errors may be caused by a high resistance in this part of the circuit. A resistance of 1 000 ohms, for example, may cause the guard plates to acquire a potential of a few volts in quadrature with the voltage on the condenser, and to introduce into the low-voltage plate a small current 90° in advance of the condenser current from the high-voltage plate, producing an apparent negative power factor. Such a contact resistance of 1 000 ohms put the N.P.L. condenser in error by 0·0008 radian. An error of this nature was found in a condenser sent to the Laboratory for examination. The error disappeared on making a more positive connection.

The importance of definiteness of contact in apparatus and instruments for dealing with capacitance currents at low and high voltages cannot be too much emphasized. In the case mentioned, reliance had been placed on the contact between the flange of a hole and the nut of a bolt 1¼ in. in diameter passing through it, which would normally suffice for large currents. Though in many cases a moderately high resistance in circuits involving electrostatic currents may have no appreciable effect on the measurements made, yet such resistances may at times be very high indeed until broken down by an appreciable current passing. For such reasons it is sometimes found that unsatisfactory results are obtained owing to obscure causes which are remedied by a sufficient current, such as flows on the flashing-over of a high-voltage condenser by raising the voltage until this occurs. In fact, experience shows that the occasional flashing-over of an air condenser, making measurements on some load before and after, may be found useful as a test of its condition. A "cleaning up" effect of flashing-over is not uncommon. Though every care may be taken to keep condenser plates clean, it very frequently happens that the first of a series of flash-overs made between surfaces at high voltage is notably less than the later ones. An increase of about 20 per cent may take place.

Design of Water Resistor.—A column of flowing water forms a valuable resistor for use at high voltages because of the high loading which is possible. High resistances of negligible capacity for use at high voltages are impracticable, but by using a material which can be continually discarded as it becomes hot the dimensions, and hence the capacity, of such resistances can be greatly reduced. The disadvantage of a water resistor is its indefinite and variable resistance, making it unsuitable for use as a precision resistor or for measurements of power by a direct wattmeter method. For phase-angle measurements by a compensated wattmeter method, however, this variability does not matter, and such methods are more convenient to use than deflectional wattmeter methods, and give the extra sensitivity usually associated with null methods.

The effect of earth capacity on an unshielded resistor may be illustrated by the case of a column of resistance material 2 m long, 1 cm in diameter, and of resistance 1 megohm. The current in such a resistor would lag at the low-voltage end behind the voltage across the whole by about 0·001 radian, and would lead at the high-voltage end by about 0·002 radian. 1 megohm at 150 kV would dissipate more than 20 kW, and higher resistances for such voltages are generally desirable to reduce the energy to be provided and the difficulty of its disposal. It is important to note that the error is proportional to the resistance and to the length; so that increase of length for the sake of reduction of the power consumed causes a rapid increase in the phase displacement between current and voltage.

TABLE 2.

	(Power factor of air condenser) + (Angle by which resistor current leads the voltage)			
	Low-voltage end		High-voltage end	
	Measured	Calculated	Measured	Calculated
Uncompensated resistor with bent tubes	+0·0002	—	+0·0005	—
Uncompensated resistor with straight tubes	0·0000	−0·0002	+0·0005	+0·0004
Compensated resistor	+0·0002	0·0000	0·0000	0·0000
Effect of compensation	+0·0002	+0·0002	−0·0005	−0·0004
Compensated resistor with centre tubes 1 cm high ..	+0·0004	—	0·0000	—
Effect of raising centre tubes 1 cm	+0·0002	+0·0001	0·0000	−0·0001
Compensated resistor with centre tubes 1 cm low ..	0·0000	—	+0·0001	—
Effect of lowering centre tubes 1 cm	−0·0002	−0·0001	+0·0001	+0·0001

Capacity errors would be eliminated if the resistor were shielded at every point by an electric field at its own potential. This is to a very considerable extent practicable by surrounding the main water column by others to which the same voltage is applied. Various arrangements have been assembled with 0, 3, 6 and 12 guard tubes, of resistances in the central water column from 1 to 4 megohms, and of lengths from 2 to 4 metres. The reduction in capacity under practical conditions may be 95 per cent. Methods of calculating the capacity effects are described in Appendix 2. The close agreement (to 0·0001 or 0·0002 radian) between calculation and experiment indicated the possibility of the construction of resistors which could be regarded as standards, their phase angle being determinable from their design. The number of guard tubes used in the final construction was 12; but the main water column has still a small capacity to earth as the shielding is not complete. The effect of this may be counteracted by prolonging the main tubes beyond the guard tubes at the high-voltage end. By this compensation the current in the main tube at both high- and low-voltage ends can be caused to be in phase with the applied voltage.

A description of the resistor finally constructed and used at 150 kV is given in Appendix 2, together with methods of calculating capacities and capacity effects, and the temperature-rise of the water. On account of the large temperature coefficient of the resistivity of water, the temperature-rise depends considerably on the inlet temperature. For voltages of 50 kV and upwards the local water supply, of resistivity 3 000 ohms per cm^3, was unsuitable, and distilled water of 30 000 ohms resistivity was used in a circulatory system containing a cooler. Even with water of this resistivity temperatures were reached at which serious distortion of the tubes occurred. Experiments on sample tubes of a new mixture of Keramot recently supplied indicate much greater mechanical rigidity in the new material at temperatures near 100° C., and a resistor of more satisfactory geometrical stability might be constructed of this material.

COMPARISON OF AIR CONDENSER AND WATER RESISTOR.

The two sides of the large-plate air condenser were compared directly by a Schering bridge, and measurements were made against the resistor by a compensated dynamometer method at voltages up to 150 000, and by a bridge method up to 80 000 volts, above which the resistance of the water was not sufficiently steady for bridge measurements. When the errors referred to earlier had been eliminated it appeared that the condenser had the same power factor at all distances up to 30 cm, and at all voltages up to 150 000 volts. (There appears to be a slight increase of power factor with voltage at 40 cm separation.) This is strong evidence that the power factor is small, for any power loss would be expected to vary with one of the variables, either distance or voltage. The measurements against the water resistor give the sum of the power factor of the condenser and the phase angle of the resistor. The results are given in Table 2 and the figures agree closely with the calculated angle of the resistor, confirming the conclusion that the power factor of the condenser is negligibly small. Measurements at the high-voltage end of the water tube could not be made above 100 kV, as the wooden frames carrying the guarded plates of the air condenser would not withstand higher voltages. They were made of pitch pine. If methods involving the use of the measuring plates and instruments at high voltages were regarded as important, it would be better to use American whitewood which, in a plain unvarnished condition, has been found to have exceptionally good insulating properties.

The results obtained, indicating close agreement between such different types of apparatus, appear sufficient to justify the use of condenser or resistor for making phase-angle measurements with an accuracy of the order of 0·0001 radian.

Recent measurements of air condensers sent by cable manufacturers for comparison have provided confirmation of the " purity " of the N.P.L. condenser. As far as the evidence goes (i.e. up to 150 kV), no measurable power factor appears before flash-over, and at 20 cm separation the condenser appears to be suitable for use at 200 kV. Measurements on a length of cable of about 50 ft. have actually been made at 190 kV. The condenser is simple in theory and design, requiring no high precision in dimension. It involves no great difficulty (beyond that of space) on account of the high voltage.

On the other hand, a resistor using a closed water circuit is a relatively troublesome piece of apparatus requiring the maintenance of high resistivity in the water and geometrical accuracy in construction. For these reasons it is not so convenient or so reliable a standard as an air condenser of good design.

CONCLUSION.

The authors' conclusions are that an air condenser designed on the lines indicated in this paper is the most reliable standard for phase-angle measurements, and that by its use, and taking the necessary precautions, accurate measurements should be obtained on a Schering bridge. If other methods are employed it is desirable to calibrate the equipment under actual conditions of use against an air condenser.

It is to be noted that the most suitable methods of measuring power factor have proved to be those which measure the quantity desired most directly and conveniently. Of the two principal methods available, the Schering bridge and the compensated wattmeter method, neither requires a knowledge of voltage, current, or power. The required information is obtained as a time/phase relation given in terms of the frequency and of simple variable capacitances, inductances and resistances.

APPENDIX 1.

A diagrammatic scale drawing of the condenser appears in Fig. 14. The plates are made of aluminium, riveted to steel angle-frames. The high-voltage plate is situated between the two low-voltage plates, and has a rounded edge of 3 in. radius to avoid ionization of the air. The two low-voltage plates have a surface 8 ft. (240 cm) long by 4 ft. (120 cm) high, giving a total capacity to the centre plate, at a separation of 10 cm, of about 500 $\mu\mu$F. The guard plates project 20 cm beyond the measuring plates, and cover them at the back except where holes are cut to admit porcelain supports. The low-voltage and guard plates are supported on a wooden frame by porcelain insulators of the pin type, all pins in the wooden frame being connected to guard or to earth. The frames are mounted on rollers so that separation between high- and low-voltage plates may be varied.

The high-voltage plate is suspended by porcelain rods at the two upper extremities, one from three and the other from two points in the roof. Large flat plates are difficult to obtain, and the high-voltage plate (14 ft. × 7 ft.) is 1 cm out of flat at the centre, i.e. about 10 per cent of the separation when the latter is 10 cm.

Design of the Edges of the Plates.—The design of the edges of the plates was based on the results of an investigation of the electrical stress at the surface of model electrodes immersed in an electrolytic tank. The method is used by the Aerodynamics Department of the National Physical Laboratory for studying flow past aerofoils, the hydrodynamical problem being mathematically identical with the electric-field problem. Equipotential surfaces are traced out by a pantograph attached to an exploring electrode in a tank 4 ft. 3 in. × 2 ft. 3 in. × 1 ft. deep, a valve amplifier transmitting to telephones the potential difference between this electrode (a fine platinum wire projecting from a thin glass tube) and a point chosen on a potential divider connected across the supply (Fig. 10). The main object was to study the increase of stress at the edges of the plates, trying various curvatures, so that the design could be founded on a knowledge of what reduction of working voltage might be expected due to local increase of the electric field. Typical results of these experiments are given in Figs. 12 and 13. The section of the condenser is shown diagrammatically in Fig. 11. The boundaries to be considered are the edge of the high-voltage plate (radius Q), the external edge of the guard plate (radius S), and the adjacent edges of the guard and low-voltage plates (radius R). It is desirable to make

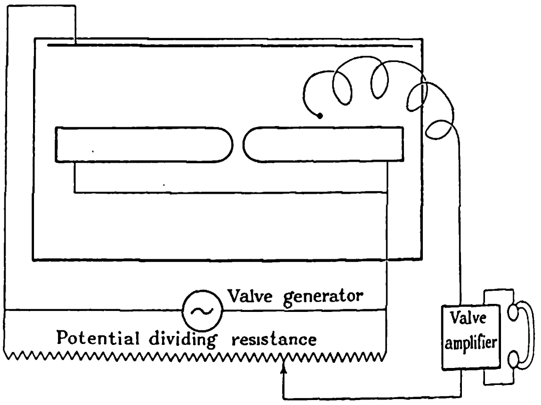

FIG. 10.—Diagram of connections in experiments.

the radius R fairly large compared with the irregularities of the flatness of the surfaces and comparable with the dimension X of the gap between the guard and low-voltage plate. From general principles, the increase in electric stress at the surfaces near such gaps in the case of a parallel-plate condenser will depend chiefly on the ratio of the curvature to the size of gap, and will be nearly independent of the distance of the high-voltage plate when this distance is fairly large compared with the gap and the curvature. A series of experiments was made, varying the gap X for a given value of R. These measurements were made for varying values of the main separation D, and the results are given in Table 3, which indicates the increase of the electric stress in the neighbourhood of the gap X, the experimental results for various gap distances being shown in Fig. 14.

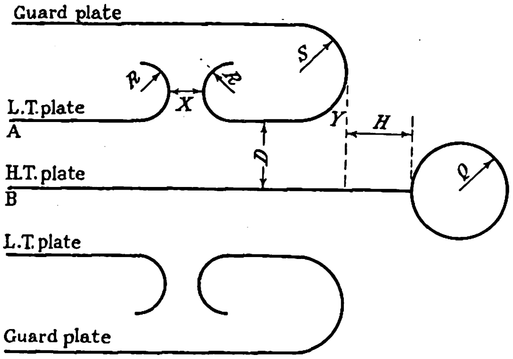

FIG. 11.—Proposed section of air condenser.

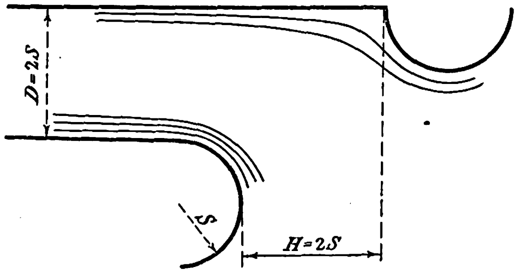

FIG. 12.—Curvature of edge of guard plate.

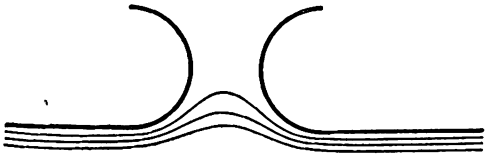

FIG. 13.
Separation $D = 2R$
Gap $= R$

The "crowding ratio" is defined as $(a - b)/a$, where b is the distance between equipotential surfaces near X where they are most crowded, and a is the distance apart of the same surfaces where the gradient is uniform at some distance from the edges. The sensitivity and consistency of the measurement of the crowding ratio, using models of a radius of curvature of 2 in., was about 0·05 and the values are given to this accuracy, with sometimes a plus or minus sign to indicate a little more or less when the measurements appeared to justify it. Table 4 gives the results for the exposed edge of the guard plate; a corresponding experimental diagram is shown in Fig. 12.

The increase in stress at the adjacent edges of the low-voltage plate and the guard plate does not appear to vary appreciably with the distance from the high-voltage plate when this distance is fairly large (Fig. 13). If the edges are rounded with a radius of a value more than twice the gap between them, the local increase in stress appears to be less than 10 per cent, at any rate for edges having a radius greater than 0·1 of the distance between high- and low-voltage plates. Smaller radii could not be accurately studied with the equipment available. The radius, S, required for the outer edge of the guard plate for the same local increase appears to be at least 0·75 of the distance between the high- and low-

$10R$	0·1−	0·1+	0·1+	0·15+	0·25

voltage plates. The radius Q of the edge of the high-voltage plate depends on the shape and proximity of walls, floor, etc., and may reasonably be about the same as S, that of the outer edge of the guard plate.

The values adopted for the condenser have been $X = \frac{1}{2}$ in., $R = 1$ in., $S = 3$ in., $Q = 3$ in. and $H = 7\frac{1}{2}$ in.

The results, as indicated in the description of the experiments made on the condenser, have shown that the design has proved a satisfactory engineering compromise between the various factors involved. When the voltage is raised to the flash-over point it has been found that, if the separation is 10 cm, spark-over usually occurs to the measuring plate, sometimes at the measuring plate and sometimes at the guard at 15 cm separation, and at the guard plate at 20 cm separation; so that the edges of the plates do not appear to be a source of weakness at working distances. A separation of 10 cm is suitable for measurements at 100 kV, and a separation of 20 cm for 200 kV.

TABLE 4.

Separation D	"Crowding ratio" at Y. Radius $Q = S$

$4S$	—	0·35	—	—	0·3

The problem of electrical stress may also be investigated mathematically.* The theoretical treatment appears to give higher values for the increase of stress at edges than those obtained by the experimental method.

APPENDIX 2.

The measuring section of the resistor consists of 2 tubes in the centre about 1 in. apart, and the guard system of 12 tubes symmetrically spaced on a circle of 9 in. diameter around the main tubes. The tubes are 2 metres long. The water flows up half the tubes and down the other half; it is circulated through the tubes and a tin-lined cooler by a small centrifugal pump lined with tin to prevent contamination. A 20-gallon galvanized reservoir is also included in the circuit. The end connections of the tubes are constructed of gun-metal castings and $\frac{1}{2}$-in. copper tubes and are also lined with tin. Glass tubing was found to be too fragile, and specially-drawn Keramot tubing was obtained from Messrs. Siemens Bros. and Co. The guard tubes are of $\frac{3}{16}$ in. internal by $\frac{1}{2}$ in. external diameter, and the main tubes of $\frac{7}{16}$ in. internal by $\frac{9}{16}$ in. external diameter, and all tubes of one size were forced through the same die in order to ensure uniformity of cross-section. Two lengths of 1 metre are joined to form a unit, and the mid-points of the "up" and "down" tubes are connected together electrically so as to maintain equality of potential distribution when the temperature-rise is considerable. Cocks are fitted, and the flow is adjusted to allow the same temperature-rise in main and guard tubes. The main tubes are supported at the top by porcelain from the guard casting, and at the bottom are connected by lengths of rubber hose to earthed joints in the water circuit. The water in these connections has a high resistance whose shunting effect on measuring apparatus is negligible, but it is shielded from the high-voltage field by an earthed screen and the shunting effect of its earth capacity must be allowed for. The tube system is surrounded by an earthed wire cage 6 ft. square.

Calculation of Capacity.—The assumption of a uniform distribution of charge implies an approximately uniform potential along the tubes. An approximate value for the capacity can therefore be derived on this assumption, and the capacity of the resistor can be regarded as approximately uniformly distributed.

Phase Angle of Resistor with Uniformly Distributed Capacity to Earth.—If at a point of the resistor the distance to the earthed end be x, the voltage V, and the current i, the total length, resistance, and capacity of the resistor being l, R, and K respectively, then the current and voltage relations are:—

$$-(dV/dx) = (R/l)i$$
$$-(di/dx) = (jK\omega/l)V$$

Writing V_1 for the applied voltage, I_1 for the current at the high-voltage end, and I_0 for the current at the low-voltage end, we obtain:—

$$(V_1/I_0) = R\,(1 + \tfrac{1}{6}jRK\omega - \tfrac{1}{120}R^2K^2\omega^2 \ldots)$$
and
$$(I_1/I_0) = 1 + \tfrac{1}{2}jRK\omega - \tfrac{1}{24}R^2K^2\omega^2 \ldots$$

The angle between V_1 and I_0 is therefore $\frac{1}{6}RK\omega$, I_0 lagging, and the angle between V_1 and I_1 is $\frac{1}{3}RK\omega$, I_1 leading.

Potential Distribution along Resistor.—The previous calculation assumes a uniform distribution of potential along the resistor.

The actual deviation from a uniform distribution is given by the expression $V_1(x/R)(\frac{1}{6}K\omega j)\{R - (x^2/R)\}$ which has a maximum value of $(jRK\omega/15{\cdot}6)V_1$ when $x = R/\sqrt{3}$.

For the guard system of the resistor described this value is about 0·001, corresponding to a length of about 2 mm of tubing, an amount which will not affect the efficiency of the shielding of the main tubes.

Compensation for incomplete shielding.—If the capacity between main tubes and guard be C_{MG} and the main tubes be prolonged at the high-voltage end by $\frac{1}{n}$-th of their length beyond the guard tubes, the phase angle of the current in the main tubes is altered and its lead increased by $\frac{RC_{MG}\omega}{6n}$ radian at the low-voltage end, and its lag increased by $\frac{RC_{MG}\omega}{3n}$ radian at the high-voltage end. The errors introduced by the capacity, C_{ME}, of the main tube to earth can therefore be eliminated by making n equal to (C_{MG}/C_{ME}). In the case of the resistor described, calculations of capacity were checked by audio-frequency measurements, whence C_{MG} and C_{ME} were found to be about 40 and $1{\cdot}3$ $\mu\mu$F, and compensation was obtained by increasing the length of the central tube by 7 cm.

---

* J. D. COCKCROFT: "The Effect of Curved Boundaries on the Distribution of Electrical Stress round Conductors," *Journal I.E.E.*, 1928, vol. 66, p. 385.

Temperature-rise of the Water.—The relation between the resistivity of a solution and the temperature varies with the solute and the concentration, but experiments on the water used in the resistor described indicated that the specific resistance at $t°$ C. could be expressed in the approximate form $\rho_t = 40\rho_{20}/(20 + t)$. Probably this relation holds approximately for most water supplies.*

Using this expression it is possibie to calculate the temperature-rise in a water column.

Let ρ_t = specific resistance at $t°$ C. (ohms),
t_1 = temperature at inlet (° C.),
t_2 = temperature at outlet (° C.),
I = current (amperes),
A = area of column (cm^2),
u = velocity of water (cm per sec.),
V = voltage applied, and
l = length of column (cm).

Assuming that all the heat is carried away by the water, then at a distance x along the column:—

$$dt = \frac{I^2 40\rho_{20}dx}{4{\cdot}18uA^2(20 + t)}$$

giving
$$t_2 = \frac{20 + t_1\left(\frac{1}{2} + \frac{167\cdot 2\rho_{20}lu}{V^2}\right)}{\frac{167\cdot 2\rho_{20}lu}{V^2} - \frac{1}{2}}$$

In the case of the resistor described, with ρ_{20} equal to 30 000 and a velocity of about 80 cm per sec., the application of a voltage of 150 000 should produce temperatures of 15° C. half-way up an " up " tube, 20° C. at the top, 26° C. half-way down a " down " tube and 33° C. at the outlet, the inlet temperature being 10° C. When the inlet temperature is 20° C., the temperatures produced will be 26° C., 33° C., 41° C., and 50° C. respectively. During very cold weather, with the inlet temperature below 10° C., an outlet temperature of 25° C. was observed. In more usual conditions the following readings were taken:—

Resistor inlet	22° C.
Resistor outlet	52° C.
Cooling-water inlet	15° C.
Cooling-water outlet	20° C.

Maintenance of Water Resistivity.—During the experiments the resistivity was well maintained at 30 000 ohms for 4 months. After refilling for experiments at higher voltages than 150 000, however, the resistivity, though higher at first, was after a few days lower than before, and the question of contamination appears to be troublesome if higher resistivities are required.

APPENDIX 3.

Power Factor and Power-Factor Measurement on a Non-Sinusoidal Wave-form.—The power factor of a condenser with series resistance will be proportional to frequency, and that of a condenser with shunt leakance inversely proportional to frequency. Loss due to dielectric hysteresis, however, may be a constant quantity per cycle, thus increasing with frequency at the same rate as capacity current and maintaining a constant power factor. In the following reasoning a power factor independent of frequency is assumed, and some measurements made at frequencies from 25 to 90 cycles per sec. suggest that this may be a sufficiently good approximation for the purpose.

Power Factor.—Power factor is usually defined as watts/volt-amperes, so that power loss can be calculated from cable data. Alternating-current ammeters and voltmeters give R.M.S. values, so that the power factor determined by such instruments will be

watts/[volts (R.M.S.) × amperes (R.M.S.)].

Let e_q = R.M.S. value of qth harmonic of voltage,
i_q = R.M.S. value of qth harmonic of current, and
$a = \cos\phi$ = power factor on a sinusoidal wave-form.

For a capacity load, $(i_q/i_1) = q(e_q/e_1)$ and the expression watts/[volts (R.M.S.) × amperes (R.M.S.)] is equal to

$$\frac{\frac{\omega}{\pi}\int_0^{(2\pi/\omega)}\Sigma e_q\sin(q\omega t + \theta_q)\Sigma i_q\sin(q\omega t + \theta_q + \phi)dt}{\sqrt{\left\{\frac{\omega}{\pi}\int_0^{(2\pi/\omega)}[\Sigma e_q\sin(q\omega t + \theta_q)]^2dt\right\}}\sqrt{\left\{\frac{\omega}{\pi}\int_0^{(2\pi/\omega)}[\Sigma i_q\sin(q\omega t + \theta_q + \phi)]^2dt\right\}}} = \frac{\Sigma q\left(e_q^2/e_1^2\right)}{\sqrt{\left\{\Sigma\left(e_q^2/e_1^2\right)\right\}}\sqrt{\left\{\Sigma q^2\left(e_q^2/e_1^2\right)\right\}}}\cdot a \quad . \quad (1)$$

Measurement by Schering Bridge.—Using a tuned galvanometer, the harmonics do not affect the reading and the fundamental value is obtained.

Measurement by Compensated Wattmeter Methods.—The current in the wattmeter voltage-element is caused to lag by an angle $L\omega/(R + S)$ or $RC\omega$ (page 1133). If this angle be β for the fundamental, the angle for the qth harmonic is $q\beta$, so that the dynamometer measures

$$\frac{2\pi}{\omega}\int_0^{(2\pi/\omega)}\left[\Sigma e_q\sin(q\omega t+\theta_q-q\beta\right]\left[\Sigma i_q\sin(q\omega t+\theta_q+\phi)\right]dt$$
$$=\Sigma e_q i_q(a-q\beta)$$

The dynamometer reads zero, so that

$$\beta = \frac{\Sigma e_q i_q}{\Sigma q e_q i_q}\cdot a = \frac{\Sigma q\left(e_q^2/e_1^2\right)}{\Sigma q^2\left(e_q^2/e_1^2\right)}\cdot a \quad . \quad . \quad . \quad (2)$$

---

* J. S. Carroll: "Some Features and Improvements on the High-Voltage Wattmeter," *Transactions of the American I.E.E.*, 1925, vol. 44, p. 1010.

Inspection shows that this expression is less than a, so that a low reading is obtained.

Applications to a Bad Wave-form.—During the earlier work at low voltages, measurements were made on a length of cable using a supply of approximately triangular wave-form. The results are given in Table 5.

TABLE 5.

Measurements on a Triangular Wave-form.

Method of measuring power factor	Power factor	
	At 10 kV (R.M.S.)	At 20 kV (R.M.S.)
By wattmeter (direct) ..	$0{\cdot}007_0$	$0{\cdot}016_2$
By compensated wattmeter	$0{\cdot}006_2$	$0{\cdot}013_6$
By Schering bridge ..	$0{\cdot}007_0$	$0{\cdot}016_4$

The wave-form was analysed and the formulæ (1) and (2) were calculated. The ratios given by calculation and those obtained by measurement are compared in Table 6 and, in view of the sensitivity and accuracy of the measurements at that stage of the investigation, can be considered to be in agreement.

TABLE 6.

Measurements on a Triangular Wave-form.

Ratio	Observed		Calculated
	10 kV (R.M.S.)	20 kV (R.M.S.)	
$\left(\frac{\text{Direct wattmeter value}}{\text{Schering bridge value}}\right)$ ..	$1{\cdot}0_0$	$0{\cdot}9_9$	$0{\cdot}9_5$
$\left(\frac{\text{Compensated wattmeter value}}{\text{Schering bridge value}}\right)$	$0{\cdot}8_8$	$0{\cdot}8_3$	$0{\cdot}8_5$

The Schering bridge value at 10 kV is the same as that obtained on a sinusoidal wave-form. That at 20 kV is higher, being $0{\cdot}016_4$ compared with $0{\cdot}011_6$. The cable was evidently in bad condition with much ionization at 20 kV, particularly with the triangular wave-form, which would have a higher peak voltage.

DISCUSSION BEFORE THE METER AND INSTRUMENT SECTION, 4TH APRIL, 1930.

Dr. L. G. Brazier: An important paragraph of the paper states that although "large discrepancies were observed between the results obtained by the different methods, . . . the various sources of error were eventually determined and agreement to 0·0001 power factor was reached by all the methods." This is a fine result, and I feel that the paragraph must cover many hours' work, and the solution of many complicated problems. As Dr. Rayner has pointed out, it is difficult to assess the absolute accuracy of power-factor measurements, and this is particularly the case when the cable is buried and the lead sheath earthed. I find it rather disappointing that the special difficulties that arise in this case have not been discussed in the paper, for it is an essential condition of a large proportion of cable research work that the cable should be buried. In carrying out these measurements an alarming number of factors which cause serious errors have been discovered. As an example, there is some curious interaction between the primary and secondary of the transformers, particularly in the case of the unscreened transformers, so that errors of 100 per cent and greater can be introduced by manipulating the primary connections; for example, by changing the voltage-regulating device from the live side of the primary to the neutral side. However, we have been able to make successful power-factor measurements on buried cables up to 10 miles in length. It is interesting that at this length the effects due to the wavelength of the 50-cycle waves are beginning to become important. The result is that the apparent power factor of the cable is always greater than the true power factor of the dielectric, and on a 10-mile length the difference may amount to nearly 0·5 per cent power factor, or 50 times the accuracy aimed at by the authors.

Mr. T. N. Riley: The paper is long overdue, and would have been invaluable 10 years ago when the question of dielectric loss in cables began to assume major importance. At that time apparatus was available in convenient form for few of the methods described, the Duddell-Mather wattmeter being practically the only type on the market. Owing to the lack of information such as the authors have now put forward we carried out in the laboratories of Messrs. Standard Telephones and Cables, Ltd., a series of comparative tests by a number of methods, including three which the authors have not mentioned in addition to those which they have described. These were the a.c. potentiometer method, the Heaviside bridge method, and the thermal wattmeter method. Time does not permit a detailed description of these to be given, but it may be of interest to say that we found the Heaviside bridge at least as accurate as, and in some respects more convenient than, the Schering bridge. The thermal wattmeter, employing a Moll thermopile, was somewhat insensitive for short-length tests, but appeared to be worth further consideration for field tests on long lengths where heavy charging currents had to be dealt with. Our conclusions were generally in accordance with those of the authors, viz. that a bridge method is most suitable for accurate work, though I do not agree that the Schering bridge has any special advantage over the Heaviside which would justify its being set up as an absolute standard. Wattmeter methods are satisfactory only if the test-results have been checked against a bridge method. The former objection to the bridge methods—that they could not be satisfactorily employed on a 3-phase test—has now disappeared, since the 3-core cable without equipotential sheath or its equivalent is now practically obsolete and only single-phase tests need be carried out. The authors' method of grouping errors according to their source may shorten the paper, but I think it would be much simpler to read if, apart from cable terminations, the errors were associated with the methods which are subject to them. The arrangement hardly brings out sufficiently that the main advantage of the bridge is not so much its freedom from errors as that, when properly set up, the errors do not vary with the applied voltage as they do in other methods. In Fig. 5 the authors show the direct potentiometer method with a shielded wire resistor. While I agree that this is the most satisfactory arrangement, there are a number of testing outfits in existence having oil-immersed resistances without the shielding. In such resistances capacity between sections causes the wattmeter to read high, whereas capacity to earth causes the wattmeter to read low. Over certain limited ranges of voltage these two effects may appreciably neutralize each other, so that the corrections to be applied are not serious even without the shielding. This applies to instruments on the low-tension side as shown. If the instruments are placed on the high-tension side the errors are cumulative, both causing the wattmeter to read high. In discussing the errors arising from a non-sinusoidal wave the authors have confined their remarks to the effect on the values as measured by different methods of test. The question should really be considered from three standpoints: (1) The real change in the loss or power factor caused by a non-sinusoidal wave, i.e. if the test results are different, is it because there is a change in the quantity to be measured rather than an instrument error? (2) The effect of the non-sinusoidal wave on the measurements made by different methods, i.e. what is the instrument error? And (3) the estimation of field losses from factory tests. (1) The watt losses are always higher with a non-sinusoidal wave than with a sine wave of the same R.M.S. value. The power factor at temperatures of the order of 30° C. is practically the same on either the sine or distorted waves. At higher temperatures the power factor is rather lower for the distorted wave, since the product of R.M.S. volts and amperes increases more rapidly than the watt loss with the higher harmonics. (2) Our conclusions as regards the effect of the non-sinusoidal wave on the methods of measurement are in accordance with the authors', but as regards the direct wattmeter method I think it should be made clear that, although the measured power factor may be the same as or slightly lower than that measured by the Schering bridge, the watt losses actually measured are higher than with a sine wave. If, therefore, a guarantee is to be met in terms of watt losses, this may be exceeded if measurements are made on a distorted wave, although on a sine wave the loss would meet the guarantee. If comparative tests are to be made on the same sample in different localities under different conditions they should therefore be made by a bridge method and in terms of power factor. (3) If the value of the power factor as measured on the Schering bridge in the factory at the fundamental frequency is used to calculate the expected field losses with the cable warm, the value obtained will, in general, be higher than the real losses if the field supply is non-sinusoidal. Any error in estimating watt loss from factory tests is therefore likely to be on the safe side.

Mr. T. R. Scott: The paper gives an excellent résumé of an extremely thorough and accurate investigation carried out by Dr. Rayner and his colleagues during the last few years. Only those in direct contact with the problems associated with dielectric-loss measurements can assess the amount of painstaking work on details required to produce the degree of accuracy in measurement recorded. It is possible, however, that the condensed version of this prolonged investigation given in the present paper may create a false impression in that it may be presumed that all the problems have been worked out and simplified to such an extent that the degree of accuracy mentioned in the paper can always be obtained in practice. This is hardly the case, for when the methods of measurement are transferred from the laboratory to the routine test-bay—or even in certain tests in the laboratory—new aspects of the general problems indicated in the paper are encountered and, in many cases, the solution of these new problems is extremely difficult. It may be of interest to examine three examples of difficulties encountered which are only touched on or altogether overlooked by the authors, viz. (1) the protection of condensers from impurities in the atmosphere, (2) end losses in cable measurements, and (3) measurements with cable sheath earthed. The authors advocate the use of one of two types of air condenser, namely, the flat-plate type as described or the cylindrical type, and infer the use of ordinary laboratory atmosphere as the dielectric. When such condensers, however, are employed in test bays in the factory, especially in locations subject to fog or impure atmosphere, troubles due to the variation of the atmosphere and its impurity are encountered. Dust, either suspended in the air or settled on the apparatus, introduces undesirable features into the dielectric characteristics of the condenser. Humidity is another enemy of accuracy and, since the relative humidity is in general continually varying, the characteristics of the condenser may also vary continuously. Data recently published[*] suggest that air condensers apparently free from loss at 50 per cent relative humidity may acquire phase angles of the order of 0·0002 radian at relative humidities in the neighbourhood of 80 per cent. This variation of characteristic constitutes a serious danger, since the condenser is the sole standard of loss, and acquisition of loss in the standard may be unobserved for some time. In this connection we have found that tests with high-voltage direct current and/or high-frequency alternating current are useful in checking up the general state of the condenser from day to day, although, of course, they do not indicate the precise loss characteristic of the instrument. While robust air condensers screened off from contamination by the atmosphere can be constructed, and are in fact in commercial production, for voltages of the order of 100 kV, the position is not so satisfactory for test pressures of the order of 150 kV. This voltage is rapidly becoming of commercial importance and, since protected air condensers appear to be difficult to construct for voltages of this order, it may become necessary to employ some other type of dielectric. Compressed gases and oils have been considered in this connection and, since both types of dielectric exhibit low loss and reasonable constancy of loss, there appears to be no objection to their use, at least as factory sub-standards. Turning to the question of end losses in cables, it is somewhat remarkable that while the authors devote more than a page to the design of the boundaries of the low-tension plate and guard ring of their air condenser, they dismiss the subject of end losses in cables in a few lines. In passing it might be remarked that, considering the cable as an impure condenser, the problem of the end losses is much more difficult than that of the air condenser in that the value of the specific inductive capacity of the dielectric is tripled and the leakance characteristic may be considerably greater. Since, as the authors state in their introduction, the variation of the power absorbed in the cable with temperature, frequency, etc., affords valuable information, it is of the greatest importance that the results obtained should be independent of end effects. Doubtless owing to the condensed nature of the paper, the authors give the impression that the difficulties encountered may be overcome easily. This may be so in particular cases such as those quoted by the authors, but in the general case, particularly where short lengths of cable have to be examined, the problem is more difficult. In a paper read before the Institution two years ago by Mr. Riley and myself* the importance of the problem was indicated and certain curves illustrating the effects encountered were given. Table A gives an excellent idea of the magnitude of the error involved. The values are abstracted from the curves quoted.

---

[*] J. A. Scott, H. W. Bousman and R. R. Benedict: ' A Thermal Method of Standardizing Dielectric Power Loss Measuring Equipment,'' *Transactions of the American I.E.E.*, 1928, vol. 47, p. 824.

TABLE A.

Voltage	True power factor	Apparent power factor at guard-ring spacings of			
		¼ in.	½ in.	¾ in.	1 in.
5 000	0·0055	0·0080	0·0086	0·0091	0·0093
3 000	0·0050	0·0066	0·0074	0·0078	0·0080

The tests were taken by the Schering bridge method, the guard ring being earthed. In our experience guard rings at spacings of ¼ in. to 1 in. are totally ineffective, although it is obvious that each special case must be considered separately and the guard-ring system designed to meet the characteristics encountered. There appear to be no sound published data on the subject, and recent papers† indicate that the mechanism of end loss is imperfectly understood, although the importance of elimination of the effects is thoroughly appreciated. An investigation on the lines of that carried out by the authors in Appendix 1 on the "crowding ratio" in a case where leakance has also to be considered would appear to be considerably overdue. Dr. Brazier has already touched on certain aspects of the problem of measuring dielectric losses in cables which have their sheaths earthed. This type of test is rapidly becoming of importance, since efforts are now being made to determine the dielectric characteristics of cables actually in service or under conditions which simulate those encountered in service. A whole series of new problems are encountered in such tests, but I shall confine my remarks to one particular problem. As mentioned by the authors on page 1134, errors may be caused in any method of measurement by capacity effects between the high-voltage apparatus and the low-voltage apparatus. Certain of these effects are between the high-voltage apparatus and apparatus at earth potential. It will be observed that if the earth connection in (say) Fig. 4 is transferred to the cable sheath the capacity currents will flow through R_3 and be measured as parts of the cable loss. To eliminate this error it is necessary to take two readings, one with the cable disconnected and one with the cable connected. A considerable portion of the correction factor thus deduced may, however, be due to the capacity and leakage effects in the transformer. In cases in which, for test purposes, an auxiliary loading transformer is introduced the transformer contribution to the correction factor is inevitably large. It is found also that the stray currents in this part of the circuit vary with the load on the transformers, so that the correction factor deduced from open-circuit tests or tests under light load conditions is only an

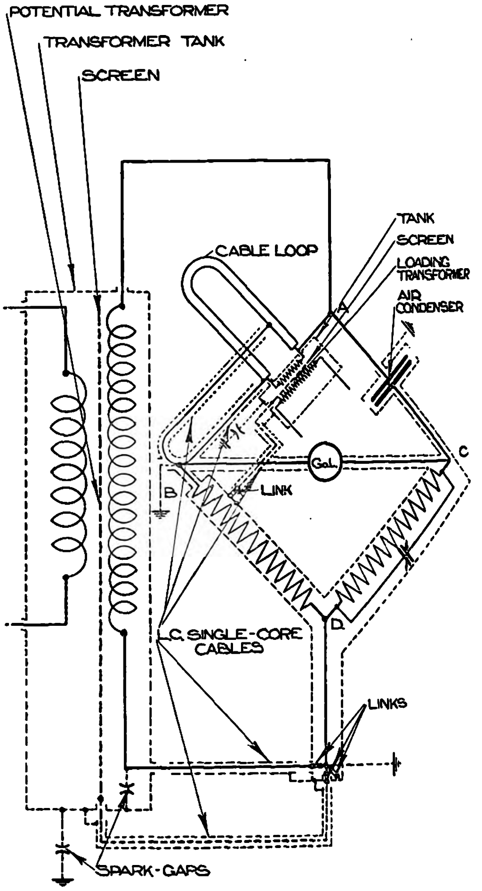

FIG. A.—Schematic diagram of Schering bridge for power-factor measurement on high-voltage power cables.

† E. H. SALTER: "Guarding and Shielding for Dielectric Loss," *Transactions of the American I.E.E.*, 1929, vol. 48, p. 1294.

approximation. To overcome this difficulty we have incorporated in our latest test plant screened transformers lightly insulated from earth. These enable us to eliminate this type of error completely. The schematic diagram of the circuit is shown in Fig. A. It will be seen that the transformer tanks and screens may be connected to the bridge screens and linked into the bridge circuit at the D point (which in this type of test is disconnected from earth), thus shunting the R_3 measuring arm. Other stray currents to earth enter the bridge circuit at B and are measured, so that the test with the cable disconnected is still necessary. This test, however, now gives a firm correction factor instead of one associated with the degree of loading on the transformers. A careful study of the circuit in Fig. A shows that the arrangement is very flexible and that the various sources of error can be determined separately if desired, and measures taken to eliminate or reduce undesirable effects. The points referred to above indicate, I think, that, notwithstanding the success obtained by the authors in standardizing certain test circuits, there is still need for a considerable amount of research work on the subject of practical dielectric-loss measurement. Many of the outstanding problems are urgent and it is to be hoped that at no distant date a series of papers on the many aspects of the subject will carry on the work so ably introduced by the present paper.

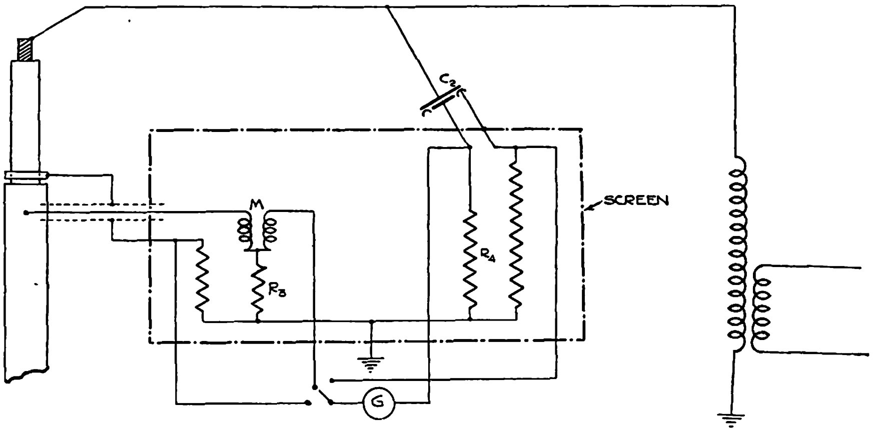

FIG. B.

Mr. R. A. Brockbank: The subject of the paper is rapidly becoming of considerable importance in general electrical research and in many branches of industry. During the last 5 years we have carried out an enormous amount of work on the measurement of dielectric losses, and the authors will, I think, agree with me that the accurate determination of such exceedingly small losses under the particular test conditions is a very fine art. After specializing on the subject for some time, we can get to know the main precautions and safeguards which have to be taken, but there still arise at times certain little discrepancies in power loss which may take a lengthy and painstaking investigation to single out. The apparent negative power factor of the authors' standard condenser is a case in point. The suggestion given is quite logical, and we have obtained a similar result. The authors have dealt mainly with the compensated wattmeter and the Schering bridge type of measurement. For these circuits they have developed resistance and capacity units which are, as far as possible, free from phase defects. One or two other circuits employing a pure resistance or capacity are also worthy of attention. The bridge circuit shown in Fig. B is closely related to the Schering bridge, and was first proposed by Prof. Dawes of Harvard University in 1926. It looks rather more complicated than it actually is, as the complete guard and shield connections have been inserted. The only difference between this circuit and the Schering bridge is that the primary of a mutual inductance M (astatic winding) is in series with the cable, and the secondary is connected in the galvanometer circuit. This variable mutual inductance replaces the Schering bridge condenser (C_4). Balance is obtained by varying M and R_4, and the power factor for normal-loss angles is given by $\omega M/R_3$. We have used this circuit for over 2½ years and have found that it possesses certain advantages over the Schering bridge. The circuit shown is quicker to manipulate, and its sensitivity is an improvement upon that of the ordinary Schering bridge type of measurement. Fig. C shows the thermal wattmeter, which was introduced about 6 or 7 years ago but has not been more fully developed lately. Although I do not suggest that this circuit rivals the Schering bridge or the modified Heaviside bridge, it is remarkable because of its ingenuity, simplicity and

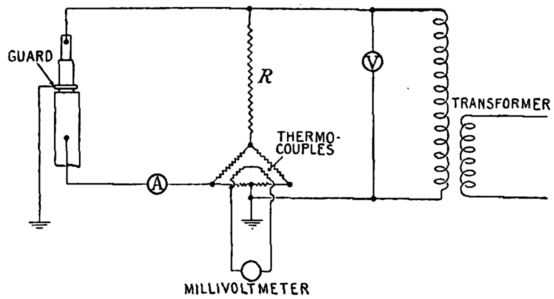

FIG. C.—Thermal wattmeter method of dielectric-loss measurement.

Watts = KR × millivolts.

general robustness. The circuit is unique in that no adjustments have to be made, for, the high-tension resistance having been fixed, it only remains to read the watts from a millivoltmeter. It is suggested that the instrument has a useful sphere in routine measurements on factory lengths of cable and on supply networks, where it could possibly be adapted to give a continuous record of the state of the system. I think that these two methods of obtaining satisfactory power-factor measurements should have been incorporated in the paper; the first because of its practical utility and advantages over the Schering bridge, and the second because it possesses certain spheres of usefulness capable of development in the future. I should like to ask whether as a general practice the authors utilize the circuit of their Schering bridge for maintaining the guards at the same potential as the galvanometer points, or rely on the use of low-value resistance arms and a knowledge of the capacity of these arms to earth. Do they find this quite sufficient in practice? I should like to point out that in the formulæ (page 1133) relating to the compensated dynamometer the authors seem to have neglected the inductance and resistance of the dynamometer and the inductance which they put in series. In their experiment these may have been negligible, but this is not normally the case in practice. R and L must include the total resistance and inductance, respectively, in the branched circuit. The authors have made a condenser 14 ft. long with a capacity of 500 $\mu\mu$F which permits it to be checked directly against the water resistor, but we have had to try other means of correlating the methods. A very usual method adopted to check the accuracy of two different methods of dielectric-loss testing is to take a power-factor run on a cable by each method in turn. This, however, is not entirely satisfactory for accurate calibration, as the state of the cable depends on its previous history; also, during the change-over, variations may occur in temperature, condition of the cable-ends, etc. We have found that it is usually possible to take loss readings by two methods at the same time on one cable. Thus one operator can work a Schering bridge, in the cable arm of which is the current coil of a dynamometer for the compensated wattmeter method, which in turn is balanced by another operator, and simultaneous readings are obtained. Suitable switches can be provided to ensure that no interference exists between circuits. This method has proved very useful and ensures a high degree of accuracy.

Mr. J. F. Watson: I have experienced considerable difficulty in the accurate measurement of the dielectric loss on short lengths of cable such as 5 to 6 yards, even when guarded, the apparent error appearing to be in excess of 20 per cent when the lead sheath of the cable was insulated. When working with lengths of 200 and 250 yards of 66-kV single-conductor cable, however, the error introduced by not guarding appeared to be quite negligible up to pressures of 80 kV. It is quite important from a manufacturing point of view to make accurate measurements on short pieces of cable, so as to find any weak spot there may be on a length of cable, as a defective portion may be as short as 1 or 2 ft. in a length of 200 or 250 yards. Thus, if we assume that one length of cable has a power factor of 0·004, another length having a power factor of 0·0044 may have somewhere along its length a defect of a serious nature. Such a variation of 10 per cent in the power factor, however, does not necessarily point to such a condition, but may be due to a general variation in the dielectric throughout the entire length of the cable, in which case no unsatisfactory performance in operation need be expected.

(*Communicated*): Since making the above remarks at the meeting I have been in touch with Dr. Rayner and his associates, and have carried out further experiments on the measurement of dielectric loss on short lengths of cable. I am now satisfied that, with effective guarding, accurate measurements can be made on lengths of cable as short as 2 yards at pressures up to 80 kV.

Mr. J. K. Webb: In connection with the electrolytic model (Appendix 1), for plotting the field at the surface of model electrodes, the authors' circuit implies the use of audio frequencies. Mr. Emanueli stated in a recent series of lectures on "High-Voltage Cables" which he gave at this Institution that, owing to capacity effects, high-frequency alternating current is unsuitable for such tests, and that he had found a frequency of 50 periods per sec. to be the most satisfactory. I should like to ask the authors what their own experience has been in this connection.

Mr. E. Fawssett: I want this Section to realize that this piece of work is of international importance. It has already formed the basis of a suggested and agreed method for measuring very low power factors, and one which may become the standard in Britain and, further, by the good offices of the International Electrotechnical Commission it may become the agreed international standard, in which case it will greatly simplify comparisons between the products of different countries. I wonder whether meter and instrument engineers realize the extent of the advance which the authors have made in obtaining an accuracy of 1 per cent in the measurement of 1 per cent power factor. Until a short time ago, 10 per cent was considered to be as good an accuracy as could be expected in the measurement of low power factors of the order of 1 per cent. To reduce the figure to one-tenth of this value must have meant a great amount of patient work, as is shown by the fact that this subject has been on the agenda of the Research Committee for 5 years. On page 1133 the authors mention various forms of voltage supply, including tertiary windings and step-down transformers. I would emphasize that our experience in other directions shows that the tertiary winding is particularly apt to give an incorrect ratio, and that it is to be avoided in the absence of most careful tests to prove that the ratio is as expected. The whole work is really summed up on page 1134: "A loss-free condenser is a simpler problem than a resistance without inductance or capacity; and the Schering bridge is the most convenient of all the methods to use." On page 1136 it is mentioned that great trouble was experienced with the contact between the flange of a hole and the nut of a bolt. I should like to ask what was the real cause of this, whether it was merely dirt, an oxidized surface, or the aluminium contact, which is apt to be uncertain.

The method of studying the electrical stress at the edges of the plates by analogy with the hydrodynamic problem is particularly ingenious, and well illustrates how a principle may often be applied to a totally different problem. In Appendix 2, dealing with resistors, it is stated that glass tubing was used at first, but later Keramot tubing was substituted. I am doubtful whether a Keramot tube would keep its proper physical shape at the temperatures which are liable to exist under certain conditions of water supply. Possibly if 50° C. were not exceeded it would be satisfactory, but I should be afraid of trouble if, owing to loading or to warm water at the inlet, the temperature rose much above this figure. The figures with regard to temperature-rise (page 1141) show how quickly the inlet temperature rises. If the inlet temperature is 10° C., which is too low for a south country water supply in summer, the temperature of the water rises 23 degrees above this, and if the inlet temperature is 20° C. the rise is 30 degrees. The increase is very rapid if the inlet temperature is any higher than this, so that this cumulative effect makes the apparatus rather difficult to control and emphasizes one's preference for the condenser.

Mr. C. Dannatt (*communicated*): I am particularly interested in the authors' air condenser, having been associated myself with the design and construction of air condensers for working voltages up to 300 kV. The flat-plate condenser illustrated in Fig. 14 has undoubted advantages from the point of view of the investigatory work described, but I am rather surprised that the authors state in their conclusions that such a condenser is a reliable standard. It appears to me that in designing their condenser they set out with a very inadequate appreciation of the effects of uncontrolled mutual capacitance between the low-tension plate and other parts of the related circuits. Were this not so, I feel they would have avoided the troubles necessitating the subsequent shielding of the insulators supporting the low-tension plate, or the sheathing of the members C (Fig. 14). I prefer to mount the low-tension plate direct from the inside of the guard-ring member. Such mounting avoids the necessity of separately shielding the insulators and earthing the pins of the insulators, which the authors found to be necessary. No specific reference is made to the ratio of guard-ring width to gap spacing, a ratio which should be made as large as is necessary to prevent any mutual capacitance between the low-tension plate and extraneous objects such as leads, or, for that matter, between the low-tension plate and the edges of the high-tension plate where discharge might occur. The effect of too small a value for this ratio is to cause an impurity dependent on the location of surrounding objects and the modification in the electric field produced by them, so that tests with one set of conditions may be no guide to the possible impurity which might arise in other circumstances. The fact that the authors' tests showed the impurity obtained to be dependent on the size of the lead FF, shows their condenser to be liable to such trouble. No attempt has been made to make the condenser a standard of capacitance as well as a standard of purity, in view, I suppose, of the immediate object of the work, but it is an undoubted advantage to cover both requirements in a standard air condenser if possible, and one feels that their work would have been much more valuable if the authors had considered this further aspect of air-condenser design at the same time. With regard to the test results, the authors are to be congratulated on the excellent agreement of the phase-defect tests made on two widely different types of apparatus. It would, however, have been of considerable use if they could have stated more explicitly the range of conditions covered in the tests with regard to stress in the air dielectric, humidity and temperature of the atmosphere, and precautions taken against dust and dirt deposits on the air-condenser surfaces. It is, for instance, quite feasible to use working stresses of 13 or 14 kV (R.M.S.) per cm with good machined surfaces, and as considerations of space occupied are very important with high-voltage condensers it is desirable to use as high a stress as is consistent with purity. The authors are also doubtless aware of certain results advanced in America regarding the effect of humidity on the power factor of air condensers. I should be glad to know their views on these matters.

Dr. E. H. Rayner and **Messrs. W. G. Standring, R. Davis** and **G. W. Bowdler** (*in reply*): It was far from our intention to suggest that the accurate measurement at high voltages of dielectric losses had now become a simple problem, and we agree with Mr. Scott that continual vigilance is necessary in making such measurements. For this reason, and also to avoid repetition, it was thought preferable to describe various types of error according to their source, suggesting to the experimenter how errors might arise, rather than hoping to give him " foolproof " instructions. The shielding of the condenser is described in detail to give an idea of the magnitude of the errors due to inadequate shielding, and the plate form proved useful for demonstrating this. The condenser was designed for use with a separation of 10 to 20 cm between the plates, and at these working distances the wooden framework did not require shielding and the high-tension conductor had no effect. The necessary dimensions of the guard depend on the proximity of neighbouring objects; but in general it may be taken that the guard plates should extend beyond the measuring plates a distance at least as great as the separation between high- and low-voltage plates. With regard to the end shielding of cables, each case must be treated on its merits, the dimensions and spacing of the guard rings depending on the length and diameter of the cable. The Keramot tubing of the water resistor has undergone distortion and this troublesome piece of apparatus is not now used as a standard, though in proving the air condenser it was considered invaluable. No effect of humidity on the phase angle of the condenser has been observed, and in the American papers referred to in the discussion there is not sufficient information to make it clear that the effect produced was due to the air and not to ineffective design or to the insulating materials used in the construction of the condenser. Considerable experience over the whole range of frequency from zero to 10 million cycles per sec. indicates that ordinary humidities do not affect the power factor of air as such, to the accuracy aimed at in this work. Secondary effects due to design and use of solid materials are another matter. The condenser described in this paper was developed as a standard of phase angle. The plate form was considered simplest for investigatory work. It enables a variable capacity to be obtained large enough for direct comparison with a resistor at different voltages. For bridge measurements a large capacity is not necessary, and for a standard of capacity the cylindrical form is certainly preferable. We now have a nitrogen-filled condenser of fixed capacity for 290 kV at 15 atmospheres gas pressure. This seems the most suitable form for a standard of convenient dimensions. The maximum electrical working stress of the plate condenser, estimated from the tables in Appendix 1, is about 13 kV (R.M.S.) per cm, occurring at the edges of the guard plates. The error referred to in a cast-iron condenser as assembled by the makers was due to a bad contact between iron and steel; this may have been caused by traces of paint. In the electrolytic experiments for plotting equipotential surfaces the water resistivity was 3 000 ohms per cm cube and the effects of capacity were negligible. The only difficulty arose from polarization effects when the electrodes were made of different metals.

The problem of making cable measurements with the sheath earthed has been ably dealt with by Dr. Brazier and Mr. Scott. The large error due to transformer capacity currents had been observed by us in developing a method for 3-phase measurements; but their method of eliminating this error by using a special transformer with shielded secondary seems much preferable to making two measurements. Dr. Brazier's observation on long lengths of cable is particularly interesting.

Of the two methods of measurement referred to by Mr. Riley and Mr. Brockbank the thermal wattmeter appears insensitive and unsuitable for use as a standard method, though it may be useful for routine purposes. The bridge method only differs from the Schering bridge in the method of obtaining phase-angle balance. Inductances are seldom perfectly astatic and for a standard method we prefer the condenser adjustment, which is not influenced by stray magnetic fields, and it can be as flexible and sensitive as the other. It is satisfactory to find that Mr. Riley's experience on measurements with different wave-forms agrees with our theory and limited experience. Our purpose was to point out that on bad wave-forms the different methods do in fact measure different quantities, and the work was done in order to obtain some idea of the relation between these quantities. If watt losses in the field be calculated from measured values of R.M.S. volts and R.M.S. amperes, using the power factor obtained with a sinusoidal supply, the figure calculated will be higher than the real losses, if the field supply be non-sinusoidal. If, however, the figure be calculated from a measurement of R.M.S. volts and the known capacity of the cable, the value obtained will be lower than the real losses.

A WIRELESS BROADCASTING TRANSMITTING STATION FOR DUAL PROGRAMME SERVICE.

By P. P. ECKERSLEY, Member, and N. ASHBRIDGE, B.Sc.

(*Paper received 4th March, and read before the* WIRELESS SECTION *7th May,* 1930.)

SUMMARY.

The B.B.C. Regional Scheme involves the construction of a number of twin wireless transmitting stations, each capable of radiating simultaneously two programmes on different wavelengths, and each at a power of 50 kW in the aerial. This paper describes the first of these twin transmitters, erected at Brookmans Park, Hertfordshire, to serve London and the Home Counties.

The paper deals with the considerations underlying the choice of sites for such broadcasting stations, the type of power supply adopted, and the factors contributing to reliability in operation, as well as with the wireless transmitters themselves. Detailed considerations underlying the design of such transmitters have been avoided in the anticipation that they will form the subject of a further paper; but, nevertheless, some information in regard to the essential and major points in their design is contained herein.

The paper deals further with the general station lay-out, the building and the auxiliary services, as well as with low-frequency apparatus for supplying modulation to the transmitter and apparatus for testing and monitoring purposes, etc.

Of particular interest is the use of high-tension direct-current machines at this station for the production of high-tension voltage for anode supply to the main power valves. The type of generator developed especially for this work is considered in some detail.

INTRODUCTION.

This paper describes a wireless broadcasting station, installed near London, designed to give two transmissions from virtually the same point on two different wavelengths. Thus a single building contains a power-supply equipment and two identical wireless broadcasting transmitters each arranged to supply modulated high-frequency energy of different frequency to two separate aerial systems.

The station is the first of the "twin" transmitting stations basic to the so-called "Regional Scheme" for British broadcasting. It is true that two different programmes have been radiated during the past two years from the Corporation's station at Daventry, but in this case the two-wavelengths service is given by the use of two separate transmitters in two different buildings a few hundred yards apart; moreover, the difference in carrier-wave frequency is larger.

The implications of the B.B.C.'s Regional Scheme are well known and it suffices to remark here that there will be 5 centres of dual-programme service. The 5 centres of transmission will be located in Scotland, North (Industrial) England, South-East England (based on London), the Midlands, and the South-West (to serve both the West and South Wales areas). Two are completed, Daventry for the Midlands and the station under discussion for London and South-East England.

CHOICE OF SITE.

The site for each of these twin-wavelength transmitters has to be chosen not only in terms of the regions and populations it has to serve, but also in relation to the distribution of the broadcasting service that it supplants.

The selection of the site for the new London station thus had to take into account the fact that, for several years, listeners in London and the neighbouring counties had been accustomed to take their service from a 2-kW station located in the heart of the West End. This location of the old single-wave-service London transmitter had accustomed listeners to a certain distribution of field strength to which they had automatically adapted themselves. Obviously, the measure of dislocation that occurs on changing over from an old to a new station is, to a number of listeners, the ratio of new to old field strength.

A site for the new London station had thus to be chosen on the periphery of the London area. The site, however, could not be so far away from the centre of London that the station erected upon it, albeit of greater power than the old, would give a weaker field strength over all London than the old, and not so near to the centre of London that it would produce intolerable "wipe out" to a great number of persons, owing to the presence of too great a field strength in densely populated areas.

These considerations determined the distance of the new site from the old. It remained to determine the direction of the new site in relation to the old. It would have been quite absurd to have chosen a site along the Thames estuary, eastwards, as much of the service area of the station would have lain over the North Sea; a southerly direction was chiefly debarred by the fact that civil aviation regulations prohibited the erection of masts on the top of the North Downs, which were about the right distance away. A western site would have given a distribution of field strength which would rob Essex and the Eastern counties of good service where strong field strength is required to overcome jamming from the transmissions from sea-going vessels, and, furthermore, would have produced quite unnecessarily strong service in an area already covered by Daventry (5XX and 5GB) transmissions. A northern location seemed, therefore, in all the circumstances to be the best. The northern site was furthermore recommended inasmuch as the existing telephone cables, essential for connecting the studio headquarters in London to the transmitter, were found to be most suitable in a northerly direction.

Description of Site.

The site finally chosen lies on the east side of the Great North Road a few miles on the London side of Hatfield. It is some 15 miles from the centre of London. Its name is derived from a large estate in the neighbourhood, Brookmans Park. The field which contains the station is 34 acres in extent and is, to all intents and purposes, perfectly flat. Flatness of site is of great advantage in laying out the aerial systems. It also allows the station to be built on one level and so produces a pleasing appearance, in addition to effecting considerable economy.

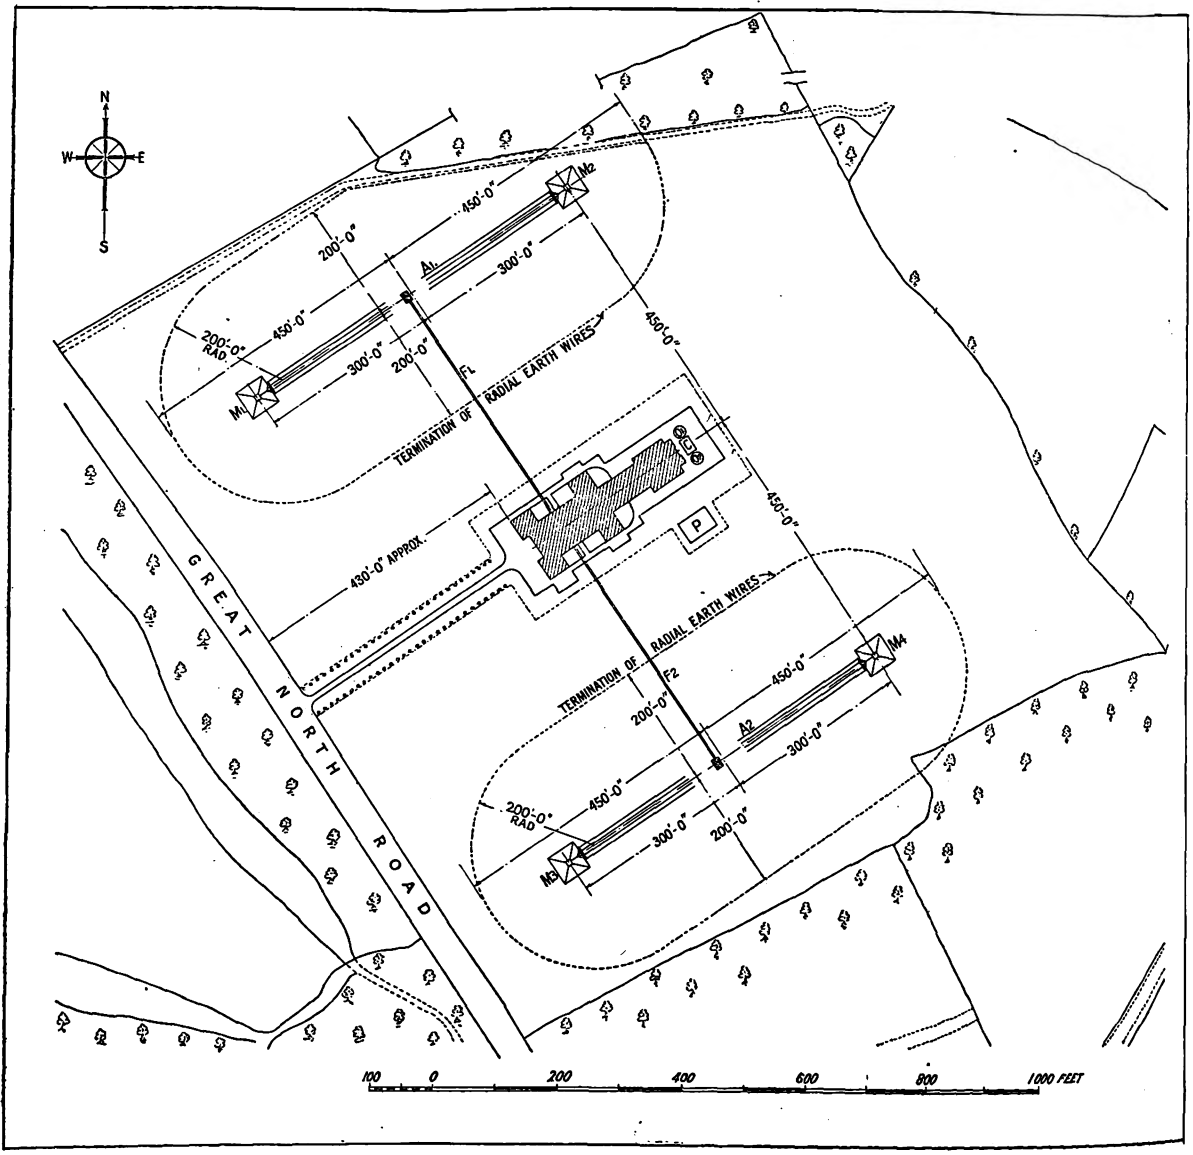

Fig. 1.—General lay-out of station. Block plan of site.

Telephone cables run close to the site; water, which is required at the maximum rate of 10 000 gallons a day, is available and is taken from the main supply.

Before purchase the site was tested for its electrical properties, as they have a bearing upon the aerial systems. Thus a 1-kW experimental mobile transmitter was erected on the selected site, in order to prove that the effective height of an aerial erected temporarily between 110-ft. masts was equal to that given by the theoretical assumption that the ground is perfectly conducting.* Certain sites give high earth losses which reduce the radiation efficiency of aerials erected upon them; it appeared from the experiments made that the site chosen behaved normally in this respect.

The experimental transmitter served the further useful purpose of giving a forecast of the expected field strength in and around the London area. Thus a motor-van containing field-strength measuring-apparatus travelled some 10 000 miles round the site and plotted the field-strength contours given by the temporarily erected mobile transmitter.

STATION LAY-OUT.

Power Supply.

It was thought advisable to install a self-contained generating plant and not to use the public supply mains. It is interesting to note that " shut-downs " of considerable duration at broadcasting stations have frequently been due to failure of the public supply mains. Moreover, it is possible to generate locally at approximately the same cost as, or in some cases a considerably lower cost than, that at which power can be bought. It is obvious that a programme may cost a great deal of money and time in preparation, and it may be of national importance. Failure to radiate the programme, due to lack of power or any other transmitter failure, is therefore a serious matter and it is particularly necessary to eliminate as far as possible all links which may involve long breakdowns. Further, it is desirable to be able to avoid fluctuations in supply voltage. Accordingly, for these two reasons Diesel-engine power units were chosen —generating direct current—so that a storage battery could be used. The battery provides a further factor of reliability in addition to compensating for variations in supply voltage.

General Plan.

The following is a general description of the station; the plant is described in greater detail in later sections.

The station building is so planned that there is a progressive evolution from the crude oil which feeds the Diesel engines (for the power supply) to the transmitters which supply the aerials with modulated high-frequency alternating currents. Thus (see Figs. 1 and 2) the oil tanks (O1 and O2) are located at the rear end of the building. These are sufficient to hold 3 months' supply of oil for the running of the station on full power on both transmitters. Between the oil tanks is the cooling tower (C). The power house contains four Diesel engines, each driving a d.c. generator. The output of the generators is floated across a 2 000-ampere-hour battery, contained in the battery room (B). The output of the power house is taken to switchboards W1 and W2 in the motor-generator room (M). In order to keep the noisy and vibration-making generation plant as far as possible away from the delicate machinery, and yet to maintain a covered communication way throughout the building for the use of the personnel, the battery room (B), packing space (Q), workshop (H) and store (K) are all interposed between the generating station and the motor-generator room. The motor-generator room contains machines which convert the 220-volt supply into the necessary forms for energizing the transmitters, which are located in the transmitter room (T). The output of the machines is led to the switchboard (W3), which is located in the transmitter room. This arrangement is adopted to facilitate operation and economize in personnel. The output from the two transmitters is passed through the two feeder lines (F1, F2) to the aerials (A1, A2). Each transmitter is capable of putting 50 kW into its associated aerial. The feeble low-frequency currents of modulation come from the distant studio in London via a cable line; this terminates in the control room (R2). The currents of modulation are there increased to a sufficient value to be injected into the modulating systems of each of the transmitters.

The valve-cooling arrangements comprise a grid of pipes (P), outside the building, through which the valve-cooling water passes. These stand in a concrete tank, and external cooling water from this tank is allowed to trickle over the outside of the pipes.

Building.

The building itself, which was erected by the Anglo-Scottish Construction Co., Ltd., under the supervision of the B.B.C.'s civil engineer, is, as far as the portions which contain the main technical equipment are concerned, of single-story construction. Many designs were considered in which galleries above the ground-level were to be erected in order to achieve an economy in building space. Calculations showed, however, that the total economic gain was fractional. It is desirable, furthermore, to ensure, as far as possible, freedom from extraneous noise in the transmitter room and so the separation of the machines and transmitters is further desirable. Silence in the transmitter room is of importance not only for the comfort of those operating the equipment, but also because the location of faults due to arcing and sparking of components of the apparatus is much facilitated if there is no extraneous noise. It might, however, have been possible to overcome noise interference by erecting the transmitter in an upper story. Here, again, there are disadvantages, inasmuch as the earthing of the transmitters would have to be made by relatively long earth leads, and it was feared that possible inductive effects between the two transmitters might be incurable. There is of necessity a large amount of ground available, and considerations of actual space are not therefore of paramount importance.

A departure from single-story construction is made in two instances, one where a vault (Y) below ground-level is arranged to contain certain subsidiary apparatus, and the other where the office block has a " first "-floor story. The object of this vault is two-fold. Firstly, it gives easy wiring runs from the machines in the motor-generator room (M) to the output switchboard (W3), and from this switchboard to the transmitters (T1, T2); and secondly it provides space for pumps, tanks, auxiliary batteries, etc. The extremely complicated wiring of the station practically necessitates the vault, because cables run in ducts would be difficult both to inspect and to install.

General Appearance.

An attempt has been made to dispel the illusion that any building connected with engineering is necessarily ugly. Extreme simplicity is the keynote of the architectural finish. Although there is no actual interior decoration in the usual sense of the word, nevertheless an attempt has been made to express in the colour scheme and general arrangement the essentially utilitarian principle of the whole lay-out. The walls of the big rooms are sprayed with white distemper over the common brick. The floors are of red tiles in the engine and

motor-generator rooms, and of red rubber and oak in the transmitter room. Ceilings and office walls are rendered. Ceilings are white but the office-block walls and passages have a grey dado high enough to prevent their showing the dirt inevitably caused by people leaning or brushing against them.

The field on which the building stands is to be left as a grass field. The station, however, is surrounded by a gravel road with a hard core so that heavy transport can deliver loads at the appropriate doors or, in the case of oil supply, to the tanks.

POWER HOUSE.

Each transmitter is designed to give a carrier-wave energy of 50 kW to the aerial, with the transmitter so adjusted as to be capable of 100 per cent peak modulation without distortion. Although actually it was intended to inaugurate the service from this station with a power of about 30 kW to each aerial, the load on the power house, when each transmitter is giving 50 kW to the aerial, has been allowed for and this is approximately 500 kW. It is made up as follows:—

Input to the two main high-tension motor-generators, each absorbing 200 kW	400 kW approx.
Input to two main filament-lighting motor-generator sets, each taking 35 kW	70 kW approx.
Input to grid negative motor-generator sets and motor-generator sets for anode power to drive, separator and modulated amplifier stages on the transmitter ..	9 kW approx.
Motor-driven power-house auxiliaries and motor-driven pumps for valve water-cooler	10 kW approx.
Lighting, cooking, etc.	25 kW approx.
Total	514 kW approx.

Further details of the motor-generator sets mentioned above are given in a later section of the paper.

In order to generate the required power of approximately 500 kW it was decided to use three units, each capable of producing 200 kW. The advantage of using Diesel engines in preference to steam engines for generating power of this description under the conditions which obtain in practice are so obvious as to need no explanation. Actually, four Diesel engines were installed, coupled to d.c. shunt-wound generators supplied by the English Electric Co. and having a voltage range from 220 to 260, the working station voltage being 230. It is intended that only three engines shall run at the same time, the fourth being held in reserve. Fig. 2 shows the general lay-out of the power house.

The size of the power unit was carefully chosen because it allows two engines to be run at just under full load when each transmitter is delivering 30 kW to the aerial, at the same time allowing a margin of about 100 kW with three engines when the whole station is running at maximum load. The decision to use direct current in preference to alternating current was taken principally in order to make it possible to float a storage battery across the mains. This matter, however, is referred to more fully in connection with the storage battery itself.

When considering the type of crude-oil engine to be adopted, the question of vibration was looked upon as being of very considerable importance; first, from the point of view of its possible effect on the transmitters themselves; and, secondly, in view of the possibility of complaints from the owners of surrounding property, since the district is rapidly being developed for residential purposes. For this and other reasons a vertical 6-cylinder engine was eventually chosen capable of developing 50 h.p. per line at 300 r.p.m., i.e. a total brake horse-power of 300. These engines were built by Ruston and Hornsby, Ltd., and are of recent design. They employ so-called " solid injection " of the fuel, and are of the full Diesel trunk-piston type (" full Diesel" is intended here to indicate that no means of igniting the fuel is employed other than the heat generated by compression). Forced lubrication is fitted to all important points, with stream-line filters, integral with the engines, for the lubricating oil.

It is not proposed to give further details of the design of these engines, since they are a standard production intended for general industrial purposes, but the figures under actual working conditions for one commercial grade of fuel may be of interest.

Specific gravity of oil ..	0·915.
Calorific value of oil.. ..	19 200 B.Th.U. per lb.
Full-load consumption ..	0·422 lb. per b.h.p.-hour.
Half-load consumption ..	0·47 lb. per b.h.p.-hour.

Although the type of engine chosen creates comparatively little vibration, nevertheless it was considered necessary to take every precaution to ensure that no detectable vibration should reach the transmitters. With this object in view the engines were mounted on a special bed, constructed in the following way. The four engine units are mounted on a single block of concrete measuring 45 ft. 6 in. × 32 ft. × 6 ft. deep. This block weighs some 600 tons, and the concrete mixture was so specified that the weight should not be less than a fixed amount. The block rests on a raft, but is insulated from it by blocks of material known by the trade name of " Corosil." This material consists of cork mounted in iron frames and given a special treatment to ensure durability. Each frame is approximately 2 ft. 6 in. square, and the cork material is 2½ in. thick. The pressure on the cork is approximately 7·5 lb. per sq. in. Between the foundation block and the retaining walls of the raft there is an air space 3 in. wide which is closed by removable teak boards, fitted flush with the floor of the power house. The special foundations were designed by Christie and Grey, Ltd. Fig. 3 shows a section through the foundation block and raft. This arrangement has proved entirely effective in preventing any detectable vibration from reaching the transmitter; in fact there is no perceptible vibration even in the battery room, which adjoins the power house. The power-house accessories are on standard lines, and for this reason only a very brief description will be given.

Two external tanks, each capable of holding 75 tons, have been provided for the storage of fuel oil, the contents of the two tanks together being sufficient to run the whole plant at full load for three months, assuming the normal hours of working. A fuel-oil filter of the centrifugal type is installed for use in the event of the oil being found to contain water or solid impurities. The circulating water for the engines is cooled by means of an external cooling tower of standard design, and the make-up water is taken, so far as is possible, from a concrete pond which receives rain water from the roof of the whole building, the object being to supply soft water to prevent excessive deposit in the water jackets.

The exhaust system was carefully designed to give complete silence 100 yards from the building, and includes a waste-heat boiler capable of supplying sufficient heat by hot-water radiators to all rooms requiring artificial heating.

BATTERY AND SWITCHBOARD.

It has already been mentioned that a storage battery is floated across the main supply. This battery, which was supplied by the D.P. Battery Co., Ltd., has a capacity of 2 000 ampere-hours at the 10-hour rate of discharge, and its uses are as follows:—

(*a*) To take the load of one generating set in the event of the sudden failure of an engine or generator. To cover this requirement the battery is rated to give a discharge of 1 000 amperes for 1 hour when discharging to a voltage of 1·75 volts per cell.

(*b*) To supply power for lighting, etc., and to run auxiliaries and workshop motors when no programme is being transmitted and the load is, therefore, comparatively very light.

(*c*) To assist in maintaining a constant voltage, especially when, for any reason, the load is rapidly varying. In general such occasions will be infrequent, but they arise when one transmitter is being run up while the other is taking the programme, or when some temporary trouble develops on a transmitter or machine.

Requirement (*b*) is sufficient to keep the battery in healthy condition without having recourse to trickle-charging or other special arrangement of this kind.

Two plain shunt-wound battery boosters (one of which acts as a reserve) are provided for battery charging and discharging, no end-cell connections being used. These boosters are hand-controlled by reversing potentiometer-type field regulators. It was not considered justifiable, from the point of view of expense, to install automatic reversible boosters, owing to the fact that the load is practically constant in normal circumstances. In the event of a sudden engine failure, which should, of course, be an infrequent occurrence, the attendant can readjust the voltage in a few seconds when the battery is called upon to take a large load, and the very temporary general drop in voltage will scarcely be detected by a listener.

The power-house switchboard, which was supplied by the English Electric Co., Ltd., is on standard lines and contains the following panels: 4 main generator panels; 2 booster motor panels; 1 battery panel; 2 main feeder

panels; 1 power auxiliary panel; 1 lighting panel; and 1 spare panel.

The main feeders running to the motor-generator room are so arranged that the supply to each transmitter can be kept separate and furnished, if necessary, by different generating sets. Thus if experimental work, such as valve-testing, is being carried out on one transmitter while the other transmitter is radiating a programme, one engine set can be isolated so as to supply the load for the test, obviating any risk of affecting the radiated programme by a short-circuit or other accident. This scheme of connections is also particularly useful in the event of some complicated breakdown of one of the transmitters, the cause of which is difficult to trace and which necessitates the frequent running-up of the set. Normally, however, the two sets of busbars and feeders are paralleled. The feeders themselves consist of bare 4 in. × 0·5 in. copper strips run on porcelain insulators along the roof of the passage leading to the motor-generator room.

MOTOR-GENERATOR ROOM.

Each transmitter when working on full load requires the following inputs:—

Supply	Volts	Amperes	kW
Main supply to anodes of all water-cooled valves ..	10 000	16	160
Filament-heating for all valves, water-cooled and air-cooled, except the master oscillator	22	1 100	24·2
Grid negative voltage for final power stage	200	4	0·8
Grid negative voltage for penultimate stage	2 000	0·2	0·4
Grid negative voltage for modulator, modulated amplifier and separator	500	0·5	0·25
Anode supply for the master oscillator	2 000	0·06	0·12
Anode supply for the modulator, modulated amplifier and separator	3 500	0·35	1·2

The above are the *actual* inputs for 50-kW working.

Fig. 2 shows the general lay-out of the motor-generator room. It contains three general allocations of space. S1 contains all the small-power machines for grid negative and small high-tension supply, etc. These are very small machines of the order of 1 kW each. They are mounted on pedestals 3 ft. from ground-level and surrounded by a stainless-steel guard which can be quickly removed. This arrangement facilitates the maintenance and repair work, in that the maintenance personnel need not undertake the necessary work in cramped positions. Space S2 is allocated to the high-tension d.c. generators, which take in power at 220 volts and deliver it to the transmitters at 10 000 to 12 000 volts. The remaining space S3 is taken up by the filament-lighting machines, which supply a very large current at a low voltage. The reliability of the machine-room supply is guaranteed in terms of three machines of every kind for two transmitters. Thus there is always a condition where two machines of each kind are working, leaving one spare to be put into service in case of breakdown.

MAIN HIGH-TENSION SUPPLY.

The switchboards controlling the motor side of the convertors are located at W1 and W2. W1 operates the high-tension machines and the filament machines, and W2 the small auxiliaries in the space S1.

The question of the best method of obtaining the main high-tension supply was discussed in a previous paper by one of the authors.* For reasons given in that paper it was decided to use motor-generators in preference to thermionic rectifiers, adopting as simple a design of motor-generator as possible, consistent with reliability. The machines adopted were developed to suit the requirements of this station by Mr. J. E. Calverley, of the English Electric Co. Their maximum output is 160 kW at 750 r.p.m., and the voltage range is 7 000 to 12 000, the machines being capable of giving the full 160 kW at any voltage between these limits. The lower limit of voltage was chosen to cover the possibility of the machines being obliged to work at a comparatively low voltage, on account of so-called "rocky point" effects in the water-cooled valves forming the final power stage of the transmitters. This trouble was somewhat persistent at the Daventry station (5GB) when the design of these machines was under consideration, and at that time the solution was not clear. It was intended to run these machines at approximately 10 000 volts, apart from this consideration, but at the same time it was considered that it might be desirable, at some later stage, to raise the working voltage to 12 000, since the higher voltage gives improved conditions on the transmitter from the point of view of efficiency and linearity of modulated output.

The driving motor is compound-wound, and the generators are separately excited from the station busbars, the fields of the two generators per set being permanently connected in series and controlled by one regulator.

The high-tension voltage is generated in two armatures, each having two separate windings in the same slots and two commutators. All four commutators are permanently connected in series. The voltage per commutator can be varied between 1 750 and 3 000 volts with the aid of the field rheostat so as to give the total high-tension voltage range required.

FIG. 5.—Insulation and distribution of dielectric stress in high-tension machines.

Each machine has four main poles and four commutation poles. The yokes and pedestals are split on the horizontal centre-line to facilitate erection.

The heaviest parts to be handled are the two high-tension armatures and shafts, each of which weighs 2·1 tons.

The shafts of all three armatures (one motor and two generators) in the set are rigidly coupled together and carried in four sleeve-bearings with oil-ring lubrication. Extra precautions were taken in the design of these bearings and pedestals to prevent creepage of oil along the shaft into the machine or on to the commutators. The armatures are mounted on very stiff shafts and were dynamically balanced to ensure smooth running and freedom from vibration.

The insulation scheme and distribution of the electric stress is probably the most interesting feature in the machines (see Fig. 4). Neither the couplings nor the foundations are insulated, the frames, shafts, bearings and bedplate being at earth potential. The English Electric Co.'s graded-potential system was adopted, the object of which is to remove the heavy electric stress from the slot insulation and apply this to a secondary layer of insulation built into the armature hub. The slot insulation consists of pressed mica 0·06 in. thick, and this is subject to a stress having a peak value of 3 000 volts twice per revolution, equivalent to an a.c. voltage of 2 120 at 24 cycles per sec. The stress on the slot insulation is identical in both armatures, though one is operating in series with the other, the system being earthed at the negative side.

The major insulation to earth is incorporated in the armature hub, and consists of pressed mica 0·125 in. thick. This mica is held between solid machined surfaces and projects beyond the armature hub to give a long creepage surface to earth. This layer of insulating material is made up of four overlapping sections moulded to shape and fitted round the inner hub, which is of square section with rounded corners (see Fig. 5). The armature hub in halves was assembled in position on the mica and secured by a shrink-ring at each end. To eliminate the possibility of films of air in any spaces between the mica and the steel, the moulded sections were given a good coating of insulating compound, and this was maintained in a fluid condition until the shrink-rings were in position and the hub complete. The insulating material in this position is very solid and is remote from any appreciable temperature variations. Each hub was tested to the shaft at 25 000 volts, 50 cycles, for one hour before the armature was wound.

The armature core with its hub carries also the commutator hubs, one at each end, so that the whole of the armature and commutators are well insulated from the shaft. The potential of these parts is maintained at its correct value relative to the armature windings by means of a potential equalizer. Two potential equalizers are provided for each pair of generators, one for each armature. They are totally enclosed and are mounted on the bedplate. The connections to the insulated armatures are made through a carbon brush running on an extension of one commutator and ring on each armature core. The potential equalizer maintains the potential of the armature core at a mid-value between the extreme potentials of the two commutators, and definitely determines the electric stress across the slot insulating material, the remaining voltage to earth being applied to the armature-hub insulating material.

The resistance in the potential-equalizer circuit is 70 000 ohms, which limits the fault current in the event of a breakdown of insulating material. If any current exists in this resistance owing to leakage or insulation breakdown, a relay connected in series will close two contacts on a low-potential circuit and operate the leakage-indicator gear.

All highly-inductive windings which are connected in the high-tension circuit, such as interpole coils and series windings, have reinforced insulating material on the end turns of each coil to safeguard them against breakdowns between turns due to surges or impulses. The interpole windings are provided with non-inductive shunting circuits to bypass any audio-frequency currents which may exist in the system.

The interpole coils and series coils are connected at the earth side of the armature, but are insulated for a high-pressure test of 5 000 volts (a.c.) owing to the fact that in certain circumstances higher voltages to earth than normal may exist.

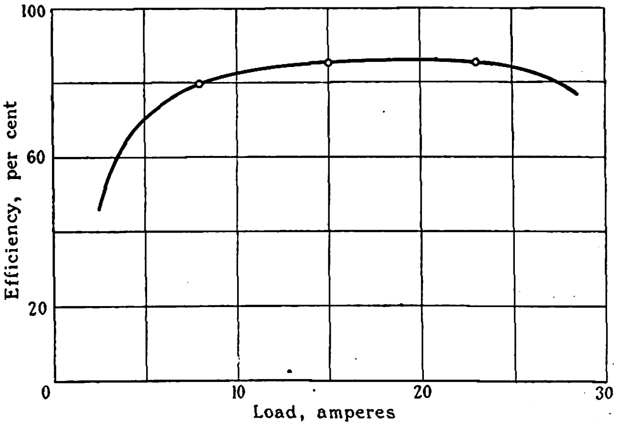

FIG. 6.—Overall efficiency of high-tension sets.

Insulation Tests.—The following high-pressure tests were carried out on the finished machines, using alternating potential from a 50-cycle circuit. All these tests were of 1-minute duration.

Armature windings to armature core ..	7 500 volts
Armature core to shaft	20 000 volts
Series and interpole windings to frame..	5 000 volts
Series winding to shunt winding ..	5 000 volts
Shunt winding to frame	2 500 volts
Potential equalizer and relay coil to bedplate	20 000 volts

Considering that the slot insulating material and the armature-hub insulating material are electrically in series, the total final test pressure between the armature windings and earth is equal to 27 500 volts (a.c.).

Efficiency and Temperature-rise.—The overall efficiency of these high-tension sets is shown in Fig. 6, from which it will be seen that the efficiency over the working range is from 85 to 86 per cent.

The machines have been designed to comply with B.S.S. No. 168—1923, as regards temperature-rise. The figures specified therein are not exceeded even if the maximum rated voltage of 12 000 and the maximum rated current of 23 amperes are taken together.

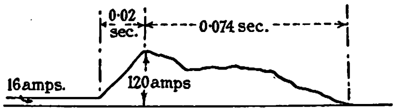

FIG. 7.—Oscillogram showing current when generator is short-circuited (with circuit breaker).

Voltage Characteristics.—Owing to the possibility of "rocky point" effects in the main transmitting valves, it was considered desirable to give the machines some form of inherent current-limiting characteristic, and for this reason the generators are heavily de-compounded with their own current. It was recognized that de-compounding could not be instantaneous in its action and prevent the first rush of current on a dead short-circuit, but as the smoothing system includes a high-value choke coil (5 henrys) in series with the machine, the rate of increase of current due to a short-circuit external to the choke and machine could be controlled and made sufficiently small to permit the de-compounding to keep pace with the current-rise.

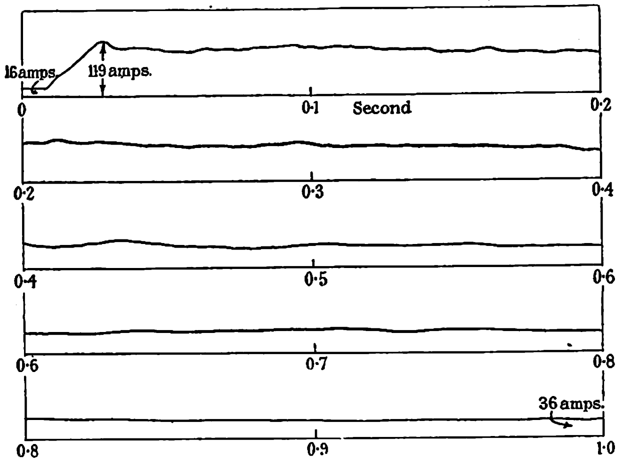

FIG. 8.—Oscillogram showing current when generator is short-circuited (without circuit breaker).

The total inductance of one pair of machines in a high-tension motor-generator set is about 1·1 henrys, and the oscillograms in Figs. 7 and 8 show that without the choke in circuit the initial rate of increase in current on short-circuit at the terminals is in the neighbourhood of 5 000 amperes per sec. The de-compounding winding has little effect at the instant of short-circuit, but after about 0·02 sec. (during which time the current is increased by about 100 amperes) the de-compounding becomes effective (Fig. 7).

With the 5-henry choke in circuit, the initial rate of increase of current is reduced to about 1 500 amperes per sec. and the current will not rise to more than about 35 amperes before the voltage begins to fall, due to the action of the series de-compounding windings. As this is the final short-circuit current, when the circulating current approaches this value it remains practically steady whilst the voltage falls to zero. This scheme has been found to be quite effective in service, and a short-circuit in the transmitter room does not cause any appreciable disturbance on the commutators of the motor-generator set.

On account of the wide range of current for which these machines are designed, the series windings on each pole are divided into two sections, and these can be connected for use on the higher current range so as to make two complete parallel circuits on each generator field. A further reason for this splitting of the series

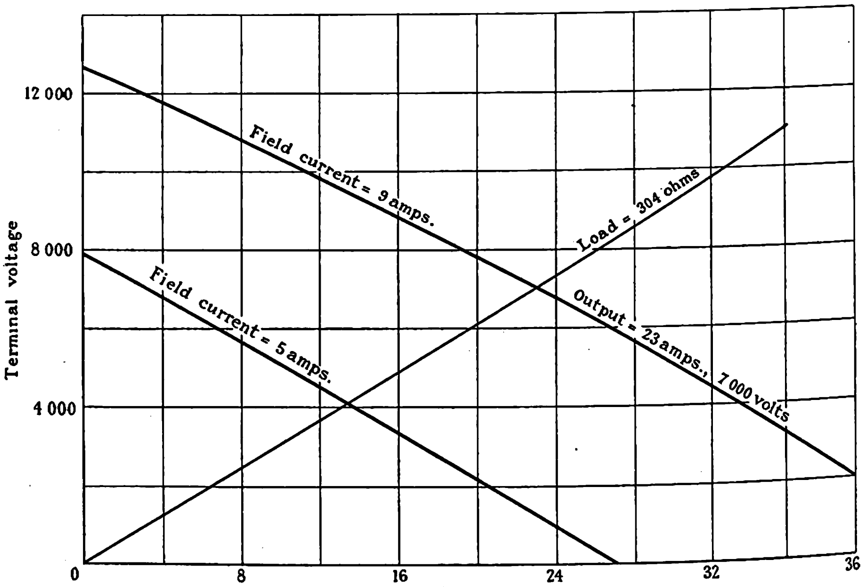

FIG. 9.—Load characteristics of high-tension machine with half de-compounding.

windings and putting half on each side of the shunt winding is to keep down to a low value the magnetic leakage between the shunt and series windings and to render the de-compounding windings quicker in their action.

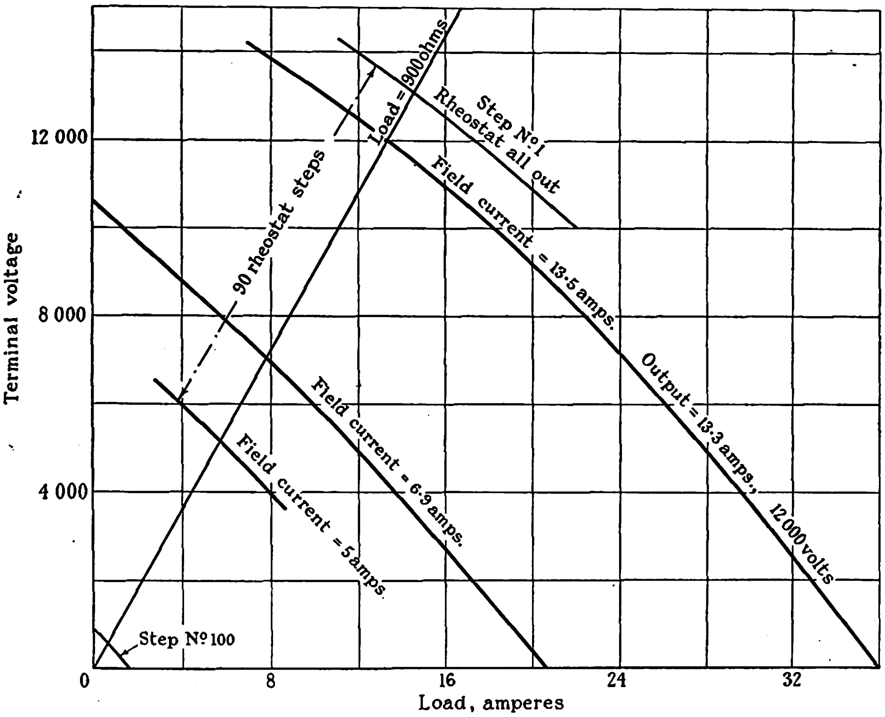

FIG. 10.—Load characteristics of high-tension machine with full de-compounding.

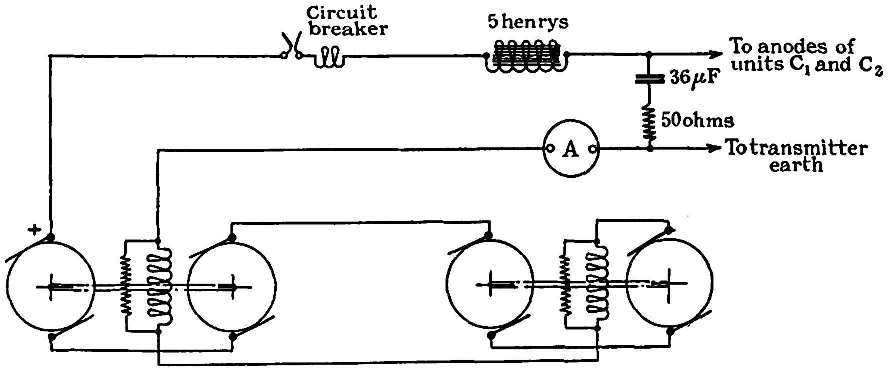

FIG. 11.—Diagram of connections of high-tension machine with smoothing set.

Links, provided on the lower portion of each magnet frame, permit of these sections being connected in series or in parallel to suit the current range required.

Figs. 9 and 10 show the characteristics of the machine with each arrangement of the connections. Fig. 10 illustrates the characteristics of the set with the de-compounding windings in series. This is a normal working condition for an output on the 9 000- to 12 000-volt range. It will be noted that the no-load voltage-rise is in the neighbourhood of 25 per cent, though this voltage-rise never occurs in practice because the machines always build up on load, and in the event of the circuit breaker operating it opens the shunt field circuit and eliminates the excitation.

The steady short-circuit current of the machine is about 36 amperes, and the curve shows how the voltage falls as the current increases. The load on these machines is practically a dead resistance load for any one adjustment of the transmitter, and under these conditions the field control is very precise and effective. Under the control of the field rheostat the machine will build up its voltage, following the straight line which is shown in the diagram to correspond to the resistance load of 900 ohms, which would absorb 13·3 amperes at 12 000 volts.

De-compounding curves for other values of the field current are also shown in Figs. 9 and 10. These all take the same shape and only differ in value with different values of the field current. Under these conditions the machine will build up along the straight line under the control of the field rheostat, and the increments of voltage per step of the rheostat are about 70 to 80 volts.

Short-circuit Characteristics.—Short-circuit tests were taken on these machines with and without the circuit breaker (see Figs. 7 and 8). The short-circuits were taken across the terminals of the machine. Fig. 7 shows the change and duration of the current with the circuit breaker in circuit. This curve was taken when the machine was delivering 16 amperes at 10 000 volts, and the maximum current recorded was about 121 amperes. This current commenced to decrease in 0·02 sec. owing to the de-compounding, and was interrupted by the circuit breaker, which brings the current to zero in about 0·095 sec. The circuit breaker is not of the special rapid type, since the impedance of the systems, together with the effect of the de-compounding, prevent any excessive current; it is, in fact, fitted with an adjustable time-lag device.

Fig. 8 shows a similar test without the circuit breaker in series. The wave is of similar shape, but instead of being interrupted by the circuit breaker the current is gradually brought down to its steady short-circuit value by the action of the de-compounding winding. The peak value of the current in this case is much the same as before, reaching its maximum value at 0·02 sec. from the instant of short-circuit. At this time the de-compounding winding becomes effective and gradually reduces the voltage and circulating current, until at the end of 0·95 sec. the current is steady at its short-circuit value.

Fig. 11 shows a diagram of connections of the machine with its associated smoothing circuit.

An oscillograph test was taken to determine the amount of the commutator ripple. It was specified that this should not exceed 1 per cent of the working voltage on either side of the mean, without the smoothing system in circuit. The ripple as actually measured in this way was approximately 0·08 per cent.

There are three of these machines installed, and each machine is enclosed by a separate iron grille the gates of which cannot be opened without closing down the machine. The main smoothing chokes, one for each machine, have a value of 5 henrys each, are oil-cooled, and are also mounted in these compartments.

Motor-Generators.

For Filament Heating.—These machines, which were also supplied by the English Electric Co., Ltd., are entirely straightforward and the only item in the specification which is in any way unusual is in connection with ripple. The maximum amount allowed was 1 per cent above or below the mean of the working voltage; the figure as measured by an oscillograph was approximately 0·5 per cent. As in the case of all the motor-generator sets for the various supplies to the transmitters, three machines were installed, one for each transmitter and one in reserve. The rating of the filament-heating motor-generator sets is as follows:—

Voltage range	15 to 30
Current	1 300 amperes
Speed	570 r.p.m.

The results of the tests were as follows:—

Efficiency	76 per cent
Highest temperature-rise	30 deg. F. (generator commutator)

For Anode Supplies to Separator, Modulator and Modulated Amplifier.—These machines were supplied by Messrs. Haslam and Newton, Ltd., and were given a specially liberal rating owing to the heavy duty required. The rating is:—

3 500 volts and 0·6 ampere; measured ripple 0·2 per cent.

The same maximum ripple was allowed as for the main h.t. machines, viz. 1 per cent.

For Master Oscillator High Tension.—These are rated at 2 000 volts and 200 mA; measured ripple 0·57 per cent.

For Grid Negative Supplies.—These are rated as follows:—

Main amplifier 250 volts, 4 amperes; measured ripple 0·5 per cent.

First power amplifier 2 000 volts, 200 mA; measured ripple 0·57 per cent.

Modulator and separator 500 volts, 500 mA; measured ripple 0·3 per cent.

TRANSMITTER-ROOM EQUIPMENT

Lay-out.

The transmitter room is 73 ft. 10 in. long, 60 ft. wide and 26 ft. high (see Fig. 2). The two transmitters T1 and T2 face one another, leaving a large space in the middle of the room. The switchboard is at right angles to both transmitters. The previously mentioned vault Y runs so that there is a corridor-shaped space below the transmitters and the switchboard. The height of the vault allows a man to walk upright, and the whole space is sufficient to take all wiring runs from machines to switchboard and from switchboard to transmitters. The main wiring was carried out by Drake and Gorham, Ltd. The vault contains, in addition, tanks, pipe runs, auxiliary batteries and pumps necessary for the valve-cooling plant.

Switchboard.

The switchboard on which the outputs of the machines are centralized and controlled before being passed on to the transmitters is divided into four partitions Wa, Wb, Wc, Wd. Wb and Wd deal with the output of the small auxiliary machines in space S1 (see Fig. 2) for grid negative, power supply for the drive, and so on. Wc contains the section for the output of the high-tension d.c. generators in space S2 (see Fig. 2). Wa deals with the output of the filament-supply machines, which are themselves located in the motor-generator room in space S3 (see Fig. 2).

It is obviously essential to arrange the switchboard in such a way that the output of any of the three machines in each group can be diverted to either of the two transmitters. The methods used are straightforward and do

not merit description in a general paper. The arrangement of the high-tension switchgear which is found in the centre of the switchboard ensures absolute protection of the operating personnel, and none of the live parts comes in contact with the actual face of the switchboard. The instruments are recessed and are protected by a glass window flush with the face of the switchboard. The circuit breakers must of necessity be in such a position that, when they interrupt the current, the ensuing flame does not burn any part of the apparatus. To this end the breakers are placed above the centre part of the switchboard. The front magnetic shields of these breakers are at full positive potential and it is, therefore, necessary to protect them with an earthed expanded-metal screen so as to be absolutely certain that the personnel shall not come into contact with the live parts of the breakers, when carrying long pieces of conducting or semi-conducting material, etc. The smoothing condensers are installed behind the switchboard. The switchboard and doors cut off all access to the components at high tension.

TRANSMITTERS.

(*a*) *General Design.*—A previous paper * outlined the reasons for the adoption by the engineering branch of the B.B.C. of what is known as "low power" rather than "high power" modulation as the basic design for the transmitters themselves. Low-power modulation involves generating oscillations of the required high frequency, modulating them at comparatively low power and then magnifying the resultant by as many stages of high-frequency amplification as is necessary.

Each transmitter proper contains four units, as follows:—

The A unit contains all the circuits for producing modulated, relatively low-power oscillations, the fundamental or middle frequency being maintained sensibly constant even under conditions of maximum distortionless modulation.

The B unit increases the power of these modulated oscillations.

The C and D units comprise apparatus which increases the output of the B unit to the value required for radiation.

The A unit contains four separate shielded circuits, the drive, separator, modulated oscillation amplifier and modulator. A schematic diagram of the A unit is shown in Fig. 12. Circuit 1 is a conventional thermionic-valve oscillation generator. The frequency of oscillation of this circuit determines the frequency of the aerial carrier-wave current. To prevent frequency-change the drive circuit must work into a constant load. This condition is achieved by using a so-called "separator," circuit 2. The output of circuit 2 energizes circuit 3, the modulated oscillation generator. This latter acts to magnify the oscillations passed to it from the separator. The modulator (circuit 4) follows the conventional choke or Heising system, and modulates the intensity of these oscillations in sympathy with the low-frequency currents of modulation fed to it from the local control rooms.

The output from unit A is passed to unit B, which contains a push-pull connection of two water-cooled valves designed to magnify the modulated high-frequency currents fed to it from unit A. The output of unit B is passed on to the identical units C1 and C2. The latter contain banks of water-cooled valves, one unit taking one side of a push-pull circuit and the other the other side. Unit D contains a closed circuit consisting of inductance and capacity which is set into full-power oscillation by connection to the valves in units C1 and C2. Arrangements are made for neutrodyning the various circuits. Schematic diagrams of connections are shown in Figs. 13, 14 and 15.

It will be seen that the system comprises essentially a high-frequency amplifier which magnifies the modulated high-frequency currents generated in unit A. The output of the last stage is passed to the aerials via feeder lines.

It is not thought necessary to include a full description of the transmitter here, because otherwise the paper would be too long, and it is anticipated that a further paper will be written, but, the general lines having been indicated, it will perhaps be of interest to consider some salient points in more detail.

(*b*) *Construction.*—The transmitters were designed by the B.B.C. engineering branch, and were constructed by Marconi's Wireless Telegraph Co., Ltd. They are based on data obtained by the design and operation of an experimental station at the Corporation's transmitting centre at Daventry, familiar to listeners as station 5GB. The transmitters are thus the outcome of experience with an existing experimental "lash-up" which has been tested under conditions of service for over a year.

An attempt has been made throughout to design the apparatus so as to ensure absolute safety for the personnel operating the station. Thus each unit contains all its associated apparatus in an earthed aluminium screen, but where it is necessary to read instruments and keep the apparatus under observation, glass doors give this facility. The cases are so made that access to the apparatus is perfectly easy by opening the doors, but no door can be opened without automatically cutting off the power, as the door handle is connected to a switch which cuts off the supply when the handle is turned to allow the door to be opened. The closed metal construction has the further advantage of minimizing stray fields.

Great care has been taken to ensure that the components of the apparatus shall be sufficiently accessible, and, furthermore, to facilitate the quick change of faulty components these are in most cases not screwed down, but rest on spigots. Thus to remove a component it is only necessary to disconnect the various wires which run to it, lift it out and substitute a new one.

The essential circuits each contain a meter for registering the current or voltage essential to its operation. Thus, among other quantities measured, every valve grid and anode has a separate meter in order that the operating personnel may have continuous assurance that all the valves of the team are behaving identically.

Water-Cooling.—In the Daventry high-power long-wave station, designed five years ago, the insulation of the valve-cooling water, which must, of course, come in contact with the anodes, which are at several thousand volts above earth potential, is obtained by running it through a perforated plate somewhat similar to the rose of a watering can. This breaks up the water into fine drops and achieves practically perfect insulation. By allowing the water to run into the valve through a spray and go out from it also through a spray, sufficient insulation is achieved. There are, however, considerable maintenance troubles with such a system, and small particles of grit inevitably get into the water and are inclined to choke up the fine holes in the spraying plate. In the station being described a more conventional method of running the water into the valves through a coil of large rubber pipe, and forming an exit for the water in the same manner, has been adopted. There is, with this system, some direct-current loss due to conduction of current to earth via the water, and there is furthermore some loss due to high-frequency currents feeding into the pipes as a capacity to earth. However, neither trouble is serious. The actual valve-cooling water is fed into the valves by gravity from a roof tank. It passes, with rubber-pipe entrance and exit, over the valve anodes and thence to a tank in the vault, whence it is pumped through the cooler into the roof tank. The water which comes in contact with the valve anode is thus in a totally enclosed system, and this allows water having the correct degree of hardness to be used. The cooler itself consists of a bank of tubes mounted over an open concrete pond, water from which is sprayed over the outside of the pipes by means of a pump situated in the vault. The cooling system is so designed that the maximum temperature of the valve-cooling water leaving the valve jackets shall not exceed 110° F. under summer conditions. A separate bank of tubes is installed for each transmitter, but the external water system is common to both. This portion of the plant was supplied by Messrs. Rosser and Russell, Ltd. Instruments of the remote-indicating type give a continuous reading of rate of flow and temperature. Great care has been taken to ensure very good cooling of the valves, seeing that some trouble with valve flash-over was experienced on the experimental station. This latter point needs some further emphasis.

---

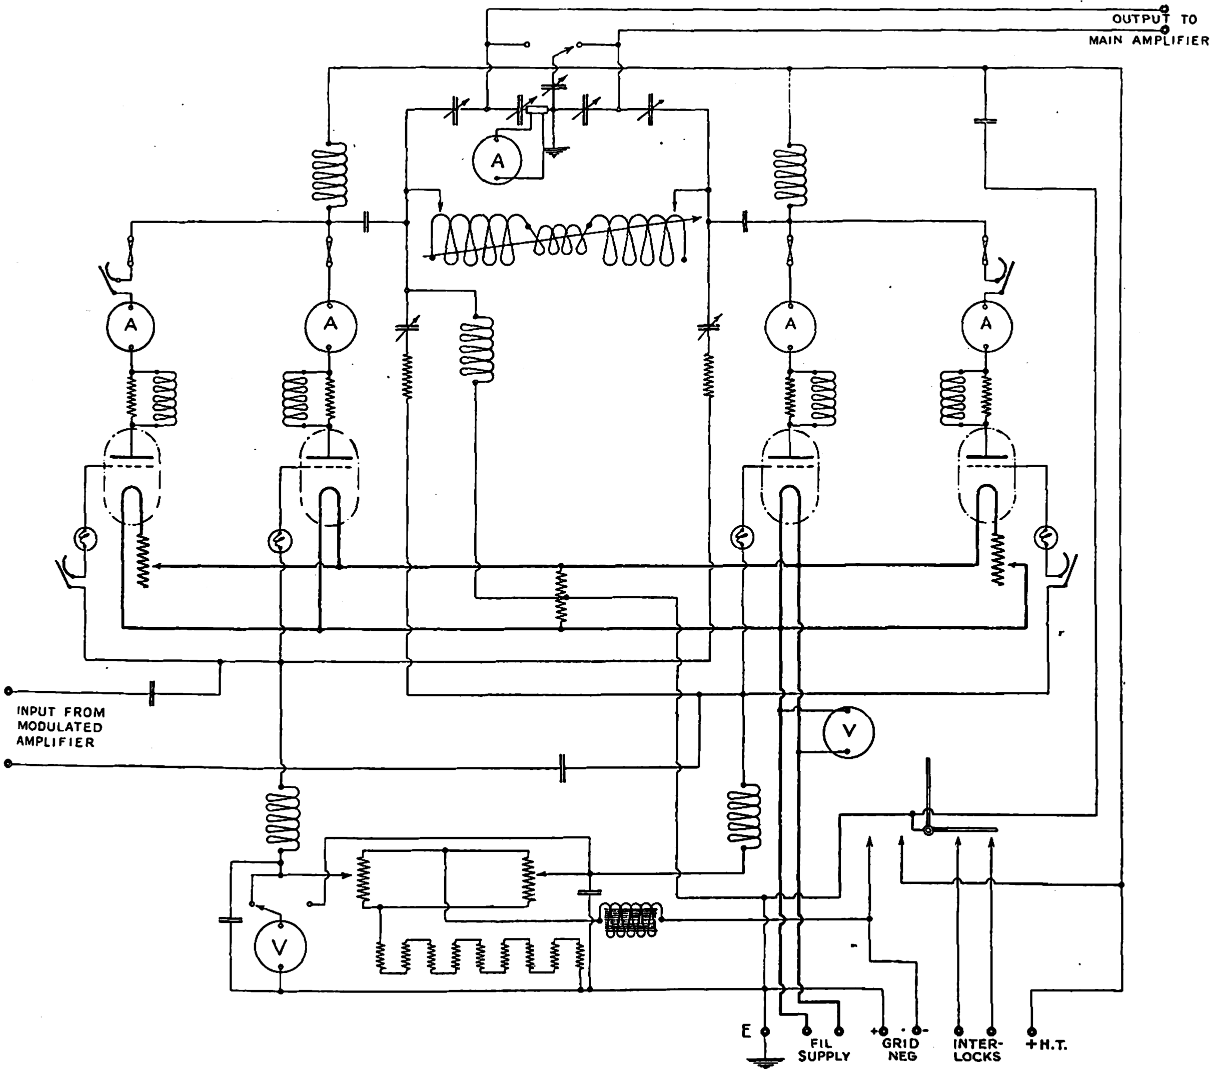

Fig. 13.—Schematic diagram of unit B.

Valve Flash-Over.—The chief difficulty met with at the experimental station was the frequent occurrence, soon after the set had been passed for service, of valve flash-over or "rocky point" effect. These flash-overs caused complete temporary shut-down of the station when d.c. generators were used, but did not cause such serious interruption when rectified alternating current was used; the latter naturally has a greater effect of limitation of current when valve flash-over occurs. While a full discussion is reserved for a further paper, it is interesting to note that the trouble was eventually cured, but there has been no opportunity to determine whether this was due to improvement in valve manufacture or to a rearrangement of the circuit. Originally the 5GB

circuit was conventional and worked on to the closed circuit in the usual "top feed" connection. It was noticed that flash-over occurred only when many valves were connected in parallel, and not on the penultimate stage where only two valves in parallel were used. The circuit was changed, therefore, to one in which each valve was fed individually through a separate air-cored choke and in which each valve anode contained a resistance. The object of individual feed was to try to arrange that each of the many valves energizing the last stage could not be influenced by the other valves. This appeared to have an influence in curing the trouble. The resistance was useful in checking incipient oscillations of much higher-frequency value than that which they were intended to magnify, and in minimizing the short-circuit current when valve flash-over occurred. It was finally decided to use a push-pull connection as well as individual valve-feed. Since this connection has been used no flash-overs have been experienced at the 5GB Daventry station, and the new transmitters at Brookmans Park appear to be perfectly stable. The interesting point to notice, however, is that the new circuits were used with new valves of better design (from the valve makers' point of view) and it is still undecided whether the new circuit or the new valves banished the trouble. There has been no opportunity, since 5GB is now a service station, to test the old circuit with the new valves or, much less, the old circuit with the old valves, since these are now either destroyed or in use on other work. The new transmitters, however, are designed not only with a circuit which is apparently stable, but also with every kind of precaution to minimize shut-down if and when "rocky points" occur (see former section of paper).

Quick Valve Replacement.—Great precautions have been taken to ensure reliability of performance. To this end, where there is one particular valve in a circuit which, if it failed, would put the rest of the apparatus out of action, arrangements have been made for throwing in a spare valve without cutting off the power from the particular unit. If, for instance, either one of the valves of unit B fails, the operator of the station can bring a new valve into operation in perhaps 15 seconds or less. To this end, a switch is mechanically arranged so that when the spare valve filament is brought up to full brightness by turning a handle operating a filament rheostat, a spring switch is released which connects the anode and grid of the spare valve. This operation does not, therefore, involve the necessity of cutting off power and water supply, taking out the faulty valve from its water jacket, substituting a new valve and switching on water and power again, as indeed has to be done with the older designs of equipment. The method of quick valve replacement is applied to all units. A carbon tetrachloride type of fuse in the anode circuit of each water-cooled valve serves to disconnect the valve which has become faulty, if indeed the fault has caused a short-circuit.

Measuring Instruments and Remote Control.—It is obviously necessary to ensure that the correct values of current and voltage are supplied to each component of the set, and continuous watch must be kept to ensure correct adjustment of supply voltages. Each transmitter has thus a remote-control table (see C, Fig. 2), and it is intended that the engineer shall sit at this table and keep a continuous watch on the various measuring instruments, which are located not only on the set but also immediately under his eyes on the table itself. Variations are taken care of by handles on the control table which regulate the voltage of supply by field-excitation regulation of the machines concerned. The quantities under direct control of the operating engineer and controlled by handles on the control table are filament voltage and high-tension supply voltage; other quantities also liable to variation can be controlled from the main output switchboard. Controls are also provided for tuning and adjustments on the units themselves.

The transmitter is theoretically capable of 100 per cent distortionless modulation, but distortion must inevitably occur when the input modulation exceeds this quantity. Voltmeters are connected in such a way that the operating personnel can, at any moment, see the amount of modulation. These meters are calibrated with instruments in the local control rooms, so that the general level of the ingoing modulation current can to some extent be regulated by local personnel. (The final authority of control is, however, given to the controlling engineer in the control room local to the studio, and the transmitting personnel, although they are given facilities for altering the degree of modulation, are under orders to make this general rather than momentary.)

Efficiency of Output Stage.—The main power valves are allowed to be operated with grid current, and precautions must therefore be taken against the occurrence of distortion due to variable loads on the input. Great loss of efficiency would occur if the positive grid region were not used. The effect of grid current is overcome by shunting a resistance from grid to filament of the power valves, of such a value that it is small compared with the effective resistance of grid to filament. In the static case, i.e. before modulation, the efficiency of the last stage is 28 per cent. This efficiency increases and decreases with modulation.

Earthing.—The earthing of the transmitter is to a grid of wires which were buried in the ground when the foundations of the building were being laid. There is thus what is called a "general station earth" which is separate for each transmitter. Great importance attaches to the symmetry of the earthing arrangements of the high-frequency units, and great care has been taken to avoid unequal earth paths. The high-frequency earths of the radiating systems are discussed later in the paper.

Feeder Lines.—The high-frequency feeder lines are connected to a high-frequency transformer circuit, the primary of which is formed by the inductance of the closed circuit in unit D, while the secondary is connected to the feeder lines. The feeder line terminates in the transformer house.

Aerial Systems.—The masts (M1, M2, M3 and M4) were supplied by the Foundation Co., Ltd. As will be seen from the general lay-out plan in Fig. 1, they are placed as far as possible from each other and from the building. The designers of the station were faced with the necessity of using relatively short masts. The Air Ministry considered that, in view of the amount of flying that takes place round the area, it would be dangerous to build masts of greater height than 200 ft. With such dimensions the problem is best solved by erecting four masts and placing them, as mentioned before, at the maximum possible distance one from another. Masts M1 and M2 support one aerial, and masts M3 and M4 support the other. A distance of 900 ft. separates one aerial from another. The object of this large separation is to ensure that there shall be no heavy induced currents in one aerial system from the other, and to try to arrange that the induced currents in any mast from the aerial it supports shall be so small as to produce little distortion of the horizontal polar diagram. The masts are insulated from the ground chiefly to give such a flexibility of adjustment that the mast can either be earthed or insulated, depending upon the wavelength used and the amount of distortion of the polar diagram found in practice. It is of interest to note that tests undertaken on specimen porcelain insulators, such as are used on the masts, showed that they were easily capable of withstanding a high-frequency voltage of 10 kV at 1 000 kilocycles per sec. without undue heating. When sprayed either with distilled or " hard " mains water no brushing was apparent. In practice very thin lead washers are fitted between the porcelains and between the mast foot and the end insulators, in order to obtain as intimate and evenly distributed a contact as possible. This was done to avoid local heating, which was observed on test if intimate contact between the metal and the porcelain and between each pair of insulators was not ensured. The technique of distant mast spacing naturally involves the use of a feeder line to conduct the high-frequency energy from the transmitter to the appropriate aerial.

Earth Systems.—A separate high-frequency earth system is arranged symmetrically under each aerial. Each earth consists of a number of copper wires radiating out from each feeder hut—one every 10°—the wires being buried about 9 in. below the surface and of such length that the earth system stretches out to about ¼ wavelength beyond the dimensions of the aerial (see Fig. 1). The wires do not terminate in plates.

OFFICE BLOCK.

The office block (Fig. 2) contains the two control rooms, with their associated battery rooms, offices and rooms for subsidiary apparatus. The offices comprise a general office, an office for the engineer-in-charge, and an office for the maintenance engineers. The ground floor is completed by a garage, waiting-room, hall and lavatories. The upper story comprises a staff mess-room to which are attached a larder and kitchen, and two listening rooms where the quality of the transmission can be checked on loud-speakers. A gallery for access to rooms on the upper story overlooks the transmitter room and gets borrowed light therefrom. The upper story also contains a test room, a studio, and a small room to be used for tuning-fork gear. A detailed description of the above follows.

LISTENING ROOMS.

Two rooms have been set aside for routine quality-checking by loud-speakers and they are intended primarily for use by the engineer-in-charge of a shift. It was considered necessary to provide two such rooms to enable simultaneous observations of the quality of each transmitter to be made by two listeners under similar conditions. There are, in fact, numerous occasions on which it is desirable to use both these rooms at the same time, and for this reason it was not considered advisable to provide only one. The equipment of each room consists of a loud-speaker which normally takes its input from the check receiver, but arrangements have been made to enable comprehensive checking also to be carried out, i.e. the input to the loud-speaker can be taken from (*a*) the B amplifier output, or (*b*) the check receiver output.

TEST ROOM.

A small room has been equipped with the necessary apparatus for taking definite measurements of the performance of either of the two transmitters. The intention is that such measurements shall be made once a week, or more often if necessary. The apparatus contained in this room is also used when any alteration has been made to a transmitter, or when the quality is considered below standard for some indefinable reason, or when special experimental work is in progress. The equipment consists of the following:—

(*a*) Cathode-ray oscillograph, used for checking the degree of modulation which the transmitter will take without distortion, and particularly for observing the linearity with a varying degree of modulation.

(*b*) A constant-amplitude variable-frequency valve oscillator with associated amplifiers, for measuring the frequency characteristics of the lines, amplifiers, etc.

(*c*) Comprehensive loud-speaker checking can also be carried out in this room, so that measurements can be taken simultaneously with observations by ear.

Permanent wiring has been installed between both control rooms and the test room, so that these operations can be carried out without disturbing the apparatus used for the routine transmission of programmes. Running from each transmitter to the test room there are also three screened leads which can be coupled to various points in the main transmitter circuit.

CONTROL ROOM.

Two rooms are provided to house the necessary amplifiers, check receiver and switchgear for controlling and checking the audio-frequency input to the transmitters. Since most of the apparatus has been developed by the B.B.C. specially for use at the Regional transmitting stations, it is proposed to describe it in some detail. Each control room is normally employed in conjunction with the transmitter adjacent to it (see Fig. 2, ground-floor building). Should the necessity arise, however, the control of each programme may be carried out from either position. In order to minimize, as far as possible, trouble from high-frequency currents which might be induced in various parts of the input equipment by the transmitters, the control rooms are screened with copper gauze built into the floor, ceiling and walls, the whole being efficiently bonded and earthed.

In each room the actual control position consists of a small mahogany desk upon which are mounted the volume-control potentiometers, monitoring meters, operating keys, etc., all leads to the desk being laid on an overhead cable rack running from the amplifier racks. Upon the latter are mounted the checking apparatus, the " A " and " B " amplifiers, etc., and, in the case of No. 2 control room, the cable terminating and testing equipment. An " A " amplifier is inserted between the " B " amplifier and the microphone when the studio is in use. The output of a " B " amplifier is connected to the input of the transmitter, while its input is derived either from the cable line to Savoy Hill or the output of an " A " amplifier.

There are two battery rooms, one adjoining each control room, that adjacent to No. 1 control room containing the anode-supply batteries and the other the filament batteries with their charging generators.

CABLE CIRCUITS.

There are five cable circuits to Savoy Hill, of which four are unloaded and suitable for music transmission, whilst the fifth is lightly loaded and is intended mainly for general communication purposes. The lines are terminated on " U " links in No. 2 control room, from which point the circuits are brought via line fuses to screened repeating coils, the latter being essential in preserving accurate capacity balance between cable and earth.

Distribution of Cable Circuits.—The secondaries of the repeating coils are brought to connection strips at the top of the test rack, at which point the actual distribution of the circuits takes place. Double jumpers connect each music line to two sets of break jacks, upon which terminates the internal wiring from the respective control desks, the main purpose of the jacks being to enable a line to be isolated from either desk should a local fault occur.

On the desks each line is common to two 3-position keys, and a " busy " lamp associated with the line in question lights on each desk as soon as one of the keys in either control room is moved from a central position and a line thus occupied.

The functions of the two keys are:—

(1) To connect a line to one or other of the " B " amplifier inputs (there are two sets of amplifiers in each control room); or

(2) To connect a line either to the break-jack field on the test rack in No. 2 control room or to the desk control telephone common for communication purposes.

With regard to the fifth line, a jumper brings it to a break jack, from which connection is made to a key on No. 2 control desk. This key, when in the normal position, connects the line through to the office, and when in the " off normal " position brings the line to both control desks, where it can be utilized in the same manner as the other lines. A " busy " lamp glows on each desk as soon as this line is occupied.

Communication with Savoy Hill.—During transmission one line is employed on each desk for communication purposes, and should this or one of the music lines fail, two courses are open, one being to utilize the office line (No. 5) and the other to share the remaining control line between both control desks. Obviously, wherever possible, the office line is used for communication and not for transmission purposes, owing to its comparatively bad frequency characteristic.

Each control position is provided with a ringing machine and a hand microphone-telephone set, the latter hanging conveniently at the side of the desk.

AMPLIFIERS.

Each control room is provided with a single " A " and two " B " amplifiers, the former being for use in connection with the local studio equipment as indicated above.

The amplifiers are mounted on the apparatus rack, their feed meters and the microphone current meter being fitted in a panel above them, whilst the " B " amplifier control potentiometers are placed in a convenient position on the control desks.

For test purposes both inputs and outputs of all amplifiers are terminated on break jacks, a strip of which is mounted on each amplifier rack. The amplifier filament circuits are completed by means of keys, placed within reach of the control engineer, on the rack just above the amplifiers themselves. H.T. and L.T. fuses are connected in each circuit.

CHECKING RECEIVER.

Each control room is provided with complete equipment for checking by wireless reception.

The performance for which the receiver was designed is as follows:—

Selectivity.—The receiver is to be capable of completely cutting out signals of equal strength separated by 50 kilocycles per sec. from the frequency to which the receiver is tuned, the selectivity to be such that there is no audible trace of the interfering signal.

Audio-Frequency Response.—The overall frequency-response characteristic of the receiver should be flat from 20 to 10 000 cycles per sec. within $\pm\ 0\cdot5$ decibel.

MONITORING ARRANGEMENTS.

(*a*) *Visual.*—Three meters are available for visual monitoring at each control desk, these being the modulation meter, the slide-back galvanometer and the speech-choke voltmeter. The latter is operated in series with that joined across the speech choke in the anode circuit of the modulated magnifier stage of the transmitter, and is calibrated accordingly. As a general rule this voltmeter is used in preference to the other meters, as it gives the engineer more direct check over the performance of the transmitter.

Slide-Backs.—Each control room is fitted with a standard slide-back unit, incorporating two separate instruments. These are each connected permanently across one of the " B " amplifiers, separate meters being mounted on the control desks.

A slide-back unit consists of a triode valve with a negative grid-potential, the low-frequency input to which can be adjusted accurately by means of a potentiometer. A sensitive d.c. milliammeter is connected in the plate circuit to indicate when anode current is flowing. The grid and anode potentials of the slide-back valve are set, and the input potentiometer is so adjusted that anode current flows only when the transmitter is receiving its maximum audio-frequency input.

(*b*) *Aural.*—Loud-speakers, operated by the comprehensive checking amplifier, are available for programme checking in both the quality rooms and the control rooms, although routine checking is carried out by means of headphones only in the latter. Jacks for the headphones are fitted at each transmitter control desk and in both control rooms, so that, if required, both programmes may be heard by the engineer on duty.

In order that telephonic communication may be carried out without interruption when the loud-speaker is in use, a pair of contacts from the desk telephone speak-ring key are arranged to operate a relay which breaks the loud-speaker circuit when the key is in the "speak" position.

The loud-speaker amplifier is not used for routine monitoring, but feeds loud-speakers in the test room, engineer-in-charge's office, mess room and waiting room, etc. Two lines are run to each of these points, one from each checking equipment, and a pair of jacks is provided to enable a choice of programmes to be made.

Test Rack.—As previously stated, any of the five circuits from Savoy Hill may be brought to the break-jack field on the test rack in No. 2 control room, by throwing a key on one or other of the control desks. Similarly, all amplifiers, etc., are terminated on break jacks, and they may thus be utilized for test or tested themselves by connecting them to the break-jack field by means of double-ended cords. Tie lines are brought from the jack field in No. 1 control room to that in No. 2, in order that the apparatus in the former may be available for use in the test bay.

Break Jacks.—All break jacks employed on the apparatus are of the double type, i.e. they consist of two 3-point jacks (tip, inner and sleeve) mounted one above the other.

The plugs used in connection with these jacks are serrated on one side of the grip, in order that polarity may be traced when they are used on a double-ended cord.

APPARATUS FOR MAINTAINING ACCURACY OF RADIATED CARRIER FREQUENCY.

A room has been set apart for apparatus for maintaining a specially high degree of constancy of the carrier wave of one of the transmitters. This has been done to cover the possibility of working one of the transmitters on the same radio frequency as one or more other B.B.C. stations. The system used at present for several of the smaller transmitters working on a single frequency depends on a thermostatically controlled tuning-fork, which produces a constant frequency of the order of 1 000 cycles per sec. This frequency is then multiplied by frequency-doubling amplifiers until the required radio frequency is obtained.* It is possible that such apparatus may also be installed at Brookmans Park for the purpose of emitting a standard frequency of declared accuracy, which would be of the order of 5 parts in a million, assuming the tuning-fork method of drive. Working the station as it is at present, i.e. relying only on the master oscillator, which is a D.E.T.2 valve working at a power level of about 200 watts, provided with filament heating from a battery and a separate motor-generator for the anode supply, the accuracy is of the order of 300 cycles over a period of two or three days for a carrier-wave frequency of 1 148 kilocycles per sec.

STUDIO.

A small studio has been provided in order to enable tests to be carried out locally, and for use in emergency. The walls are treated in the normal manner in order to give satisfactory results acoustically. Gramophone apparatus has been installed in addition to the usual microphone equipment.

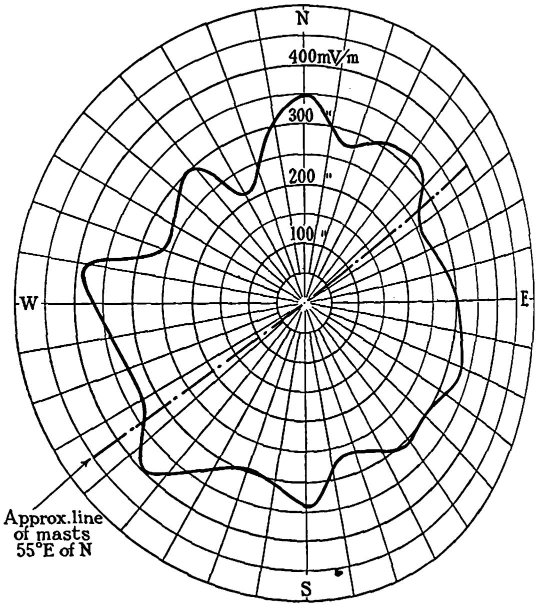

FIG. 16.—Polar diagram of 356-m transmitter, with approximately 30 kW in the aerial.

ALARM SYSTEM.

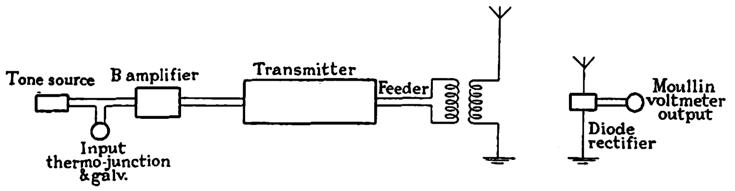
In order to summon the engineer-in-charge of a shift to any part of the building where assistance may be required, a system of coloured signal lights has been installed in several positions, such as the transmitter hall, power house, control rooms, etc. One particular colour is associated with each point, for instance a red lamp may indicate the power house, a blue lamp the transmitter hall, etc. When assistance is required, the attendant presses a button on the wall and a lamp having the colour allotted to that particular room lights up in all the other rooms where the shift engineer is likely to be, a bell ringing in each room at the same time in order to attract his attention to the lamp. The engineer can then proceed straight to the room indicated. This system, together with the internal telephone system, was installed by Ericsson Telephones, Ltd.

---

* P. P. ECKERSLEY and A. B. HOWE: "The Operation of Several Broadcasting Stations on the same Wavelength," *Journal I.E.E.*, 1929, vol. 67, p. 772.

GENERAL PERFORMANCE OF THE STATION.

The effect on the listening public of the change-over from a low-power station situated in the centre of London, to a comparatively high-power station approximately 15 miles due north of London, has already been discussed in an earlier section of the paper. This concerns, of course, the transmitter which is tuned to a frequency of 842 kilocycles per sec. (356·3 m). The input to the high-frequency feeder lines in this case is approximately 30 kW, and the polar diagram of field strength for this power, when taken at a distance of 5 km from the station, is shown in Fig. 16. It must be realized that polar diagrams express a mean of field strength, and that idiosyncrasies of particular localities produce large variations from this mean.



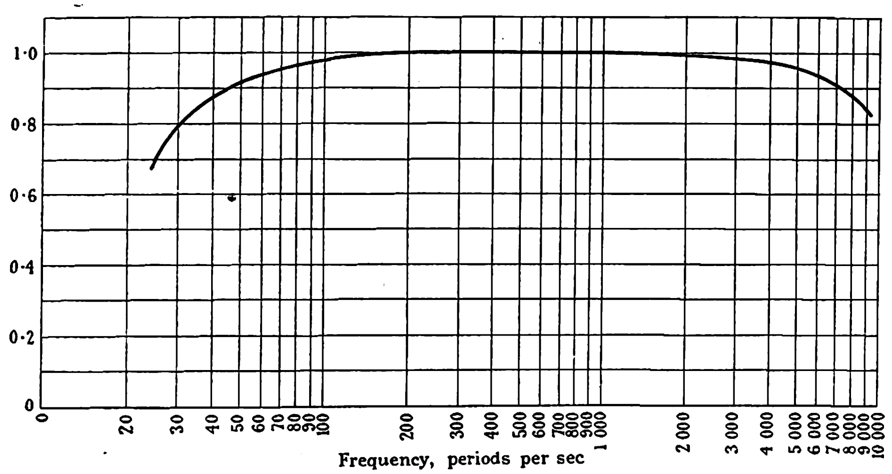


FIG. 17.—Overall response curve of 356-m transmission.

Fig. 17 gives the overall frequency-response curve including the "B" amplifier, transmitter and aerial. The response of the transmitter to varying amplitudes of audio-frequency input at a given frequency is sensibly flat up to 100 per cent modulation. The frequency of 842 kilocycles per sec. (356·3 m) is transmitted on the north masts, which are insulated at the base. The effect of the masts under these conditions is negligible at this frequency. As will be seen from Fig. 1, the two aerials are parallel and the distance between the line of each aerial is 900 ft. At this distance the effect of the masts of one transmitter on the other is also practically negligible, whether they are earthed or unearthed. This fact is apparently due to the distance alone, because the effect on either transmitter of earthing or unearthing the masts of the other transmitter is very small, while the effect of earthing or unearthing the masts in use for either transmitter is very considerable. In the case of the 1 148 kilocycle-per-sec. (261·4 m) transmitter the polar diagram can be varied by different methods of earthing the masts, and work on this problem is still proceeding, but the conditions of working at the time of writing the paper are shown in Fig. 18. The power supplied to the aerial system has since been raised to 45 kW.

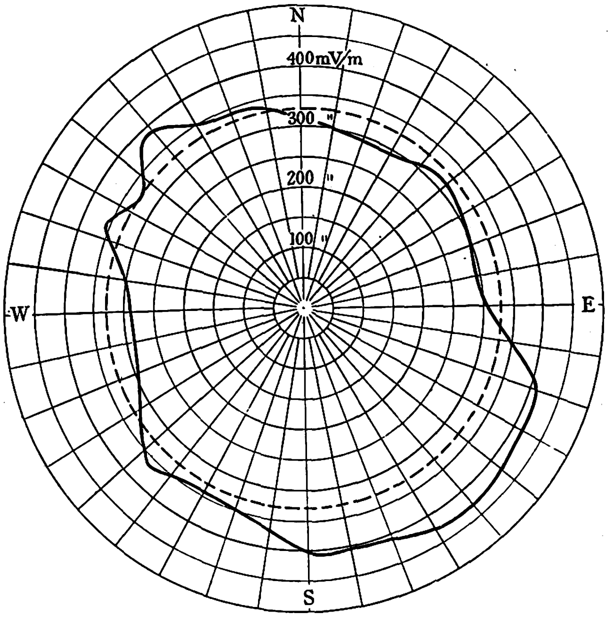

FIG. 18.—Polar diagram of 261-m transmitter with approximately 30 kW in the aerial.

Observations of variations of frequency of the carrier wave due to modulation (frequency modulation), made both in the static and dynamic conditions, indicate that this was so small that it was extremely difficult to obtain any definite figure.

No difficulties of an interesting nature were encountered when testing the station in the preliminary stages, although the transmitters had not been tested as complete units at the makers' works. Certain minor defects and omissions of little importance showed themselves, but in no case was any major alteration made.

It had been anticipated during the design stage that some difficulty would be experienced from "cross-talk" between the two programmes. There was, of course, the possibility that there might be some mutual high-frequency effect between the two transmitters themselves and between the feeder lines and aerial systems, but this effect was found to be absent to a rather remarkable extent. When the transmission from one aerial was unmodulated and a pair of telephones was connected across the check receiver at a point where the power level was suitable for a loud-speaker, no trace of the modulated radiation from the other transmitter could be heard. This was carried out with the control-room apparatus disconnected from the transmitter under test. This test is, of course, extremely drastic because no practical listening could be carried out under equivalent conditions. However, when one transmitter was radiating a programme and the other was emitting an unmodulated carrier, but with the input apparatus fully energized, distinct cross-talk was audible. This was found to be due to the fact that two earths had been provided for each control room, on the principle of a "silent" and "noisy" earth. The filaments of the amplifier valves were connected to the "silent" earth, and the amplifier screening-boxes and the gauze screen enclosing the whole control room were connected to the "noisy" earth. This scheme of connections resulted in a pick-up of the modulated high frequency from the other transmitter, which found its way through the amplifier to the transmitter, becoming sufficiently rectified on the way to produce an audio-frequency component of the unwanted programme. This was rectified very simply by using a common earth for all apparatus in the control room, no other effects being introduced by this altered method of connection.

CONCLUSION.

The authors' thanks are due first of all to the Governors of the British Broadcasting Corporation, for permission to publish this paper, and to the following members of the B.B.C. staff, who have made considerable contributions to the design and construction of the station itself: Mr. H. Bishop, the assistant chief engineer; Mr. H. L. Kirke, head of the research department, and his assistant, Mr. T. C. Macnamara; Mr. M. T. Tudsbery, the civil engineer; and Mr. B. N. MacLarty, head of the installation section. Finally, thanks are due to Mr. L. W. Hayes, for assistance in correcting diagrams and proofs, and to Mr. J. E. Calverley, of the English Electric Co., for supplying information in connection with the large high-tension motor-generators.

DISCUSSION BEFORE THE WIRELESS SECTION, 7TH MAY, 1930.

Col. A. S. Angwin: I am very interested in the essential differences between this, the most modern wireless station for broadcasting, and the general practice in radio-telephony stations for commercial point-to-point working. One of the most striking features of the new station is the finality which presents itself in the lay-out. It is obvious that the authors are not contemplating turning their twin transmitters into triple transmitters at any very early date; neither are they likely to embark on a competition with European broadcasting stations in augmenting the power of the station. The ground space is adequately filled and they have presented a complete lay-out sufficient for the immediate problem, without provision for expansion in the future. I think that this limit to the possible expansion must have largely influenced the authors in deciding whether to take power from outside or to use a self-contained system. For a station of this power (500 kW) and with the very good running load-factor, the conditions are undoubtedly as favourable as they could be for a self-contained power system, but the statement actually made by the authors in dealing with the question of their choice: "Moreover, it is possible to generate locally at approximately the same cost as, or in some cases a considerably lower cost than, that at which power can be bought," merits some attention. The authors' contention does not agree with our experience for power supply to commercial radio stations. From the remarks which Captain Eckersley made in presenting the paper, I gather that cost was not the main consideration. If power of the order of 500 kW can be generated locally more economically than it can be bought in such a location as London, close to a power supply, it does not reflect favourably on the scheme for the adequate supply of power at a reasonable cost which is at present covering the country. With regard to the factor of breakdown, the authors state: "It is interesting to note that 'shut-downs' of considerable duration at broadcasting stations have frequently been due to failure of the public supply mains." This seems to be a grave reflection on the reliability of a public supply. I think that, in spite of the fact that provision has been made for a complete spare Diesel engine and generator, the other sources of trouble common to the motor-generator plant are in themselves as likely to cause interruption as anything that might normally be expected from a well-regulated outside power system. It is interesting to note that the designers have stood their ground and have provided for a high-tension d.c. supply rather than a rectified a.c. supply. It is obvious, however, that consideration of the trouble which they have experienced was ever present with them when the station was designed, and precautionary measures have been necessary, such as the addition of chokes and resistances in the anode supply to the valves. The device of adding a resistance at each anode feed is, it seems to me, essentially a compromise. It is clear that much work remains to be done on the problem of connecting a high-tension d.c. supply from a motor-generator direct to water-cooled valves such as those at present in use. The insertion of a resistance of the high order of 500 ohms directly in the feed circuit seems rather like throwing away the efficiency which is striven for by the use of high-tension d.c. generators. I have made a small calculation which shows that a resistance of 500 ohms dissipates about 0·5 kW of energy in the anode supply to each valve. Taking the cost of power as 1d. per unit, this is ½d. per hour per valve. I estimate that the valves themselves are costing 3½d. per valve per hour to run. From this, it seems that unless an increase in the life of the valve of the order of 14 per cent is secured it is a very uneconomic means of providing for a lengthening of valve life. I presume that the station has not been running long enough for any figures to be available as to what order of life is being obtained from the valves, but it is of importance to consider how much one can afford to waste by adding resistance in the anode circuit of a valve in order to improve the life of the latter. There are other considerations which have doubtless carried weight with the designers, such as greater security from temporary breakdown. It is stated on page 1168 that the present accuracy of frequency is of the order of 300 cycles per sec. in 1 148 kilocycles per sec. I congratulate the designers on having at once obtained a tolerance which was suggested at the last C.C.I.R. Conference. This is done by the use of a master oscillator. The C.C.I.R. has also recommended that within a short time this limit of tolerance of a broadcasting station should be brought down to 50 cycles. It would be interesting if the authors could give some indication of how they hope to achieve this, whether by means of a master oscillator or by the use of a tuning fork. A photograph of the high-frequency transmission line has been shown on the screen and it is briefly mentioned in the paper. Some details of the actual type of line employed would be of great interest. I should also welcome further information regarding the methods which the authors have adopted for altering the shape of the polar diagram (Fig. 18). I infer that there is more involved than merely insulating or earthing the masts; presumably something in the nature of a tuned circuit is interposed between mast and earth.

Mr. J. E. Calverley: I should like to refer to the high-tension machines used in the station. The firm with which I am associated has been manufacturing high-tension machines for over 20 years. The first were built about 1907 and were of 50-kW capacity at 5 000 volts. They had air-insulated commutators, and insulated foundations and couplings. The present machines have been developed in the course of time from those original sets. In the meantime, about 20 different sets have been built for voltages of 10 000 and over. The first machines were used for telegraphy, and four were connected in series to give 20 000 volts. To prevent large variations of load on the generators a battery of 10 000 cells was used in parallel. There was an air of experiment throughout, but in the present station there is apparently nothing experimental at all. The machines are normal, the lay-out is normal, the cables are taken in an orderly manner in ducts and there is little to distinguish the station from one running at 500 volts d.c. This very real progress is the more evident by reason of its unobtrusiveness. The first point upon which a designer would seize when designing the high-tension machine is the apparent advantage offered by 2-pole windings with wide spacing from brush to brush. The machines adopted by the authors are of the 4-pole type, and only when one is building a 2-pole machine is its weakness apparent. The insulation to earth and between conductors of the long end-windings is a difficult matter with 2-pole machines. In d.c. machines, where the slot pitch is limited by commutating conditions, the maximum thickness of insulation is probably in the neighbourhood of 0·1 in., and with 10 000 volts to earth the stress on the slot insulation is then 100 000 volts per inch, which is too high for continuous operation. For this reason it is usual to insulate the machines from earth, but this has its disadvantages, being expensive and dangerous and necessitating insulating couplings. It is quite a definite step forward to take such precautions that the insulation stresses are graded throughout from positive to earth in such a way that the stresses are normal and, further, that they are so controlled that no undue stress can arise in any part, even in the case of accidents. I should be interested to know how extensive a development of high-tension machines will be required during the next few years. What outputs and voltages will be required? It is difficult to design machines for wireless experts owing to their constant new demands, but the limit of size for this class of machine does not seem to be in sight. It will be safe to make much larger machines than have been built up to the present. In view of the general popularity of rectifiers, I think that much credit is due to the engineers of the B.B.C. for adopting d.c. machines with their higher efficiencies and greater robustness.

Mr. E. H. Shaughnessy: I am interested to see that the B.B.C. have taken up the closed water-cooled system. I believe that the first closed system was installed at the Rugby radio station, where we used distilled water. I am also glad to note that the authors have adopted the practice which we favoured at Rugby of using d.c. machines for the high-tension supply to the valves. At Rugby we have d.c. machines made by the British Thomson-Houston Co., each unit of which is of 250 kW, has only one commutator and gives 3 000 volts, so that with two machines we develop a pressure of 6 000 to 7 000 volts for the high-tension supply. These have now been running satisfactorily for some years. I congratulate the engineers of the B.B.C. on the performance of the Brookmans Park stations. The reception that we obtain in South London is quite as good from the new station as it was from the old 2LO. On Sunday last, however, I was listening to some very quiet music, by Wagner I think, on the National programme, when I heard a religious service which was being broadcast on the same wavelength, and which was also being radiated from the second Brookmans Park transmitter. On testing my receiver I found that nothing was wrong with it. I should be interested to know whether this overhearing was due to the land lines, some coupling in the station at Brookmans Park, or the arrangement at Savoy Hill.

Mr. P. K. Turner: The new station has a good audio-frequency response curve—far better than that of any other broadcasting station I have seen. In connection with the possibility of good reception from the station, I notice that it is so designed that it can be modulated up to 100 per cent without distortion. I do not know quite what this means. Can the authors give figures showing what they regard as the mean and the peak modulation percentages of the transmitter? I would ask them not to make these figures too high, as although there is everything to be said, from certain aspects, for pushing up the modulation, it rapidly becomes almost impossible to rectify this in the receiver without undue distortion. It is quite easy to rectify matter which is modulated 60 per cent, but with modulations of 80 or 90 per cent it becomes increasingly difficult to rectify without bad wave-form distortion.

Captain P. P. Eckersley and **Mr. N. Ashbridge** (*in reply*): Colonel Angwin questions *inter alia* whether more allowance should have been made in the general design of the station for future extensions. The existing plant allows for an output from each transmitter of 50 kW, although it was intended to operate them with an output of 30 kW. The latter power was actually used when the station was opened, but in the case of the transmitter using a frequency of 1 148 kilocycles per sec. (261·3 m) the power has since been raised to 45 kW in order to minimize, as far as is possible, the effects of local shielding, which are somewhat severe in certain districts on this comparatively high frequency. We doubt whether a large increase in power over and above 50 kW to the aerial is justifiable economically, for transmitters using these frequencies when considered in relation to the increased performance obtained. With regard to the question of a large-scale extension, such as the installation of a complete additional transmitter, sufficient land is in fact available.

Colonel Angwin has expressed surprise that it should be possible to generate electric power locally at a price comparable with that charged by a public supply company. In this connection it has to be remembered that the nature of the load is very advantageous, and with Diesel engines operating at their optimum load the cost of generation should be low. In comparing the two possible methods of providing power, account must be taken, firstly, of the fact that the provision of some proportion of stand-by generating plant was considered to be essential on account of the prime necessity of continuous service; and, secondly, of the cost of cables and substation plant. With regard to the question of the relative reliability of a public supply as compared with local generation, it is not really a comparison of the reliability of one generating station with another, because in our experience the failures of public supplies have almost invariably been due to the mains and not to the generating stations. It is true that failures elsewhere in the station are likely to be more frequent than supply failures, but the breakdown of a single component cannot be compared with the complete failure of supply, which entirely puts out of action both transmitters, together with all auxiliary plant such as motor-generator sets, water pumps, etc. Apart, therefore, from the duration of the actual mains' failure, some additional time is lost in restarting the whole station.

We agree that the insertion of a 500-ohm resistance in the anode supply lead to each main power valve is a compromise, but it is hoped that with improved valves this may not be necessary in future. It is done at present more to minimize the effect of an unstable valve than to lengthen the life of the valves, although to an extent the latter is an additional advantage.

Colonel Angwin inquires what steps could be taken to increase the constancy of the carrier frequency, should this become necessary. It is probable that a thermostatically controlled tuning-fork will be used, but the possibility of a "crystal " drive will not be overlooked. The whole question is actually bound up with the ultimate object in view; for instance, whether constancy is most desired, and whether absolute accuracy is necessary in addition, and so on. It should be explained that the stability of carrier frequency of 300 cycles per sec. in 1 148 kilocycles per sec. mentioned in the paper is obtained without any day-to-day readjustment of the drive circuit of the transmitter. This figure is reduced in practice to a variation of about 100 cycles per sec. by an occasional slight re-adjustment of the drive to take account of temperature variations, the amount of re-adjustment necessary being indicated by a wavemeter of the type designed by the Union Internationale de Radiodiffusion.

The feeder lines are composed of 19/·044 phosphor-bronze wire, supported on tubular posts 13 ft. high. The insulators are of standard pattern, and were tested at 7 000 volts, 1 200 kilocycles per sec., for 4 hours. There is nothing unusual in the construction of these feeder lines, and similar feeders have been erected elsewhere in the B.B.C. system. Data as to how the shape of the polar diagram was corrected are not yet available for publication. It is probable, however, that they will be contained in a future paper.

Mr. Calverley inquires what outputs and voltages are likely to be required for high-tension d.c. motor-generator sets in the future. We do not consider that it is possible at the moment to estimate the future requirements of designers of broadcasting stations. There are, of course, alternative methods of producing the necessary high-tension direct current for wireless transmitters, and it is difficult to say which will ultimately gain the most favour for all types of radio stations. Speaking of broadcasting, it would appear that with a self-contained plant high-tension d.c. generation is most economical and flexible. If, however, a.c. mains supply is used, it is possible that the mercury-arc rectifier would show substantial economies over any other system. From the point of view, however, of the particular station under discussion, the mercury-arc rectifier is not considered to be superior to d.c. generation, and, therefore, there seems to be an important application for the method adopted by the Corporation.

Mr. Shaughnessy refers to cross-talk which occurred on a certain occasion between the two programmes radiated from Brookmans Park. It is true that cross-talk has occurred on occasions, but in most instances this has not been due to the transmitting station itself. There has been cross-talk between external telephone lines as well as in the control room at Savoy Hill, but in both cases steps are being taken by the Post Office and the B.B.C. respectively to reduce the number of occasions on which it occurs.

In reply to Mr. Turner, whilst it is true that the paper states that the transmitters are capable of being modulated linearly to the extent of 100 per cent it does not mean that the transmitters are necessarily run under these conditions. It is not possible to give a definite figure for the average modulation of a transmitter, because this varies with every type of programme. The maximum peak modulation normally reaches about 80 per cent, and the average is very roughly in the neighbourhood of 20 per cent, but, as already mentioned, the latter figure cannot be stated with accuracy.

DISCUSSION ON

"THE DEVELOPMENT OF A PRECISION AMMETER FOR VERY HIGH FREQUENCIES." *

Mr. W. F. Dunton (*communicated*): In Section (2) of the paper the author quotes a well-known but incorrect formula for the electromagnetic force between parallel conductors. The correct formula, first published by me in 1927, is now widely known among electrical engineers on the Continent. If two straight parallel conductors, each s cm long, have a direct current of I amperes uniformly distributed over their circular cross-sections, and if the distance between their axes is a cm, the force (in pounds) with which these conductors tend to attract or repel each other (according to whether the currents are similarly or oppositely directed) is not $4 \cdot 5\,(I/10\,000)^2 s/a$ but $4 \cdot 5 (I/10\,000)^2 \left\{ \sqrt{\left[(s/a)^2 + 1 - 1 \right]} \right\}$. Mr. Moullin says that the force is given by the first of these expressions when the conductors are "long"; but he does not give any idea as to the length which he has in mind, and he does not give any formula for other lengths. The second expression will, however, give the actual force in all cases and, to an engineer with a slide rule, is almost as convenient as the first. In a circuit breaker $(s/a)^2$ is frequently less than $\frac{1}{4}$, and in such cases the last factor in the second expression is approximately $\frac{1}{2}(s/a)^2$. The results given by the first expression are then $2a/s$ times what they ought to be. But a/s is frequently greater than 3, and the results obtained with the first expression are then more than six times what they ought to be, no matter how long the conductors may be. On the other hand, if $(s/a)^2$ is much greater than 1, the last factor in the second expression becomes approximately $(s/a - 1)$. Therefore, even where the length of each conductor is many times the diameter while the distance between their axes is only a few times the diameter of either conductor, the first expression would be improved by substituting $(s/a - 1)$ for s/a, a change which obviously does not make the formula less convenient. A detailed proof of the formula will be found in the *Journal of Scientific Instruments* dated November 1927, and in the *Revue Générale de l'Électricité* dated 12th May, 1928.

Mr. E. B. Moullin (*in reply*): The expression $F = 2I^2D$ per unit length is of course the limiting value which is approached when the length of the conductors is very great compared with their distance apart. In lines 20 and 24 of page 548 the length is given as 10 cm, and at the bottom of the second column of that page, and at the top of the second column of page 550, the value of D is found to be $1 \cdot 11$ cm for one instrument and $0 \cdot 87$ cm for the other. The length of the conductors is therefore about 10 times the distance between their centres. The approximate form of Mr. Dunton's formula, namely $F = 2I^2(s/D - 1)$, is a very useful and convenient abbreviation of the correct expression for the force between wires of finite length. It shows that the force in these instruments is about 10 per cent less than is given by $F = 2I^2/D$ per unit length. This deficit produces no real error, because the instrument is calibrated from another ammeter and not from the measured value of the force. It has also a small effect on the correction factors, but the effect is of the second order of magnitude. The total correction factor for proximity is about 4 per cent; over a small portion of the length this factor will be perhaps a little less than 4 per cent and so the total factor will be reduced by a very small amount, certainly less than 10 per cent. But the factor itself is small, so the correction to the correction is negligible and quite outside the accuracy of reading. The effect will be more pronounced in the correction factor for the screen tube and this is implicit in the statement near the bottom of page 550. The screen factor can, however, be measured and we need not rely on calculated values; thus it is found to be $6 \cdot 6$ per cent when the calculated value was 8 per cent. The effect of the finite length of the cylinders has been fully appreciated, but it has no measurable effect on the accuracy of the instrument, because the calibration is made from another ammeter. The "effect of irregularities at the ends of the system" was also dealt with in section (8) on page 67 of vol. 121 (1928) of the *Proceedings of the Royal Society*.

* Paper by Mr. E. B. Moullin (see page 544.)

GENERAL FORMULÆ FOR THE RADIATION DISTRIBUTION OF ANTENNA SYSTEMS.*

By R. M. WILMOTTE, M.A., Associate Member.

[From the National Physical Laboratory.]

(*Paper first received* 12*th September*, 1929, *and in final form* 27*th February*, 1930.)

SUMMARY.

Formulæ are given for the distribution of radiation in different directions. The paper is divided into the following sections:—

(1) Introduction.
(2) Antenna elements.
(3) Polarization.
(4) Current distribution.
(5) Effect of image in the ground.
(6) A straight wire inclined at any angle.
(7) A system of similar antennæ spaced in any given manner.
(8) A system of antennæ uniformly distributed around the circumference of a circle.

A number of special cases are deduced from these general formulæ, and curves are given to facilitate computation.

(1) INTRODUCTION.

It was considered that it might be of value to combine in one paper some general formulæ for the distribution of radiation from antennæ in various directions as far as present theories permit. These theories are not yet rigorously established and much experimental confirmation is still required. Many special cases of radiation from antenna systems have already been worked out by a number of authors. These, as far as they are known to the present author, are given in the Bibliography [items (1) to (10)]. Most of the formulæ are special cases of those given below, but special credit should be given to Abraham,† who initiated the principle of representing an antenna by a series of doublets, and to Pierce,‡ who first extended it.

In employing the formulæ given below it must be remembered that all the conducting currents must be taken into account. The presence of masts, stays and even underground conductors may affect the radiation distribution of an antenna system to a very considerable extent, owing to the currents induced in these conductors from the main antenna system. The extent to which this may occur is strikingly shown when an attempt is made to screen a portion of an antenna. Smith-Rose and Barfield § published some interesting results on this subject. They found that, on long waves, practically no effect on the signal strength was produced when the vertical portion of an inverted "L" antenna was surrounded by a metal screen. Evidently the currents induced in the screen induced in the horizontal portion an e.m.f. roughly equal to that which would have been induced in the vertical portion of the antenna had the screen not been there. Removal of the horizontal portion reduced the signal practically to zero. If such is the case it is to be expected that considerable alterations in the radiation distribution may be expected to be produced by any neighbouring conductor. It is probable that the result obtained by many workers, that a horizontally polarized ray on the ground is always rapidly rotated into a vertically polarized ray, is largely due to this effect. The horizontally polarized ray is so rapidly attenuated compared with the vertically polarized ray that its strength at any reasonable distance is negligible and the signal received is produced by vertical conductors in the neighbourhood of the transmitting system. This may also be produced by groups of horizontal and vertical conductors sufficiently close to the transmitter for the currents induced in the horizontal members to induce sufficient current in the vertical members to enable a definite signal to be received on a vertical antenna at a reasonable distance.

Many of the formulæ given below are very cumbersome. For computation purposes the curves given in Figs. 4 to 9 and 12 and 13 will be found useful.

Before embarking on the analysis it may be of interest to consider what is exactly meant by "radiation distribution." The property of the antenna system which this term is intended to convey quantitatively is the variation of field strength in different directions when the attenuation is neglected. In this connection there are two terms which are commonly used but have no rigorous meaning and largely overlap one another. They are "polar diagram" and "effective height." Effective height is a factor which, when suitably applied in Hertz's radiation formulæ, gives the field strength. A single number as a representation of this property is meaningless when applied to a directive system. Often there is no ambiguity in its meaning, but a combination of this with the polar diagram, which itself purports to give the variation of field strength with direction, would be more rigorously correct. This then would be a function of angular directions which, when applied, as explained below, in Hertz's equations, gives the signal strength in various directions when the attenuation is neglected. This factor may for convenience be called the "radiation distribution of the antenna system."

This function should give not only the strength of the field but also its direction and phase. A convenient method of expressing this is by means of two functions, one for each of the components of the electric field, these two components being perpendicular to the direction of propagation. The radiation distribution will, therefore, consist of two functions containing direction (relative to the antenna) and phase as variables. The field at a point P having polar co-ordinates $(r,\ \theta,\ \phi)$, where θ is the vertical angle, ϕ the horizontal angle (see Fig. 1) and r the distance, is large compared with the dimensions of the antenna system, is given by

---

* The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† See Bibliography, (1). ‡ *Ibid.*, (2). § *Ibid.*, (11).

$$E_\theta = \frac{60\pi I}{\lambda r}\Big[f_\theta \cos \omega\big\{t - (r'/c)\big\} - f'_\theta \sin \omega\big\{t - (r'/c)\big\}\Big] \text{ volts per metre} \quad . \quad (1)$$

$$E_\phi = \frac{60\pi I}{\lambda r}\Big[f_\phi \cos \omega\big\{t - (r'/c)\big\} - f'_\phi \sin \omega\big\{t - (r'/c)\big\}\Big] \text{ volts per metre} \quad . \quad (2)$$

where E_θ is the longitudinal and E_ϕ the latitudinal component of the electric field, λ (metres) is the wavelength, c (metres per sec.) the velocity of light, ω is 2π × frequency, and r' (metres) is the equivalent distance, as explained in a previous paper by McPetrie and the author.*

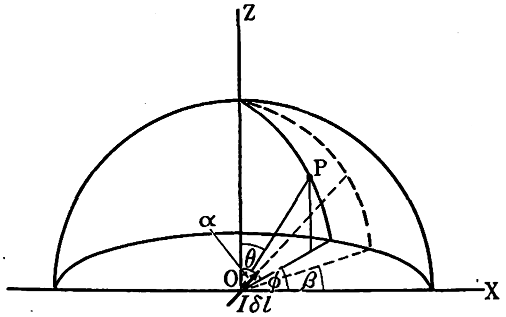

FIG. 1.

The radial component is not given, as the distances are usually so large as to make this negligibly small. These equations give the field strength in any direction when there flows in the antenna current of value $I \sin \omega t$ amperes. As this current is not the same in all parts of the antenna system it is essential to state the point where it is measured. The functions f_θ, f'_θ, f_ϕ, f'_ϕ are all functions of direction and represent the radiation distribution. It will be convenient to write the radiation distribution in the form

$$(f_\theta + jf'_\theta); \quad (f_\phi + jf'_\phi).$$

(2) RADIATION DISTRIBUTION OF ANTENNA ELEMENTS.

(*a*) *Straight Element of Wire.*

The variation of field strength around an element of straight wire is sinusoidal and symmetrical about the axis of the wire. It is, therefore, possible to resolve the element of wire into components as though it were a vector. Consider an element of wire in free space of lengths δl metres situated at the origin in the plane $\phi = 0$ and making an angle a with the axis OZ (Fig. 1). Suppose it carries a current $I \sin \omega t$ amperes. The field in the plane $\phi = 0$ will be given by

$$E_\theta = \frac{60\pi}{\lambda r} I\delta l \sin(\theta - a) \cos \omega\big\{t - (r'/c)\big\} \text{ volts per metre}$$

and $$E_\phi = 0.$$

These formulæ do not take account of the image in the ground.

In order to find the field at the point P (Fig. 1) having co-ordinates $(r,\ \theta,\ \phi)$ from a similar wire element but in a plane making an angle β with the plane XOZ, the element can be resolved in and perpendicular to the plane POZ. It can then be readily shown that

$$f_\theta + jf'_\theta = \big[\cos a \sin \theta - \sin a \cos \theta \cos(\phi - \beta)\big]\delta l \quad (3)$$

and $$f_\phi + jf'_\phi = -\sin a \sin(\phi - \beta)\delta l \quad . \quad . \quad (4)$$

(*b*) *Element of Coil.*

A straight element of wire is not the only form of antenna which can be represented by a line and treated as a vector. The field from a coil has also cylindrical symmetry and varies sinusoidally with the angular direction relative to that axis. It is, therefore, possible to represent a small coil by means of a vector perpendicular to the plane of the coil and passing through its centre. It is necessary to use some arbitrary convention regarding the direction of this vector, and the author suggests that, by analogy with other conventions of signs, the right-handed screw rule should be used as explained by Fig. 2. There is an important difference between the vector representation for a straight wire and for a coil. From a straight wire the direction of the electric field is in the plane containing the vector representing the element of wire and the direction of propagation considered, while for a coil it is perpendicular to this plane. Such a representative vector can be resolved into components as desired and, by reasoning similar to that followed in the case of elements of straight wire, the following results can be obtained for a coil represented by the arrow in Fig. 1.

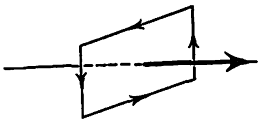

FIG. 2.

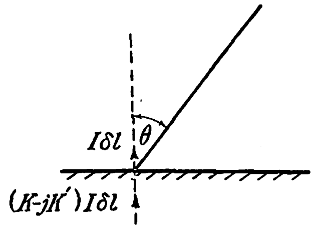

FIG. 3.

If δA represents the area-turns of the coil in square metres, and the current is $I \sin \omega t$ amperes, then the field in the plane $\phi = 0$ will be given by

$$E_\theta = 0$$

$$E_\phi = -\frac{120\pi^2}{\lambda^2 r} I\delta A \sin(\theta - a) \sin \omega\Big(t - \frac{r'}{c}\Big) \text{ volts per metre}$$

As before, these formulæ do not take account of the image in the ground.

---

* See Bibliography, (12).

Hence, from the field at any point P, we shall have

$$f_\theta + jf'_\theta = j\frac{2\pi}{\lambda}\sin\alpha\sin(\phi-\beta)\delta A \quad . \quad . \quad (5)$$

and

$$f_\phi + jf'_\phi = j\frac{2\pi}{\lambda}[\cos\alpha\sin\theta - \sin\alpha\cos\theta\cos(\phi-\beta)]\delta A \quad (6)$$

It follows that any result which applies to a given distribution of vectors representing elements of straight wires will also apply to an identical distribution of vectors representing elementary coils, if we write $-E_\theta$ for E_ϕ, E_ϕ for E_θ, $2\pi I\delta A/\lambda$ for $I\delta l$ and advance the field by 90°.

(*c*) *Special Cases.*

The above formulæ are seldom required in their complete form. The following are the more usual:

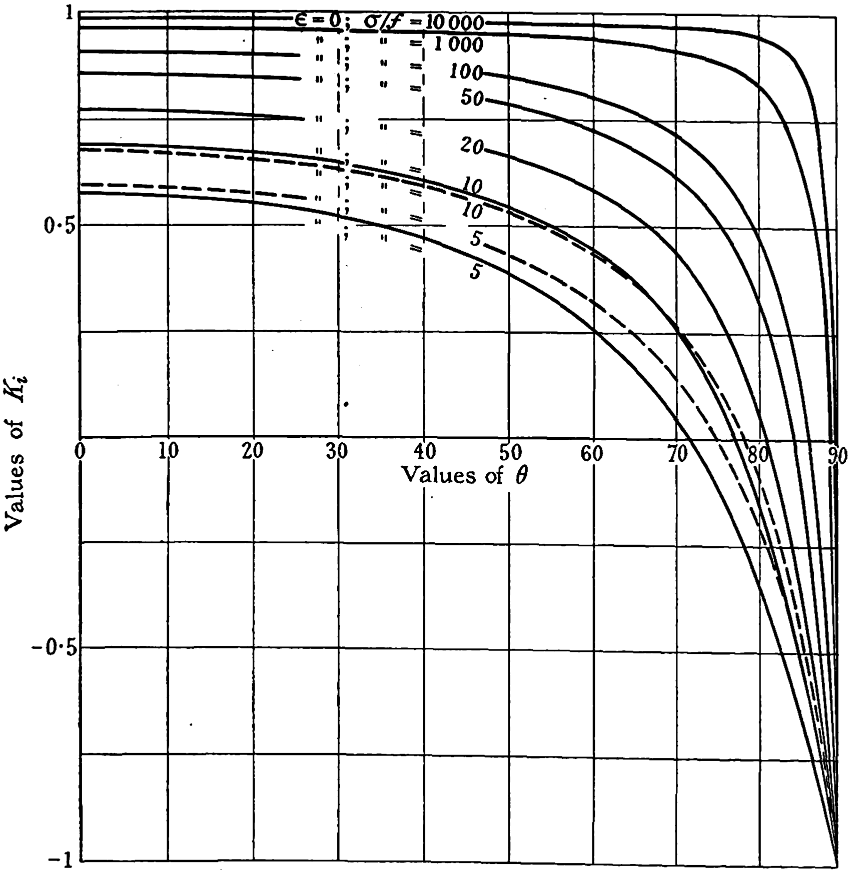

FIG. 4.

$$K_i = \frac{(\varepsilon^2 + 4\sigma^2/f^2)\cos^2\theta - (c^2 + d^2)}{(\varepsilon^2 + 4\sigma^2/f^2)\cos^2\theta + (e^2 + d^2) + 2\cos\theta\,(\varepsilon e + 2d\sigma/f)}$$

where $c^2 = \frac{1}{2}\left[(\varepsilon - \sin^2\theta) + \sqrt{\{(\varepsilon - \sin^2\theta)^2 + 4\sigma^2/f^2\}}\right]$

$d^2 = \frac{1}{2}\left[(-\varepsilon - \sin^2\theta) + \sqrt{\{(\varepsilon - \sin^2\theta)^2 - 4\sigma^2/f^2\}}\right]$

When $\varepsilon = 0$

$$K_i = \frac{2(\sigma/f)\cos^2\theta - 1}{2(\sigma/f)\cos^2\theta + 2\sqrt{\{(\sigma/f\cos\theta) + 1\}}}$$

(i) Vertical wire:—

$$f_\theta + jf'_\theta = \sin\theta\delta l; \quad f_\phi + jf'_\phi = 0 \quad . \quad . \quad (7)$$

(ii) Horizontal wire parallel to X axis:—

$$f_\theta + jf'_\theta = -\cos\theta\cos\phi\delta l; \quad f_\phi + jf'_\phi = -\sin\phi\delta l \quad (8)$$

(iii) Horizontal wire parallel to Y axis:—

$$f_\theta + jf'_\theta = -\cos\theta\sin\phi\delta l; \quad f_\phi + jf'_\phi = \cos\phi\delta l \quad (9)$$

(iv) Vertical coil. Vector parallel to X axis:—

$$f_\theta + jf'_\theta = \frac{j2\pi}{\lambda}\sin\phi\delta A; \; f_\phi + jf'_\phi = -\frac{j2\pi}{\lambda}\cos\theta\cos\phi\delta A \quad (10)$$

(v) Vertical coil. Vector parallel to Y axis:—

$$f_\theta + jf'_\theta = -j\frac{2\pi}{\lambda}\cos\phi\delta A;$$

$$f_\phi + jf'_\phi = -j\frac{2\pi}{\lambda}\cos\theta\sin\phi\delta A \quad . \quad (11)$$

(vi) Horizontal coil. Vector parallel to Z axis:—

$$f_\theta + jf'_\theta = 0; \quad f_\phi + jf'_\phi = j\frac{2\pi}{\lambda}\sin\theta\delta A \quad . \qquad (12)$$

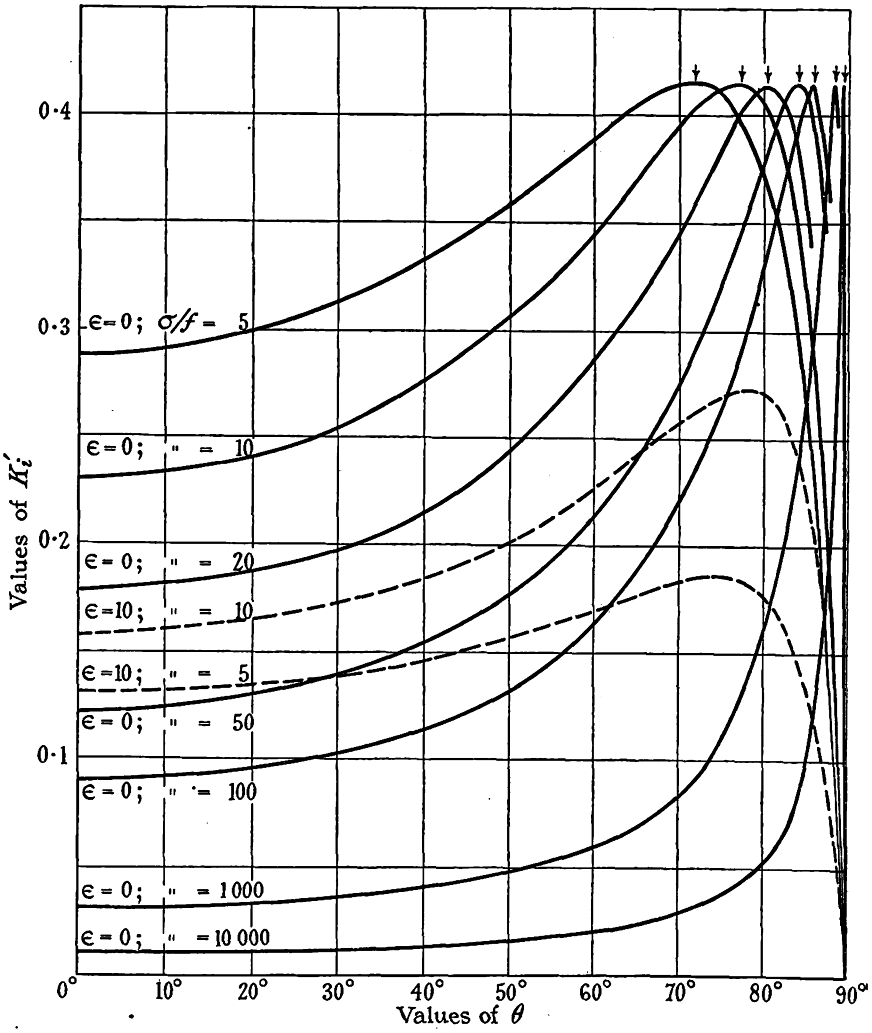

FIG. 5.

$$K_i = \frac{2\cos\theta(2c\sigma/f - \varepsilon d)}{(\varepsilon^2 + 4\sigma^2/f^2)\cos^2\theta + (c^2 + d^2) + 2\cos\theta(\varepsilon c + 2d\sigma/f)}$$

where $c^2 = \frac{1}{2}\left[(\varepsilon\sin^2\theta) + \sqrt{\{(\varepsilon - \sin^2\theta)^2 + 4\sigma^2 f^2\}}\right]$

$d^2 = \frac{1}{2}\left[-(\varepsilon - \sin^2\theta) + \sqrt{\{(\varepsilon - \sin^2\theta)^2 + 4\sigma^2/f^2\}}\right]$

When $\varepsilon = 0$

$$K'_i = \frac{2\sqrt{(\sigma/f)}\cos\theta}{2(\sigma/f)\cos^2\theta + 2\sqrt{(\sigma/f)}\cos\theta + 1}$$

giving maximum of $K'_i = 0{\cdot}414$ when $\cos\theta = \sqrt{(f/2\sigma)}$

(3) POLARIZATION.

The propagation of electromagnetic waves in or on the surface of an absorbing medium depends considerably on the polarization of the waves. In equations (1) and (2) E_θ is usually known as the vertically polarized component and E_ϕ as the horizontally polarized component.

A vertical current element can only produce vertically polarized components, but a horizontal current element may produce either and usually produces a combination of both. This is readily seen from equations (7), (8) and (9). A horizontal element will only produce purely horizontally polarized waves in a plane perpendicular to the plane in which the element lies, while it will produce purely vertically polarized waves in the plane in which it lies. In any other plane it will produce a combination of horizontally and vertically polarized waves.

(4) Current Distribution.

(a) Case of a Uniform Wire.

On the assumption of uniformly distributed inductance and capacity and negligible resistance it can readily be shown that the current distribution along a simple straight-wire antenna should be sinusoidal. That is, if the origin is taken to be the open end of the antenna, the current at a distance x from it will be

$$I \sin\left(\frac{2\pi x}{\lambda}\right) \quad . \quad . \quad . \quad . \quad . \quad (13)$$

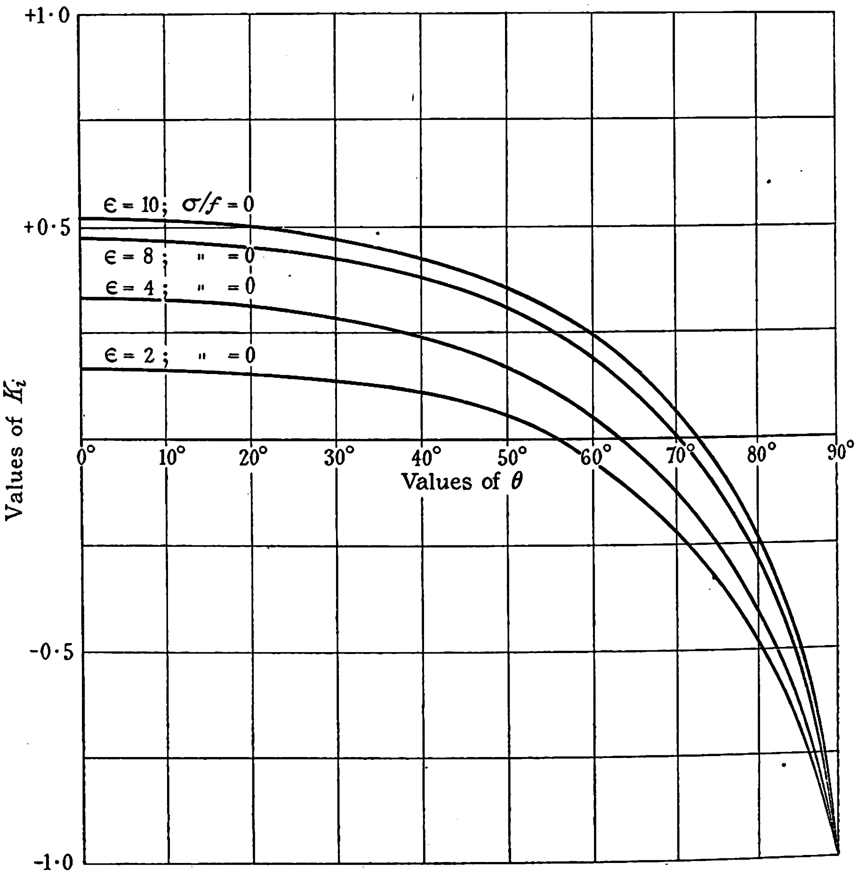

FIG. 6.

When $\sigma/f = 0$

$$K_i = \frac{\varepsilon \cos\theta - \sqrt{(\varepsilon - \sin^2\theta)}}{\varepsilon \cos\theta + \sqrt{(\varepsilon - \sin^2\theta)}}$$

$$K_i' = 0$$

This simple sinusoidal law of distribution of current was proved experimentally by the author * to hold with sufficient accuracy, except for local end-effects, for lengths up to $\frac{3}{4}\lambda$, and there is no reason to suppose that it will fail, except possibly when the total is very many wavelengths long.

In applying this formula it is necessary to be particularly careful, when there are discontinuities in the antenna such as multiple branches, a change in the diameter of the wire, lumped inductances, etc. On the simple theory, the voltage and current at any point distant x from the end of a length of uniform wire can be written in the form

$$v = jIa \cos\frac{2\pi}{\lambda}(x + b) \quad . \quad . \quad . \quad (14)$$

and

$$i = I \sin\frac{2\pi}{\lambda}(x + b) \quad . \quad . \quad . \quad . \quad (15)$$

In these equations I depends on the amplitude of the current, while b depends on the type of impedance connected at the end of the wire from which the distance x is measured. (This impedance is generally of the form of one or several lengths of wire.) a is a constant depending on the distributed constants of the wire and is equal to $\sqrt{(L/C)}$, where L is the self-inductance per unit length and C the capacity per unit length. We may write

$$a = \sqrt{(L/C)} = \frac{1}{cC} = cL \quad . \quad . \quad . \quad (16)$$

since c, the velocity of light, is very nearly equal to $1/\sqrt{(LC)}$.

---

* See Bibliography, (13).

It will be noted that b has the dimensions of a length, so that the impedance at the end of the wire may be represented by a length so far as the current and potential along the wire are concerned. When there is no impedance at the end of the wire, that is when that end is open, $b = 0$. It will be shown that any discontinuity can be represented, as far as the current distribution is concerned, by a loss or a gain of length of the wire at the point of discontinuity, together with a change in amplitude of the current.

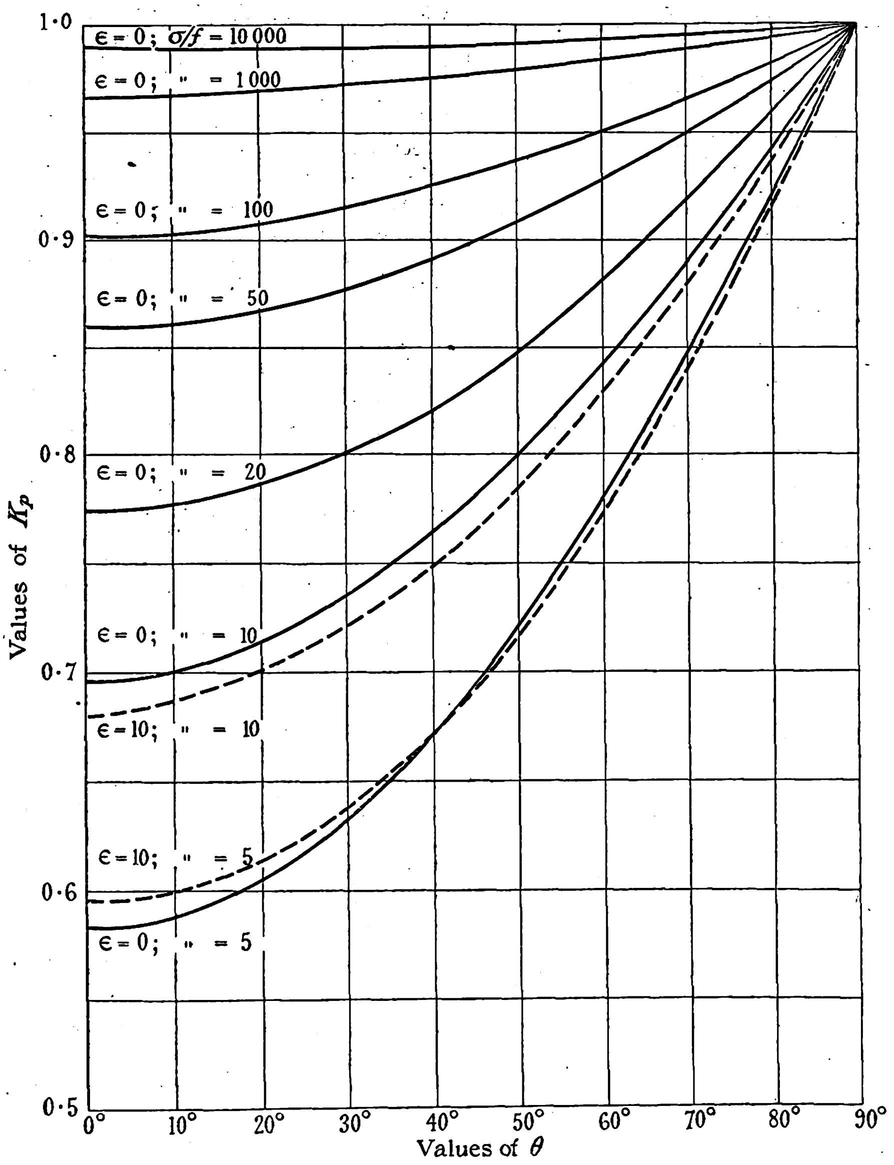

FIG. 7.

$$K_p = \frac{c^2 + d^2 - \cos^2\theta}{c^2 + d^2 + \cos^2\theta + 2c\cos\theta}$$

$$\text{where } c^2 = \tfrac{1}{2}\Big[(\varepsilon - \sin^2\theta) + \sqrt{\{(\varepsilon - \sin^2\theta^2) + 4\sigma^2/f^2\}}\Big]$$

$$d^2 = \tfrac{1}{2}\Big[-(\varepsilon - \sin^2\theta) + \sqrt{\{(\varepsilon - \sin^2\theta) + 4\sigma^2/f^2\}}\Big]$$

When $\varepsilon = 0$

$$K_p = \frac{2(\sigma/f) - \cos^2\theta}{2(\sigma/f) + \cos^2\theta + 2(\sigma/f)\cos\theta}$$

(*b*) *Case of n Branches meeting in a Point.*

Consider an antenna consisting of a single wire from the end of which n wires branch off. It does not matter what wires are connected to the end of these. Let the lengths of these branches be $l_1, l_2 \ldots$ and the equivalent lengths of the impedance at their ends be $b_1, b_2 \ldots$

Let the current and potential along the single wire, with the point O as origin, be respectively

$$I \sin \frac{2\pi}{\lambda}(x+b) \text{ and } jIa \cos \frac{2\pi}{\lambda}(x+b) \quad . \quad (17)$$

Then, if v_0 is the potential at the point O, we have

$$\begin{aligned} v_0 = jIa \cos\left(\frac{2\pi b}{\lambda}\right) &= jI_1a_1 \cos \frac{2\pi}{\lambda}(l_1+b_1) \\ &= jI_2a_2 \cos \frac{2\pi}{\lambda}(l_2+b_2) = \ldots \quad . \quad (18) \end{aligned}$$

and

$$\begin{aligned} I \sin\left(\frac{2\pi b}{\lambda}\right) &= I_1 \sin \frac{2\pi}{\lambda}(l_1+b_1) \\ &\quad + I_2 \sin \frac{2\pi}{\lambda}(l_2+b_2) + \ldots \quad . \quad (19) \end{aligned}$$

From equations (18) the ratios of the currents in the various branches can be calculated. Also, combining equations (17) and (18), we have

$$\begin{aligned} \frac{1}{a} \tan\left(\frac{2\pi b}{\lambda}\right) &= \frac{1}{a_1} \tan \frac{2\pi}{\lambda}(l_1+b_1) \\ &\quad + \frac{1}{a_2} \tan \frac{2\pi}{\lambda}(l_2+b_2) + \ldots \quad . \quad (20) \end{aligned}$$

from which b can be readily obtained, thus giving the current distribution from equations (17).

The branches are commonly the same in diameter and of equal lengths l, in which case equations (19) and (20) reduce to

$$\left.\begin{aligned} I &= I_1 n \sin\left(\frac{2\pi l}{\lambda}\right) \sin\left(\frac{2\pi b}{\lambda}\right) \\ \text{and} \quad \tan\left(\frac{2\pi b}{\lambda}\right) &= n \tan\left(\frac{2\pi l}{\lambda}\right) \end{aligned}\right\} \quad . \quad . \quad (21)$$

In the special case when $\tan(2\pi l/\lambda) = 0$, $I = I_1$.

Thus, at the point of discontinuity there is an effective loss of length equal to $(l - b)$ as far as the current distribution is concerned.

(c) Effect of a Lumped Inductance.

Suppose that at a distance l along the length of an antenna there is a self-inductance L_0 having negligible capacity. Let the current and potential above this inductance be given by

$$i = I \sin \frac{2\pi}{\lambda}(l+b) \quad \text{and} \quad v = jIa \cos \frac{2\pi}{\lambda}(l+b)$$

while that below the inductance is given by

$$i' = I' \sin \frac{2\pi}{\lambda}(l+b') \quad \text{and} \quad v' = jI'a' \cos \frac{2\pi}{\lambda}(l+b')$$

Since $i = i'$ and $v - v' = jL_0\omega i$, we have

$$\left.\begin{aligned} \cot \frac{2\pi}{\lambda}(l+b') &= \frac{L}{L'} \cot \frac{2\pi}{\lambda}(l+b) - \frac{2\pi}{\lambda} \cdot \frac{L_0}{L'} \\ &= \frac{C'}{C} \cot \frac{2\pi}{\lambda}(l+b) - \frac{2\pi}{\lambda} c^2 C' L_0 \end{aligned}\right\} \quad (22)$$

while

$$\frac{I'}{I} = \frac{\sin 2\pi(l+b')}{\sin 2\pi(l+b)} \quad . \quad . \quad . \quad . \quad (23)$$

where L, C and L', C' are the distributed constants of the wire above and below the self-inductance respectively. Thus the effect of the discontinuity is to change the ratio of the maximum currents in the ratio given by equation (23) and at the same time produce the effect as though a length of antenna wire equal to $(b' - b)$ were concentrated at the point of discontinuity as given by equations (22).

In most cases the wire will have the same diameter above and below the lumped inductance, in which case $L = L'$ and $C = C'$.

(d) Effect of a Change in the Distributed Constants.

If there be a sudden change in the diameter of the wire, the effect of the discontinuity can be obtained directly by putting $L_0 = 0$ in equations (22), whence we obtain

$$\cot \frac{2\pi}{\lambda}(l+b') = \frac{L}{L'} \cot \frac{2\pi}{\lambda}(l+b) = \frac{C'}{C} \cot \frac{2\pi}{\lambda}(l+b) \quad (24)$$

$$\text{and} \qquad \frac{I'}{I} = \frac{\sin 2\pi(l+b')}{\sin 2\pi(l+b)} \quad . \quad . \quad . \quad . \quad (25)$$

It is difficult to calculate accurately the value of C/C' or L/L', chiefly because the exact meaning of the distributed constants is somewhat vague and their use is essentially dependent on an approximation.* We may obtain a sufficiently good approximation by calculating the antenna capacity in two cases, assuming first that the distributed constants are L and C over the whole antenna and secondly that the distributed constants are L' and C'. It will generally be a sufficiently close approximation for this purpose to use the simple relation

$$\frac{L}{L'} = \frac{C'}{C} = \frac{\log(2l/d)}{\log(2l/d')} \quad . \quad . \quad . \quad . \quad (26)$$

where d and d' are the diameters of the wire and l the total length of the antenna. If the antenna is several wavelengths long, it will be close enough to assume $l = \frac{1}{4}\lambda$.

It will be seen that, if the diameter of the wire is greater *above* than it is *below* the point of discontinuity, there is an effective *loss* of length at that point, and vice versa.

(5) EFFECT OF IMAGE IN THE GROUND.

The full formulæ for calculating the effect of an imperfect earth have been given by the author.† Unfortunately, owing to an unnoticed ambiguity, errors were made in some of the signs. The corrected equations are given below. On this theory, which was first suggested by T. L. Eckersley ‡ and amplified by the author,§ an element of current $I\delta l$ has for image a similar element as shown (Fig. 3) but of strength $(K - jK')I\delta l$, where K and K' are real functions of the angle of transmission or reception to the vertical and also depend on whether the element of current lies in the plane or perpendicular to that in which propagation is considered, i.e. on the polarization of the ray.

---

* See Bibliography, (14). † *Ibid.*, (15). ‡ *Ibid.*, (16). § *Ibid.*, (17).

In the special case that is approached at long waves and over water when the earth acts as a perfect conductor, $(K - jK') = 1$.

When the element of current lies in the plane of propagation under consideration K and K' are represented by K_i and K_i' and have values given by

$$K_i - jK_i' = \frac{(\epsilon^2 + 4\sigma^2/f^2)\cos^2\theta - (c^2 + d^2) - 2j\cos\theta\left\{2c(\sigma/f) - \epsilon d\right\}}{(\epsilon^2 + 4\sigma^2/f^2)\cos^2\theta + c^2 + d^2 + 2\cos\theta(\epsilon c + 2d\sigma/f)} \quad . \; . \; . \; . \; . \; . \quad (27)$$

where σ is the conductivity in electrostatic units, ϵ is the dielectric constant, f is the frequency, $j = \sqrt{-1}$, and c and d are given by $c^2 - d^2 = \epsilon - \sin^2\theta$ and $cd = \sigma/f$, c and d being both real and positive. These two equations are easily solved by using Pierce's tabulated f and g functions.*

When σ/f can be neglected in comparison with ϵ this expression reduces to

$$K_i - jK_i' = \frac{\epsilon\cos\theta - \sqrt{(\epsilon - \sin^2\theta)}}{\epsilon\cos\theta + \sqrt{(\epsilon - \sin^2\theta)}} \quad . \quad (28)$$

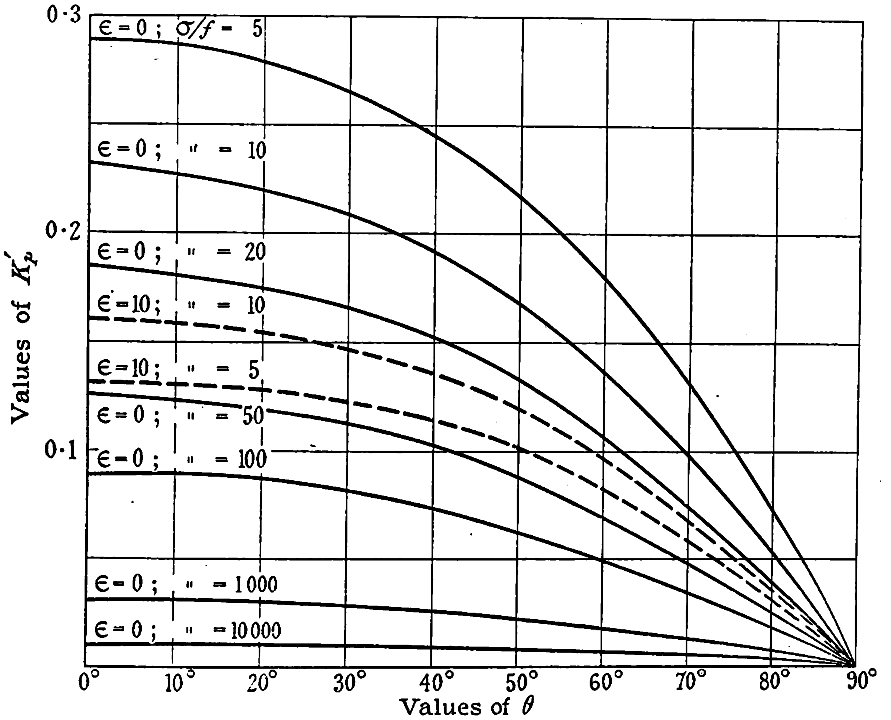

FIG. 8.

$$K_p' = \frac{2d\cos\theta}{c^2 + d^2 + \cos^2\theta + 2c\cos\theta}$$

where $c^2 = \frac{1}{2}\left[(\varepsilon - \sin^2\theta) + \sqrt{\{(\varepsilon - \sin^2\theta)^2 + 4\sigma^2/f^2\}}\right]$

$d^2 = \frac{1}{2}\left[-(\varepsilon - \sin^2\theta) + \sqrt{\{(\varepsilon - \sin^2\theta)^2 + 4\sigma/f^2\}}\right]$

When $\varepsilon = 0$

$$K_p' = \frac{2(\sigma/f)\cos\theta}{2(\sigma/f) + \cos^2\theta + 2(\sigma/f)\cos\theta}$$

When ϵ and $\sin^2\theta$ can be neglected in comparison with σ/f, the expression reduces to

$$K_i - jK_i' = \frac{(2\sigma/f)\cos^2\theta - 1 - 2j(\sigma/f)^{\frac{1}{2}}\cos\theta}{(2\sigma/f)\cos^2\theta + 1 + 2(\sigma/f)^{\frac{1}{2}}\cos\theta} \quad (29)$$

In the same way, when the plane of propagation under consideration is perpendicular to the current element, $K - jK'$ is written $K_p - jK_p'$ and is given by

$$K_p - jK_p' = \frac{c^2 + d^2 - \cos^2\theta - 2jd\cos\theta}{c^2 + d^2 + \cos^2\theta + 2c\cos\theta} \quad (30)$$

When σ/f can be neglected in comparison with ϵ this expression becomes

$$K_p - jK_p' = \frac{\sqrt{(\epsilon - \sin^2\theta)} - \cos\theta}{\sqrt{(\epsilon - \sin^2\theta)} + \cos\theta} \quad . \quad (31)$$

---

* See Bibliography, (18).

When ϵ and $\sin^2\theta$ can be neglected in comparison with σ/f the expression reduces to

$$K_p - jK_p' = \frac{(2\sigma/f) - \cos^2\theta - 2j(\sigma/f))^{\frac{1}{2}}\cos\theta}{(2\sigma/f) + \cos^2\theta + 2(\sigma/f)^{\frac{1}{2}}\cos\theta} \quad (32)$$

These expressions are somewhat laborious to evaluate, and a number of curves have been calculated. These are shown in Figs. 4 to 9. It may be noted that the value of K_i is not very much affected by the dielectric constant of the ground unless this is larger than $2\sigma/f$, but this is not so for K_i'. This means that the amplitude of the reflected ray will not in general be very much affected by the dielectric constant but that the phase of this ray will be affected to a much greater extent. This leads incidentally to the deduction that, if a method of measuring the dielectric constant of the ground based on the electromagnetic wave propagation is developed, it is desirable that it should depend on a phase measurement rather than on amplitude, unless the measurement is made in the neighbourhood of Brewster's angle.

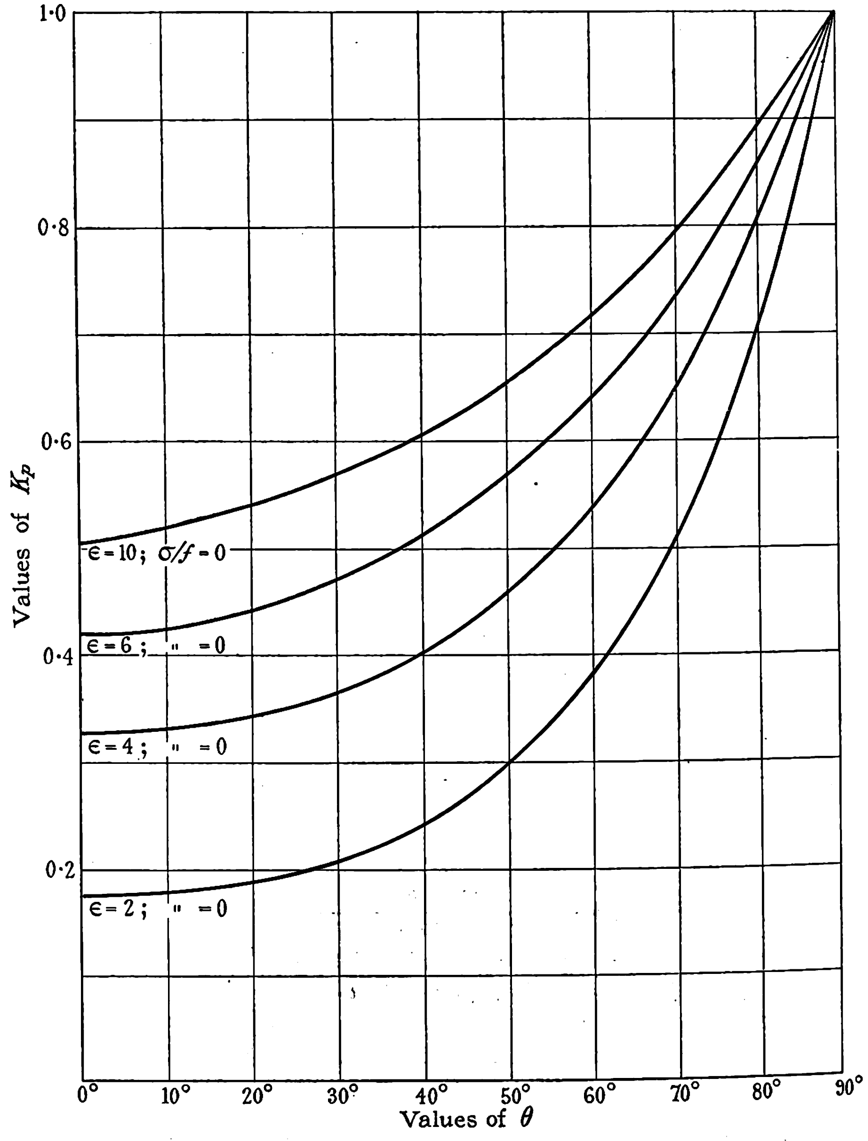

FIG. 9.

When $\sigma/f = 0$

$$K_p = \frac{\sqrt{(\varepsilon - \sin^2\theta)} - \cos\theta}{\sqrt{(\varepsilon - \sin^2\theta)} + \cos\theta}$$

$$K_p' = 0$$

From the curves given in Figs. 4 to 9 we can readily deduce the field from any element of current over an imperfect earth. Consider the field at a distant point P the radius vector of which makes an angle θ with the vertical. If h is the height of a vertical element above the ground we have, for the field E_v at P,

$$E_v = \frac{60\pi I\delta l \sin\theta}{\lambda r}$$
$$\left\{(1 + K - jK')\cos\gamma + j(1 - K + jK')\sin\gamma\right\} \quad (33)$$

where $\gamma = \dfrac{2\pi h \cos\theta}{\lambda}$

Therefore

$$|E_v| = \frac{60\pi I\delta l \sin\theta}{\lambda r}$$
$$\sqrt{[1 + K^2 + K'^2 + 2K\cos^2\gamma - 2K'\sin 2\gamma]} \quad . \quad (34)$$

In the case of a horizontal element lying in a plane perpendicular to the direction of transmission or reception it can be readily shown that the field E_h is given by

$$|E_h| = \frac{60\pi I\delta l \cos\theta}{\lambda r}$$
$$\sqrt{[1 + K^2 + K'^2 - 2K\cos 2\gamma + 2K'\sin 2\gamma]} \quad (35)$$

By differentiation it may be shown that E_v is a maximum and E_h is a minimum when

$$2\gamma = (2n - 1)\pi - \text{arc tan } (K'/K) \quad . \quad (36)$$

while E_v is a minimum and E_h a maximum when

$$2\gamma = 2n\pi - \text{arc tan } (K'/K) \quad . \quad . \quad (37)$$

where n is an integer. It should be noted that K may either be K_i or K_p, depending on the direction of the antenna element, and similarly for K'.

As K'/K is always positive except for angles with the vertical greater than Brewster's angle, we should expect all those maxima and minima of the radiation distribution, which are produced by the interference of the antenna with its image, to tend to shift towards the Brewster's angle as the conductivity of the ground decreases. In any given case the amount of this shift should be a measure of the ratio K'/K, from which the conductivity of the ground might be deduced.

(6) RADIATION DISTRIBUTION OF A STRAIGHT WIRE INCLINED AT ANY ANGLE.

(a) *General Case.*

For the computation of many of the formulæ the curves given in Figs. 12 and 13 will be found useful.

Consider the straight wire AB (Fig. 10) lying in the plane $\phi = \beta$. Let this antenna be of length l and let it make an angle α with the vertical, its lowest point A having co-ordinates $(r_0 \cos\beta,\ r_0 \sin\beta,\ z_0)$. That is, its lowest point is at a height z_0 and its projection on to the horizontal plane is at a distance r_0 from the origin. To make the problem as general as possible, we shall assume that the antenna is loaded at its end B with a load equivalent to a length l_1 of the antenna, so that the current, i, flowing in the direction AB, at any point Q on the antenna, distant z from A, is given by

$$i = I_0 \sin\frac{2\pi}{\lambda}(l + l_1 - z)\sin\omega t \quad . \quad . \quad (38)$$

The general formula, which will be given below, can be used for any individual straight portion of an antenna, and, by adding the field due to all these portions which form the whole antenna system, it is possible to obtain an expression for the radiation distribution of any antenna system. In complicated systems, however, the expressions are much too cumbersome and a combination of formulæ and graphical methods becomes more suitable.

Consider the distant point P having its horizontal projection at N. Let PO make an angle ψ with the antenna AB. If the distance of the point P is large compared with the length of the antenna, the value of ψ will not vary materially, whatever be the position of the point Q on AB, and we may assume that the angle ψ is constant, so that

$$\cos\psi = \sin\alpha\sin\theta\cos(\phi - \beta) + \cos\alpha\cos\theta \quad (39)$$

Now the field at P due to the element of wire of length δz at Q is inversely proportional to the distance PQ. As before, we may assume that the distance PQ is independent of the position of Q on AB and is equal to r. We must, however, take into account the phase at which the radiation from Q reaches P, for this is dependent on the position of Q, unless the length AB is small compared with the wavelength. A current at the origin in phase with that at Q would send a radiation which would arrive at P, τ seconds after that from Q, where

$$c\tau = \text{PO} - \text{PQ} = d + z\cos\psi \quad . \quad . \quad (40)$$

where d is the length of the projection of OA on OP and is given by

$$d = x_0 \sin\theta\cos(\phi - \beta) + z_0\cos\theta \quad . \quad . \quad (41)$$

From equations (3), (4) and (38) we obtain for the radiation distribution of the whole antenna AB that

$$f_\theta + jf'_\theta = \int_0^l \sin\frac{2\pi}{\lambda}(l + l_1 - z)\left\{\cos\alpha\sin\theta - \sin\alpha\cos\theta\cos(\phi - \beta)\right\}\left\{\cos\pi l\,(d + z\cos\psi) + j\sin\frac{2\pi}{\lambda}(d + z\cos\psi)\right\}dz$$

and

$$f_\phi + jf'_\phi = \int_0^l \sin\frac{2\pi}{\lambda}(l + l_1 - z)\sin\alpha\sin(\phi - \beta)\left\{\cos\frac{2\pi}{\lambda}(d + z\cos\psi) + j\sin\frac{2\pi}{\lambda}(d + z\cos\psi)\right\}dz$$

where the current is measured at the mathematical current maximum, even if such a maximum does not occur within the length AB.

If F is the resultant of $(f_\theta + jf'_\theta)$ and $(f_\phi + jf'_\phi)$, so that

$$F^2 = (f_\theta + jf'_\theta)^2 + (f_\phi + jf'_\phi)^2$$

then the above integrals reduce to

$$F = \frac{\lambda}{2\pi \sin\psi}\Big[\cos A \cos D - \cos B \cos C - \cos\psi\,(\sin A \sin D - \sin B \sin C) + j\big\{\cos A \sin D - \cos B \sin C + \cos\psi\,(\sin A \cos D - \sin B \cos C)\big\}\Big] \quad . \quad (42)$$

$$f_\theta + jf'_\theta = \frac{\{\cos\alpha \sin\theta - \sin\alpha \cos\theta \cos(\phi - \beta)\}}{\sin\psi}F \qquad (43)$$

and

$$f_\phi + jf'_\phi = -\frac{\sin\alpha \sin(\phi - \beta)}{\sin\psi}F \quad . \quad . \quad (44)$$

where $A = 2\pi l_1/\lambda$
$B = 2\pi(l + l_1)/\lambda$
$C = 2\pi d/\lambda$
$D = 2\pi(d + l\cos\psi)/\lambda$

The values of $\cos\psi$ and d are given by equations (39) and (41). The sign of $\cos\psi$ will come automatically from equation (39), while that of $\sin\psi$ is immaterial so long as it is taken consistently the same, for $\sin\psi$ only occurs in the final expression for the field strength as a square.

In order to find the effect of the image it is necessary to put $(\pi - \alpha)$ for α, $-z_0$ for z_0 in the above expressions, and multiply the result by the factor $-(K - jK')$ as explained in section (5) above and given in Figs. 4 to 9. The result should then be added to the radiation distribution for the antenna without its image in the ground.

These expressions as they stand are much too complex for practical use. They reduce considerably, however, in a large number of special cases, some of which will now be considered.

(b) *Vertical Antenna Loaded at the Top.*

In this case $\alpha = 0$ and $x_0 = 0$, so that $d = z_0 \cos\theta$ and $\cos\psi = \cos\theta$.

Hence

$$f_\theta + jf'_\theta = \frac{\lambda}{2\pi\sin\theta}\Bigg[\cos\frac{2\pi l_1}{\lambda}\Big\{\cos\frac{2\pi\cos\theta(l + z_0)}{\lambda} + j\sin\frac{2\pi\cos\theta(l + z_0)}{\lambda}\Big\} - \cos\frac{2\pi(l + l_1)}{\lambda}\Big\{\cos\frac{2\pi z_0\cos\theta}{\lambda} + j\sin\frac{2\pi z_0\cos\theta}{\lambda}\Big\} - \cos\theta\Big[\sin\frac{2\pi l_1}{\lambda}\Big\{\sin\frac{2\pi\cos\theta(l + z_0)}{\lambda} - j\cos\frac{2\pi\cos\theta(l + z_0)}{\lambda}\Big\} - \sin\frac{2\pi(l + l_1)}{\lambda}\Big\{\sin\frac{2\pi z_0\cos\theta}{\lambda} - j\cos\frac{2\pi z_0\cos\theta}{\lambda}\Big\}\Big]\Bigg]^{*} \quad . . . . \quad (45)$$

and $f_\phi + jf'_\phi = 0$.

The expression for the image, if we assume a perfect earth, is identical with expression (45), except that $(l + z_0)$ becomes $(l - z_0)$ and all the imaginary terms have their signs reversed, so that, if $z_0 = 0$, the total effect of the antenna and its image together is to double the real part of equation (45) and bring the imaginary part to zero.

If there is no load at the top and the antenna reaches to the ground (i.e. $l_1 = 0$ and $z_0 = 0$), expression (45) reduces (not taking the image into account) to

$$f_\theta + jf'_\theta = \frac{\lambda}{2\pi\sin\theta}\Big[\cos\frac{2\pi l\cos\theta}{\lambda} - \cos\frac{2\pi l}{\lambda} + j\Big\{\sin\frac{2\pi l\cos\theta}{\lambda} - \cos\theta\sin\frac{2\pi l}{\lambda}\Big\}\Big] \quad . \quad (46)$$

(c) *Horizontal Antenna not Loaded at the End.*

In this case $\alpha = \frac{1}{2}\pi$, $x_0 = 0$, $l_1 = 0$.

Hence
$$F = \frac{\lambda}{2\pi\sin\psi}\Big[\cos\frac{2\pi(z_0\cos\theta + l\cos\psi)}{\lambda} - \cos\frac{2\pi l}{\lambda}\cos\frac{2\pi z_0\cos\theta}{\lambda} + \cos\psi\sin\frac{2\pi l}{\lambda}\sin\frac{2\pi z_0\cos\theta}{\lambda} + j\Big\{\sin\frac{2\pi(z_0\cos\theta + l\cos\psi)}{\lambda} - \cos\frac{2\pi l}{\lambda}\sin\frac{2\pi z_0\cos\theta}{\lambda} - \cos\psi\sin\frac{2\pi l}{\lambda}\cos\frac{2\pi z_0\cos\theta}{\lambda}\Big\}\Big] \quad . . . . \quad (47)$$

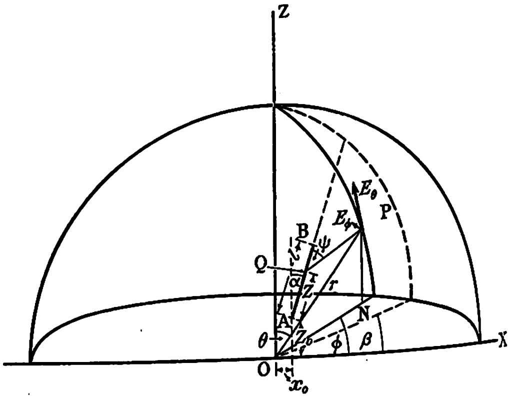

FIG. 10.

---

* Curves of $\cos\{2\pi(l/\lambda)\cos\theta\}$, $\cos\{2\pi(l/\lambda)\sin\theta\}$, $\sin\{2\pi(l/\lambda)\sin\theta\}$ and $\sin\{2\pi(l/\lambda)\cos\theta\}$ for various values of l/λ are given in Figs. 12 and 13.

$$\left.\begin{aligned} f_\theta + jf'_\theta &= -\frac{\cos\theta\cos(\phi-\beta)}{\sin\psi}F \\ \text{and}\qquad f_\phi + jf'_\phi &= -\frac{\sin(\phi-\beta)}{\sin\psi}F \end{aligned}\right\} \quad . \quad . \quad (48)$$

where $\cos\psi = \sin\theta\cos(\phi-\beta)$.

The expression for the image, if we assume a perfect earth, is identical with expression (47), except that z_0 becomes $-z_0$ and F becomes $-F$. The expression for the total field due to the antenna and its image in the earth will be given by equations (48), where

$$F = \frac{\lambda}{\pi\sin\psi}\sin\frac{2\pi z_0\cos\theta}{\lambda}\left[\cos\psi\sin\frac{2\pi l}{\lambda} - \sin\frac{2\pi l\cos\psi}{\lambda} + j\left\{\cos\frac{2\pi l\cos\psi}{\lambda} - \cos\frac{2\pi l}{\lambda}\right\}\right] \quad (49)$$

By adding the expressions in this section to the suitable expressions from section (6) (*b*), the radiation distribution of any inverted "L" antenna can be obtained.

(*d*) *Two Equal Horizontal Antennæ in One Straight Line with Currents Flowing in Opposite Directions.*

If we put $(\pi+\beta)$ for β in equations (47), (48) and (49) we shall obtain the expression for an equal horizontal antenna with current flowing in the opposite direction to that in the first. The two expressions can be added together, giving the formula required.

For the antenna alone we have, together with equations (48),

$$F = \frac{\lambda}{\pi\sin\psi}\left\{\cos\psi\sin\frac{2\pi l}{\lambda} - \sin\frac{2\pi l\cos\psi}{\lambda}\right\}\left\{\sin\frac{2\pi z_0\cos\theta}{\lambda} - j\cos\frac{2\pi z_0\cos\theta}{\lambda}\right\} \quad . \quad (50)$$

The expression for the total antenna with its image in a perfect earth is given by equation (48), where

$$F = -\frac{2\lambda}{\pi\sin\psi}\sin\left(\frac{2\pi z_0\cos\theta}{\lambda}\right)\left\{\cos\psi\sin\left(\frac{2\pi l}{\lambda}\right) - \sin\left(\frac{2\pi l\cos\psi}{\lambda}\right)\right\} \quad . \quad (51)$$

It should be noted that the current measured is the mathematical maximum of either limb of the antenna. By combining the expressions in this section with the suitable expressions from section (6)(*b*), the radiation distribution of any "T" antenna can be obtained. In doing this the effect of discontinuity produced by the double branch at the top of the vertical portion must be taken into account. For this purpose equations (21) should be used.

(*e*) *Two Equal Horizontal Antennæ in One Straight Line with Current Flowing in the Same Direction.*

This is similar to the problem of the preceding paragraph. The required expression is obtained by putting $(\pi+\beta)$ for β in equations (47), (48) and (49) and subtracting the two expressions in each case.

For the antenna alone we have, in combination with equation (48),

$$F = \frac{\lambda}{\pi\sin\psi}\left\{\cos\frac{2\pi l\cos\psi}{\lambda} - \cos\frac{2\pi l}{\lambda}\right\}\left\{\cos\frac{2\pi z_0\cos\theta}{\lambda} + j\sin\frac{2\pi z_0\cos\theta}{\lambda}\right\} \quad . \quad (52)$$

The expression for the total antenna and its image in a perfect earth is given by equations (48), where

$$F = j\frac{2\lambda}{\pi\sin\psi}\sin\frac{2\pi z_0\cos\theta}{\lambda}\left\{\cos\frac{2\pi l\cos\psi}{\lambda} - \cos\frac{2\pi l}{\lambda}\right\} \quad . \quad (53)$$

These expressions represent the radiation distribution of a horizontal antenna excited at the centre.

(*f*) *General Case when Current is Uniform instead of Sinusoidal.*

It has been pointed out by the author[*] that an increase in directivity could be obtained by reducing the space taken by those portions of the antenna in which the current is small. This can be done in practice by means of the device employed by Franklin in which the antenna wire is bent on itself several times, so that large portions of the current distribution for a simple straight wire are concentrated into a relatively small space. Carrying this out to the extreme would result in a nearly uniform current distribution along the antenna instead of the usual sinusoidal distribution. It may be of interest for design purposes to find whether the attainment of a more uniform current distribution is of value. For this purpose it is necessary to know what is the limiting condition that can thus be obtained. Such a condition can, of course, never be actually reached, but in many cases it could be very nearly obtained. The following formulæ refer to such limiting cases, in which the current is assumed perfectly uniform over the whole antenna.

The general case gives the following:—

$$f_\theta + jf'_\theta = \frac{\cos\alpha\sin\theta - \sin\alpha\cos\theta\cos(\phi-\beta)}{\sin\psi}F \quad (54)$$

$$f_\phi + jf'_\phi = -\frac{\sin\alpha\sin(\phi-\beta)}{\sin\psi}F \quad . \quad . \quad (55)$$

where

$$F = \frac{\lambda}{2\pi}\tan\psi\left[\sin\frac{2\pi(d+l\cos\psi)}{\lambda} - \sin\frac{2\pi d}{\lambda} + j\left\{\cos\frac{2\pi d}{\lambda} - \cos\frac{2\pi(d+l\cos\psi)}{\lambda}\right\}\right] \quad . \quad (56)$$

$$\cos\psi = \sin\alpha\sin\theta\cos(\phi-\beta) + \cos\alpha\cos\theta$$

$$\text{and}\qquad d = x_0\sin\theta\cos(\phi-\beta) + z_0\cos\theta$$

As before, F is the resultant of $(f_\theta + jf'_\theta)$ and $(f_\phi + jf'_\phi)$.

---

[*] See Bibliography, (19).

(7) A System of Similar Parallel Antennæ Spaced in any Given Manner.

(*a*) *General Case.*

It often occurs in a system of antennæ that there are a number of parallel portions of equal length and carrying similar distributions of current. Instead of adding the field due to each portion separately, we may proceed as follows.

Let there be n such portions and let $O_1, O_2, \ldots, O_n$ be points on the 1st, 2nd, . . ., nth portion respectively. These points are in the same relative position on each individual portion. Taking a single portion we can calculate its radiation distribution from the equations given in section (6). Let this be $(f + jf')$, this expression representing in fact two functions, one for each component in space of the field.

Supposing that the co-ordinates of $O_1, O_2, \ldots, O_n$ are $(x_1, y_1, z_1), (x_2, y_2, z_2), \ldots (x_n, y_n, z_n)$ respectively, and that the currents $I_1, I_2, \ldots I_n$ flowing at these points are in advance on some arbitrary phase by $\beta_1, \beta_2, \ldots, \beta_n$ respectively, we may write for the radiation distribution $(F + jF')$ of the whole system

$$F + jF' = (f + jf') \left[\frac{\sum\limits_{r=1}^{r=n} I_r \cos\left\{\beta_r + \frac{2\pi d_r}{\lambda}\right\} + j \sum\limits_{r=1}^{r=n} I_r \sin\left\{\beta_r + \frac{2\pi d_r}{\lambda}\right\}}{\sum\limits_{r=1}^{r=n} I_r} \right] \tag{57}$$

where $d_1, d_2, \ldots, d_n$ are the projections of $OO_1, OO_2, \ldots, OO_n$ on the direction considered, O being the origin. Thus, if the direction considered is (θ, ϕ),

$$d_r = (x_r \cos\phi + y_r \sin\phi) \sin\theta + z_r \cos\theta \quad . \tag{58}$$

If there are not several systems to add together, it is unnecessary to consider the phase of the radiation distribution. Hence, if f_0 is the resultant of $(f + jf')$ and F_0 that of $(F + jF')$, equation (57) reduces to

$$F_0^2 = f_0^2 \frac{\sum\limits_{r=1}^{r=n} \sum\limits_{s=r}^{s=n} \left[I_r I_s \cos\left\{\beta_r - \beta_s + \frac{2\pi}{\lambda}(d_r - d_s)\right\}\right]}{\left(\sum\limits_{r=1}^{r=n} I_r\right)^2} \tag{59}$$

It was mentioned in section (1) that the point of the antenna system at which the current is measured should be stated; in this particular case the current is not measured at a single point, but it is taken as the sum (irrespective of phase) of all the currents at the points $O_1, O_2, \ldots, O_n$.

(*b*) *Uniform Spacing, Uniform Variation of Phase and Equal Currents.*

This is a condition frequently met with in practice, and for this case equation (57) adopts a simpler form. If the portions of the antenna system are uniformly spaced, the projection of the lengths $OO_1, OO_2, \ldots, OO_n$ on to the direction required can be written in the form $d_1,\ d_1 + d, \ldots,\ d_1 + (n-1)d$ respectively, the values of d_1 and d being readily obtained from equation (58). If, in the same way, the phases are $\beta_1, \beta_1 + \beta, \ldots, \beta_1 + (n-1)\beta$ and the current is of the same amplitude in each portion of the antenna system, equation (57) becomes

$$F + jF' = \frac{(f + jf')}{n} \left[\frac{\cos\left\{\beta_1 + \frac{2\pi d_1}{\lambda} + (n-1)\left(\frac{\beta}{2} + \frac{\pi d}{\lambda}\right)\right\} \sin n\left(\frac{\beta}{2} + \frac{\pi d}{\lambda}\right)}{\sin\left(\frac{\beta}{2} + \frac{\pi d}{\lambda}\right)} + j \frac{\sin\left\{\beta_1 + \frac{2\pi d_1}{\lambda} + (n-1)\left(\frac{\beta}{2} + \frac{\pi d}{\lambda}\right)\right\} \sin n\left(\frac{\beta}{2} + \frac{\pi d}{\lambda}\right)}{\sin \frac{\beta}{2} + \frac{\pi d}{\lambda})} \right] \quad . \tag{60}$$

If there are not several systems to add together, it is unnecessary to consider the phase of the radiation distribution. In this case the resultant, F_0, is given by

$$F_0 = \frac{f_0}{n} \cdot \frac{\sin n\left(\frac{\beta}{2} + \frac{\pi d}{\lambda}\right)}{n \sin\left(\frac{\beta}{2} + \frac{\pi d}{\lambda}\right)} \quad . \; . \; . \tag{61}$$

In the limiting case, as $n \to \infty$ and the spread of the antenna system remains constant, i.e. $n\left(\frac{\beta}{2} + \frac{\pi d}{\lambda}\right) = \frac{\beta_0}{2} + \frac{\pi d_0}{\lambda}$, equation (61) becomes

$$F_0 = f_0 \frac{\sin\left(\frac{\beta_0}{2} + \frac{\pi d_0}{\lambda}\right)}{\left(\frac{\beta_0}{2} + \frac{\pi d_0}{\lambda}\right)} \quad . \; . \; . \tag{62}$$

As before, the current is the sum of the currents in all the portions of the antenna system irrespective of phase.

In the special case, when $n = 2$, we have

$$F_0 = f_0 \cos\left(\frac{\beta}{2} + \frac{\pi d}{\lambda}\right) \quad . \; . \; . \tag{63}$$

(8) Antennæ Having Symmetrical Radiation About a Vertical Axis.

(*a*) *General Case.*

If the vertical axis of symmetry pass through a point O, in order to keep rigorous symmetry the antenna system must be uniformly distributed around the circumference of one or more horizontal circles having O as centre. The individual antennæ on each circle must be identical and must carry the same amplitude of current. Symmetry can still be kept if the currents in the antennæ are not in the same phase, but in this case the phase must vary uniformly round the circumference of each circle, and the total phase difference in a complete revolution must be a multiple of 2π, otherwise a discontinuity would occur.

The above conditions are necessary for exact symmetry. It may be possible to devise systems which do not conform with the above conditions, and yet give fairly correct symmetry, but it will probably be found that they approximate in some way to these conditions.

Let us consider the general case of n identical antennæ, uniformly distributed along the circumference of a circle of radius R (Fig. 11). Since the radiation is symmetrical about the vertical axis through the centre O, it is only necessary to consider the radiation distribution in a single vertical plane. Let it be OX. We shall take as the basis of phase the current in the antenna M, so that the phase of the current in the antenna A is $(n\phi)$ in advance of that in the antenna M. In order to preserve symmetry, n must be an integer.

The phase of the radiation in the vertical plane through OX at an angle of θ with the vertical from the antenna A will be in advance of that from an imaginary antenna at O, excited in the same phase as the antenna M, by an angle $(n\phi + \delta \cos \phi)$

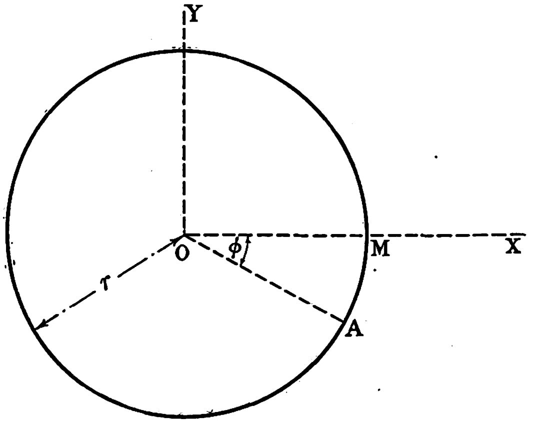

FIG. 11.

where

$$\delta = \frac{2\pi R}{\lambda} \sin \theta \quad . \quad . \quad . \quad . \quad (64)$$

If $(f + jf')$ is the radiation distribution of each individual antenna, the radiation distribution $(F + jF')$ for the whole circle will be given by

$$F + jF' = \int_0^{2\pi} \frac{1}{2\pi}(f + jf') \left\{ \cos (n\phi + \delta \cos \phi) + j \sin (n\phi + \delta \cos \phi) \right\} d\phi \quad . \quad (65)$$

As in section (7), the current is not measured at a single point but is taken to be the sum (irrespective of phase) of all the currents in the individual antennæ. The current in each of these is measured at the point which makes their radiation distribution $(f + jf')$.

The integral of equation (65) can be solved in certain special cases. In order to obtain as general a case as possible, let us assume that f and f' can each be expanded in Fourier series with the angle ϕ as variable.

$$f + jf' = \sum_m \left\{ (A_m + jA'_m) \sin (m\phi) + (B_m + jB'_m) \cos m\phi \right\} \quad . \quad (66)$$

where m is an integer and A_m, A'_m, B_m, B'_m are functions of θ.

Equation (65) can be shown to reduce, when $m > n$, to

$$F + jF' = \tfrac{1}{2}\sum_m (-1)^{\frac{1}{2}(m-n+1)} \Big[(A_m + jA'_m) \left\{ J_{m-n}(\delta) + (-1)^{n+1} J_{m+n}(\delta) \right\} + (B'_m - jB_m) \left\{ J_{m-n}(\delta) - (-1)^{n+1} J_{m+n}(\delta) \right\} \Big] \quad . \quad . \quad . \quad (67)$$

when $(m + n)$ is odd, and to

$$F + jF' = \tfrac{1}{2}\sum_m (-1)^{\frac{1}{2}(m-n)} \Big[(B_m + jB'_m) \left\{ J_{m-n}(\delta) + (-1)^{n} J_{m+n}(\delta) \right\} - (A'_m - jA_m) \left\{ J_{m-n}(\delta) - (-1)^{n} J_{m+n}(\delta) \right\} \Big] \quad . \quad . \quad . \quad (68)$$

when $(m - n)$ is even, where J_r is a Bessel function of the first kind, tables of which are readily available.

Equations (67) and (68) only hold if $m > n$. When $m < n$ it is necessary to put m for n and n for m in these equations without changing any of the signs.

These general formulæ simplify considerably in a large number of special cases, some of which will now be considered.

(b) *Circle of Vertical Antennæ all Excited in the Same Phase.*

In this case $m = n = 0$, and from equation (7) $f'_\theta = f_\phi = f'_\phi = 0$, so that the radiation distribution of each individual antenna is a single function of the angle θ (this function is not complex). Let it be f_θ. The radiation distribution of the whole circular system will then be given by

$$\left. \begin{aligned} F_\theta + jF'_\theta &= f_\theta J_0(\delta) \\ F_\phi + jF'_\phi &= 0 \end{aligned} \right\} \quad . \quad . \quad . \quad (69)$$

When the height of the individual antenna is small $f_\theta = \delta l \sin \theta$ [see equation (3)].

It may be noted that the number of antennæ in the circle does not enter into equation (69). That is so because, as in section (7), the total current is measured and not the current in an individual antenna. This convention will be adopted in all the following cases.

(c) *Circle of Small Vertical Radial Coils Excited in the Same Phase.*

If the vector representing the coil at M [see section 2 (b)] is along the Y axis (Fig. 11), then equation (11) gives

$$f_\theta = 0, \quad f_\phi = 0, \quad f'_\theta = -(2\pi/\lambda) \cos \phi \, \delta A$$

and

$$f'_\phi = -(2\pi/\lambda) \cos \theta \sin \phi \delta A$$

Hence, the radiation distribution of the whole circle is given by

$$\left.\begin{aligned} F_\theta + jF'_\theta &= j\frac{2\pi\delta A}{\lambda}J_1(\delta) \\ F_\phi + jF'_\phi &= 0 \end{aligned}\right\} \quad . \quad . \quad . \quad (70)$$

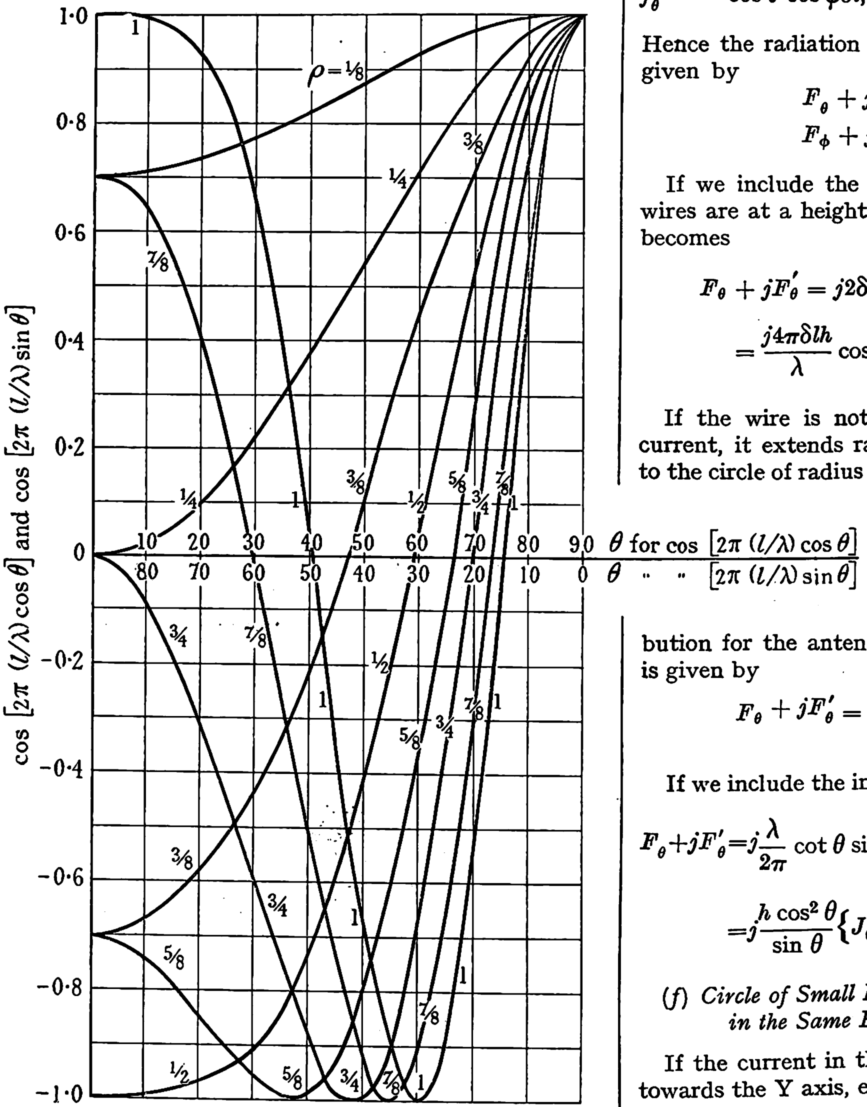

FIG. 12.—Curves of cos $\{2\pi(l/\lambda)\sin\theta\}$ and cos $\{2\pi(l/\lambda)\cos\theta\}$ for various values of l/λ.

(*d*) *Circle of Small Vertical Tangential Coils Excited in the Same Phase.*

If the vector representing the coil at M is radially outwards, then equation (10) gives

$$f_\theta = 0, \quad f_\phi = 0, \quad f'_\theta = (2\pi/\lambda)\sin\phi\delta A,$$
$$f'_\phi = -(2\pi/\lambda)\cos\theta\cos\phi\delta A$$

Hence the radiation distribution for the whole circle is given by

$$\left.\begin{aligned} F_\theta + jF'_\theta &= 0 \\ F_\phi + jF'_\phi &= j\frac{2\pi\cos\theta\delta A}{\lambda}J_1(\delta) \end{aligned}\right\} \quad . \quad . \quad (71)$$

(*e*) *Circle of Small Horizontal Radial Wires Excited in the Same Phase.*

If the current is flowing radially outwards, equation (8) gives

$$f_\theta = -\cos\theta\cos\phi\delta l, \quad f_\phi = -\sin\phi\delta l, \quad f'_\theta = 0, \quad f'_\phi = 0$$

Hence the radiation distribution for the whole circle is given by

$$\left.\begin{aligned} F_\theta + jF'_\theta &= \delta l\cos\theta J_1(\delta) \\ F_\phi + jF'_\phi &= 0 \end{aligned}\right\} \quad . \quad . \quad . \quad (72)$$

If we include the image in a perfect earth, and the wires are at a height h above the ground, equation (72) becomes

$$F_\theta + jF'_\theta = j2\delta l\cos\theta\sin\left(\frac{2\pi h\cos\theta}{\lambda}\right)J_1(\delta) \quad . \quad (73)$$

$$= \frac{j4\pi\delta lh}{\lambda}\cos^2\theta J_1(\delta) \text{ if } (h/\lambda) \text{ is small} \quad . \quad . \quad (74)$$

If the wire is not small, but still carrying uniform current, it extends radially from the circle of radius r_1 to the circle of radius $r_2 (r_2 > r_1)$, and the radiation distribution for the antenna system alone without its image is given by

$$F_\theta + jF'_\theta = \frac{\lambda}{2\pi}\cot\theta\left\{J_0(\delta_1) - J_0(\delta_2)\right\} \quad . \quad (75)$$

If we include the image in a perfect earth this becomes

$$F_\theta + jF'_\theta = j\frac{\lambda}{2\pi}\cot\theta\sin\left(\frac{2\pi h\cos\theta}{\lambda}\right)\left\{J_0(\delta_1) - J_0(\delta_2)\right\} \quad (76)$$

$$= j\frac{h\cos^2\theta}{\sin\theta}\left\{J_0(\delta_1) - J_0(\delta_2)\right\} \text{ if } (h/\lambda) \text{ is small} \quad (77)$$

(*f*) *Circle of Small Horizontal Tangential Wires Excited in the Same Phase.*

If the current in the vector at M (Fig. 11) is flowing towards the Y axis, equation (9) gives

$$f_\theta = -\cos\theta\sin\phi\delta l, \quad f_\phi = \cos\phi\delta l, \quad f'_\theta = 0, \quad f'_\phi = 0$$

Hence the radiation distribution due to the whole circle without its image is given by

$$\left.\begin{aligned} F_\theta + jF'_\theta &= 0 \\ F_\phi + jF'_\phi &= -\delta l J_1(\delta) \end{aligned}\right\} \quad . \quad . \quad . \quad (78)$$

If we include the image in a perfect earth, this becomes

$$F_\phi + jF'_\phi = -j2\delta l\sin\left(\frac{2\pi h\cos\theta}{\lambda}\right)J_1(\delta) \quad . \quad . \quad . \quad (79)$$

$$\doteq -j\frac{4\pi h\delta l}{\lambda}\cos\theta J_1(\delta) \quad \text{when } (h/\lambda) \text{ is small} \quad . \quad (80)$$

(8) Example.

A case which occurs in engineering practice is that of the beam antenna. As an example, suppose a beam system to consist of n equal vertical antennæ carrying equal currents and spaced a distance d apart. Let us further suppose that each antenna consists of m positive half-waves of current superposed one above the other, the negative half-waves being suppressed by the Franklin or other system.

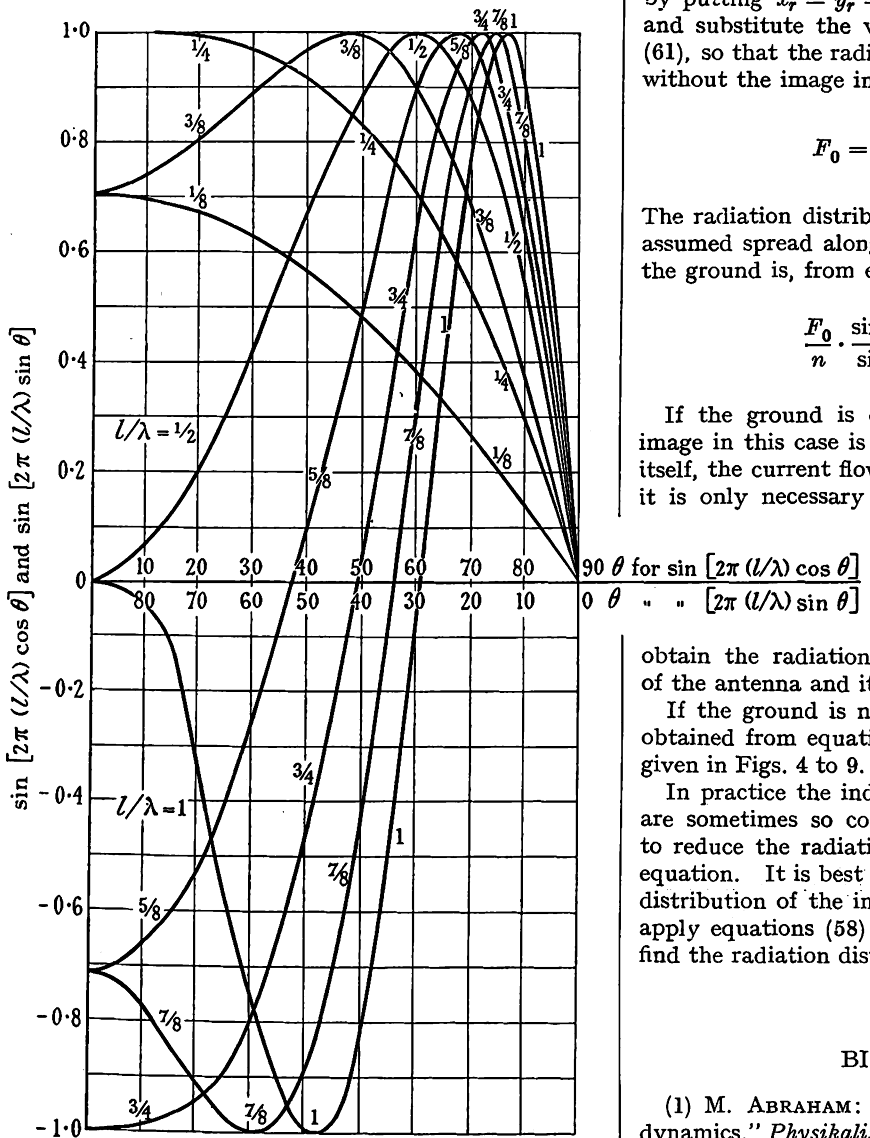

Fig. 13.—Curves of sin $\{2\pi(l/\lambda)\sin\theta\}$ and sin $\{2\pi(l/\lambda)\cos\theta\}$ for various value of l/λ.

From equation (46) a half-wave vertical antenna has a radiation distribution given by

$$f_0 + jf'_0 = \frac{\lambda}{2\pi\sin\theta}\left\{\cos(\pi\cos\theta) + 1 + j\sin(\pi\cos\theta)\right\} \quad . \quad (81)$$

The resultant of this is given by

$$f_0 = \frac{\lambda}{\pi\sin\theta}\sqrt{\left[\tfrac{1}{2}\{1 + \cos(\pi\cos\theta)\}\right]}. \quad . \quad (82)$$

By means of equations (58) and (61) we can superpose m of these half-wave elements on the top of one another by putting $x_r = y_r = 0$ and $z_r = \frac{1}{2}\lambda$ in equation (82), and substitute the value of d obtained from equation (61), so that the radiation distribution of each antenna without the image in the ground is given by

$$F_0 = \frac{f_0}{m}\cdot\frac{\sin(m\pi\cos\frac{1}{2}\theta)}{\sin(\pi\cos\frac{1}{2}\theta)} \quad . \quad . \quad . \quad (83)$$

The radiation distribution for the whole antenna array assumed spread along the X axis without the image in the ground is, from equations (58 and (61),

$$\frac{F_0}{n}\cdot\frac{\sin(n\pi d\cos\phi\sin\theta/\lambda)}{\sin(\pi d\cos\phi\sin\theta/\lambda)} \quad . \quad . \quad . \quad (84)$$

If the ground is of perfect conductivity, since the image in this case is identical with the antenna system itself, the current flowing in the same direction in both, it is only necessary to replace m by $2m$ in order to obtain the radiation distribution for the combination of the antenna and its image.

If the ground is not perfect, the total result can be obtained from equation (34), making use of the curves given in Figs. 4 to 9.

In practice the individual antennæ forming an array are sometimes so complicated that it is not practical to reduce the radiation distribution to the form of an equation. It is best in this case to obtain the radiation distribution of the individual antennæ graphically, and apply equations (58) and (61) to the result in order to find the radiation distribution for the whole array.

THE RADIATION DISTRIBUTION OF ANTENNÆ IN VERTICAL PLANES.*

By R. M. WILMOTTE, M.A., Associate Member.

[From the National Physical Laboratory.]

(*Paper first received* 16*th November*, 1929, *and in final form* 22*nd February*, 1930.)

SUMMARY.

The radiation distribution of an antenna in a vertical plane was obtained by measuring in an aeroplane the strength of a received signal from an excited antenna on the ground. The position of the aeroplane relative to the antenna was obtained by means of a theodolite on the ground, the signal strength being recorded on a cinematograph film.

Although the ground site appeared very good, it was found that spurious radiations were obtained and these were probably the cause of the discrepancies found between the theoretical and the experimental results. The measurements were made on a horizontal antenna at several frequencies. The reason for this particular arrangement is that it should be possible to separate the effect of the reflection of the antenna in the earth from that of the antenna itself, and thereby obtain a double result from a single measurement.

The results showed very definite maxima and minima and the position of these could be ascertained accurately within a few degrees, but the difficulties of the experiment prevented an accurate value of the field strength being obtained. Substantial agreement was obtained between theory and experiment, the discrepancies increasing with the frequency.

The radiation distribution was also obtained for one of the beam stations erected by the Marconi Co. Owing to the sharpness of the beam, considerable experimental error was liable to occur. Nevertheless, substantial agreement between theory and experiment was also obtained in this case.

(1) INTRODUCTION.

A considerable amount of experimental data has been obtained on the radiation distribution from antennæ in a horizontal plane, and all the evidence strongly shows that the theoretical and the experimental results are in very close agreement, particularly for short-wave stations. On longer waves the mast system is usually a much more important part of the whole erection and it is probable that the discrepancies, which are often found where steel masts are used, are due to induced currents in the masts which are not allowed for in the calculations. There are very few cases, with the conspicuous exception of the Beverage antenna, in which the radiation distribution in a horizontal plane depends on the distribution of current along a horizontal wire, and it was with the double purpose of investigating whether such a radiation distribution could be calculated and of examining the effect of the reflection in the earth that the experiments described in this paper were undertaken.

The distribution of current along a transmitting antenna has been discussed theoretically by Macdonald * and Abraham † with substantial disagreement as to the size of the first loop near the end of the wire. Macdonald makes the distance to the first current node as low as $\lambda/5$ in some cases, while Abraham obtains $\lambda/4{\cdot}2$ for this distance. Abraham considered the case of a thin ellipsoid, and Lord Rayleigh ‡ has shown that, in spite of the tapering of the wire which this assumption involves, the result is applicable to a thin circular wire. The experimental evidence is to some extent conflicting, but most of the results date from the time when spark sets were the only available source of oscillations. Few experiments have been carried out on current distribution since the advent of the wireless valve. The author § recently published some results on an 11-metre vertical antenna over a range of wavelengths from 15 m to 800 m and found agreement with Abraham's theory to an order of accuracy of some 5 per cent. This means that the accuracy was not sufficient to discriminate between Abraham's theory ($\lambda/4{\cdot}2$) and the simple sinusoidal theory ($\lambda/4$). The current was measured by ammeters, the capacity and self-inductance effects of which were accurately considered. C. R. Englund || also obtained agreement with the simple theory, by finding the natural frequency of straight rods. It would therefore appear that, to a sufficient degree of accuracy, one can assume that the current distribution follows a simple sinusoidal law with small corrections for the end effects (see Appendix 1), the distance between nodes and antinodes being $\lambda/4$.

There is some further evidence from certain field-strength measurements that the simple sinusoidal law of current distribution holds and that, moreover, there is no appreciable change in phase along the antenna. One of these confirmatory results was recently given by P. P. Eckersley, T. L. Eckersley and H. L. Kirke,¶ who showed that the field strength on the ground from the half-wave vertical antenna was double that of a quarter-wave antenna to an accuracy of 5 per cent (well within the limits of experimental error), showing that both quarter wavelengths of the antenna were radiating equally and were in the same phase. Further evidence was obtained from investigations carried out by G. H. Munro in connection with attenuation experiments undertaken by R. H. Barfield.** In order to obtain the effective height of an antenna, Munro suggested using a "T" antenna and increasing the length of the horizontal portions until the signal received from a constant source remained substantially constant, when the effective height could be assumed to be equal to the actual height. The variation of effective height, calculated by the author from the simple sinusoidal current distribution theory,* is shown in Fig. 1. The crosses represent the experimental values obtained by Munro. It is interesting to note how closely the experimental and theoretical results agree.

There is considerable evidence, therefore, in favour of the simple sinusoidal theory of current distribution, and this is the theory used in this paper in comparing the theoretical and experimental radiation distribution diagrams. A number of general formulæ for this have been obtained by the author.†

The other factor that enters into the theoretical consideration of this problem is the effect of the earth and its imperfect conductivity. A theory has been put forward by T. L. Eckersley‡ and amplified by the author § (Appendix 2), but there has not yet been any satisfactory experimental confirmation of this theory.

the instrument. The galvanometer was fitted with shunts of several values so that, by means of a switch, it could be made more or less sensitive, and it was the duty of the observer in the aeroplane to operate the switch in order to keep the galvanometer at some suitable deflection.

A better, method but one which would be slightly more cumbersome to apply satisfactorily, would have been to insert a potentiometer or attenuator device in the intermediate-frequency amplifier (as in the field-strength measuring set due to Friis and Bruce*) and thus control the galvanometer deflection, but it was not considered at first that the experimental accuracy, especially in locating the aeroplane over the whole flight, would warrant this extra encumbrance. The experience gained, however, showed that this was an error of judgment and that more reliable field-strength measurements would have been useful.

The receiving set was calibrated on the ground by means of a small local oscillator in which the antenna current could be varied and measured over a range of 100 to 1.

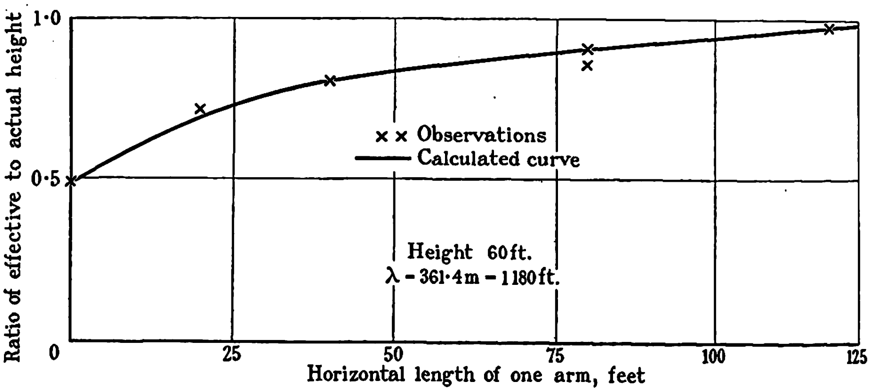

FIG. 1.—Effective height of " T " antenna.

(2) APPARATUS AND PROCEDURE.

For the purpose of these experiments the Air Ministry kindly placed an aeroplane at the disposal of the Radio Research Board. It was fitted with a " T " antenna having a horizontal portion 27 ft. long spread between two uprights 4 ft. high at each wing tip and supported at the centre. A supersonic heterodyne receiver was used. The intermediate- and low-frequency amplifiers were standard R.A.F. equipment. The low-frequency output was measured on a valve voltmeter using anode rectification. The detecting instrument consisted of a double-pivot microammeter from which the pointer had been removed, a small mirror being substituted. A small 2-volt lamp was focused on the mirror and reflected on to a cinematograph film kept moving by means of a gramophone motor at the rate of about 30 ft. per hour. The sensitivity for full-scale deflection was 50 μA. The whole was, of course, completely screened from external light. In order that the observer in the aeroplane might ensure that the spot of light remained on the film, the beam was intercepted by a semi-silvered mirror which reflected some of the light on to a red ground-glass screen on which the observer could see the deflection of

The transmitting antenna was spread between two wooden masts. The ground was flat and free from obstructions, and the site appeared to be very suitable and likely to approach fairly closely to the ideal case. There were a number of buried metal pipes and electric cables in the neighbourhood, as well as an earth which consisted of long aluminium strips embedded in the ground and spreading out radially from the centre of the antenna.

The aeroplane was piloted to glide from a height of 5 000 ft. down to 500 ft. from one side of the antenna to the other in such a direction that the two masts and the aeroplane remained in the same vertical plane. In this way it was possible to ascertain the position of the aeroplane from the horizontal and vertical angles obtained with a single theodolite. The theodolite was situated at a distance of some 3 miles from the station in a direction perpendicular to the direction of flight. At this distance three men were able after some practice to follow accurately the course of the flight and take readings on the theodolite every 10 seconds.

It is no easy matter for a pilot to keep his aeroplane flying accurately in one plane for, when a cross wind is blowing, as was almost invariably the case, the nose of the aeroplane may point 30° or more away from the true direction of flight. In order to give the pilot an indication by which to correct his direction of flight his telephones were connected in series with those of the observer in the aeroplane so that he could hear the modulated signal transmitted from the ground station. This signal was stopped for the space of a dot or a dash. A dot meant that he should turn one way and a dash the other way: if he were much out of his course a double signal would be sent. In this way the pilot could adjust his course correctly within a few degrees.

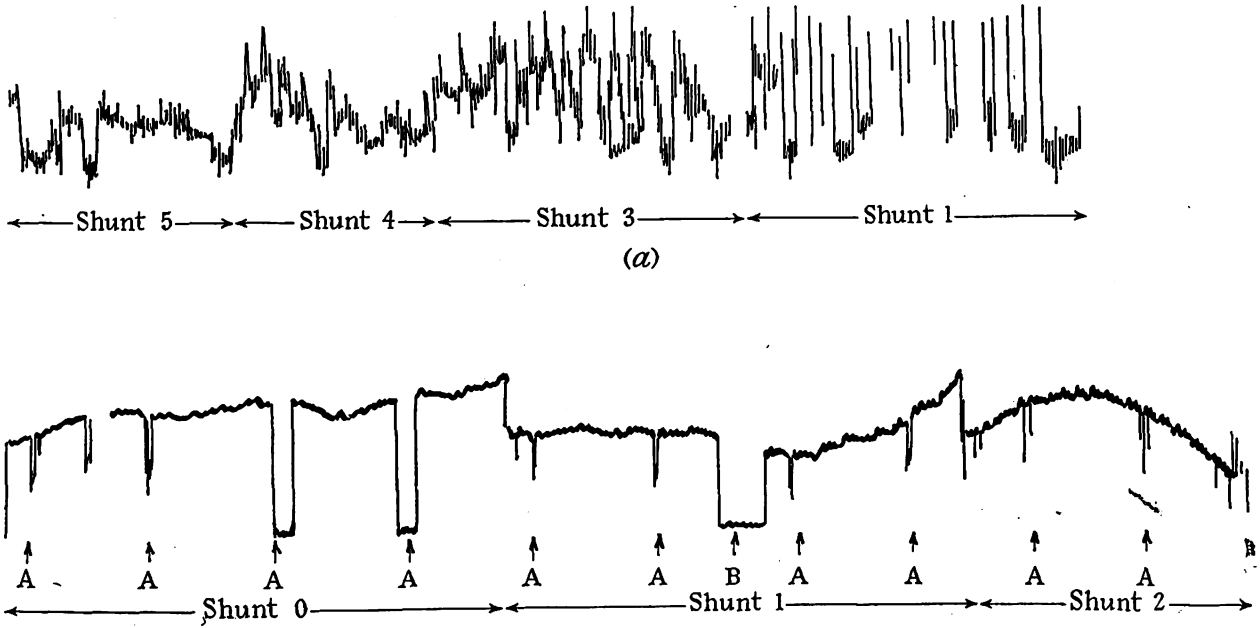
* See Reference (10).

The directional signals were sent every 10 seconds in synchronism with the readings taken on the theodolite, so that the cinematograph film on which the signal strength was recorded had a time scale automatically recorded on it [see Fig. 2 (*b*)]. Every minute a special signal was sent.



(*a*)

(*b*)

Fig. 2.

It may be realized that the experiments might have been inversed, i.e. a transmitter might have been installed in the aeroplane and the signal received on the ground. Such an arrangement would have permitted the use of a more elaborate signal-measuring set, but the directional indications to the pilot by means of the scheme described would not have been possible. Such indications would have necessitated communication on another frequency and probably the erection of a second antenna on the aeroplane. This was not considered advisable, for the radiation distribution of the aeroplane antenna is an unknown quantity and it seemed dangerous to distort it unnecessarily.

Baldus and Hase,[*] while investigating the radiation distribution of a trailing antenna in an aeroplane, employed transmissions from the aeroplane. They did not use any signal to direct the pilot, who found it almost impossible to fly correctly. The method employed in this case to locate the aeroplane was to take photographs of the ground and read the height. This method is liable to considerable error, first because the aeroplane may not be flying horizontally and a correction has to be applied from the readings of the levels, and secondly because the height is not easily measured. An accurate pressure altimeter was installed in the aeroplane used by the author. On one occasion when it was checked against the theodolite reading it showed very good agreement, but when the temperature correction was applied considerable divergence was found.

The preliminary experiments consisted mainly in adjusting the sensitivity of the receiver. The engine was found to be insufficiently screened. The comparison of the film readings shown in Fig. 2 are interesting. Fig. 2 (*a*) shows the type of field strength received when the aeroplane was first tried. After investigating the sources of radiation on the engine and screening a 2-in. length of exposed lead, the signal received was steadied to that shown in Fig. 2 (*b*). To compare Figs. 2 (*a*) and 2 (*b*), it is necessary to compare those parts for which the receiving set was of the same sensitivity. As explained above, variation of sensitivity was obtained by means of a series of shunts numbered from 0 to 6 (shunt 0 being the condition for which the set was most sensitive). Changes in shunt can be seen by the sudden changes in the signal strength, which are readily noticed in Fig. 2 (*b*). The sudden dips marked A in Fig. 2 (*b*) are the directional signals explained above, and the long dash seen at B is the distinguishing signal sent every minute. A more quantitative investigation of shielding in aeroplanes has been carried out recently by Drake.*

---

[*] See Reference (11).

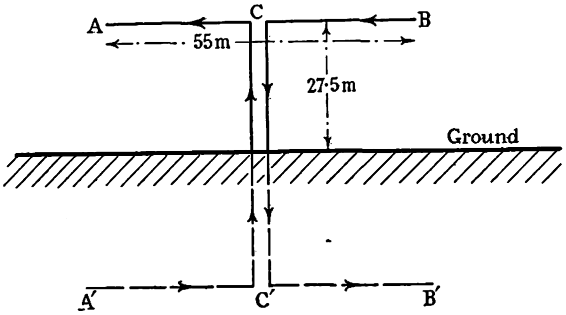


Fig. 3.

The antenna investigated was a horizontal one (Fig. 3) supported by wooden masts 150 m apart. It was excited by means of a push-pull oscillator, and the currents in the two leads were adjusted to equality at the foot of the antenna. The vertical leads were spaced 6 in. apart and the radiation from them was calculated to be quite negligible. This type of antenna is particularly interesting in this experiment because the whole of its radiating portion is at a constant height above the ground. Suppose an element P of the antenna together with its image has a radiation distribution of $I_p f_r$, where I_p is the current, then the function f_r will be the same for all the other elements of the antenna. If the whole antenna AB, considered in free space without its image, has a radiation distribution of f_a, then the total radiation distribution of the complete antenna with its image will be $f_a \times f_r$. By investigating such an antenna it should be possible to gain information regarding both f_a and f_r separately.

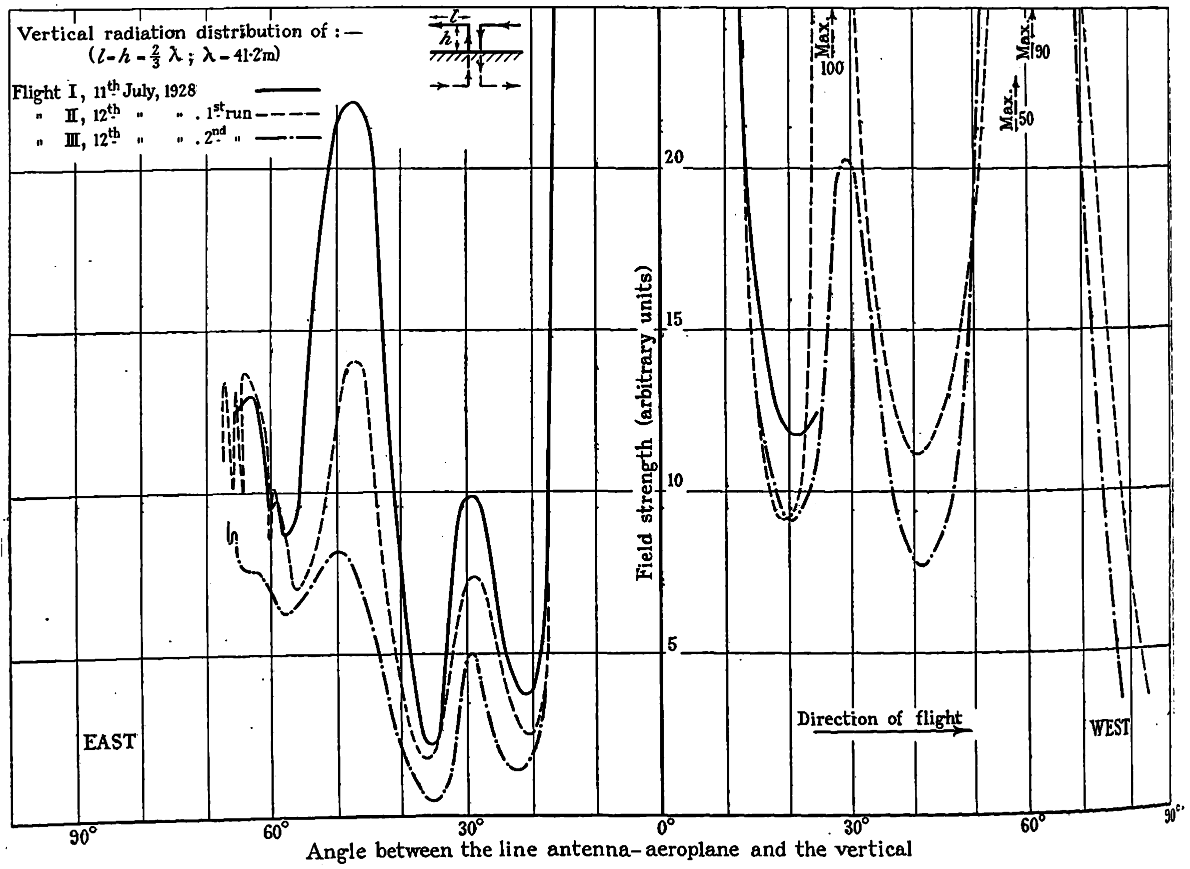

Fig. 4.

From the theory for the effect of the earth, mentioned above, it can be shown that, if $f_r = 0$ for a certain angle to the vertical in the case of a perfect earth, f_r will reach a minimum at a larger angle to the vertical when the earth is imperfect, and, moreover, f_r will never become zero in this case.

The variation of field strength recorded on the cinematograph film can only be construed into radiation distribution on two assumptions, viz.

(*a*) That the field strength varies inversely as the distance, and

(*b*) That the radiation distribution of the aeroplane antenna is sinusoidal.

The first assumption would appear to be incorrect for the ground ray, on account of attenuation, but along any other line there is no reason to suppose that this would be so. In fact, experimental evidence in support of the assumption is given below.

---

* See Reference (12).

Some experiments described below were carried out in an endeavour to verify or alter the second assumption, but the results did not justify the use of any more definite law than the simple sinusoidal distribution, which is based on the fact that the aeroplane antenna was invariably small compared with the wavelength. It will be seen that this gives rise to considerable difficulty when the aeroplane is vertically above the transmitting antenna, for, in that case, if the signal strength in the aeroplane is not zero, the calculated strength of the radiation from the transmitter will be infinite. In fact, for all angles within some 7° of the vertical the radiation distribution will be very inaccurate indeed and will consequently be omitted in the radiation distribution diagrams found experimentally. These diagrams are not plotted in the usual polar co-ordinates but in cartesian co-ordinates, so as to make the discrepancies more clearly visible. The angles in degrees measured from the vertical are plotted along the abscissæ, while the field strengths are plotted along the ordinates. Since the absolute values of field strengths were not determined the units used are absolutely arbitrary.

(3) Experimental Results on Simple Antennæ.

The first tests were carried out at a wavelength of 41·1 m ($h = \frac{2}{3}\lambda$) on a horizontal antenna as shown in Fig. 3, and the results of three flights all in the same direction are shown in Fig. 4.

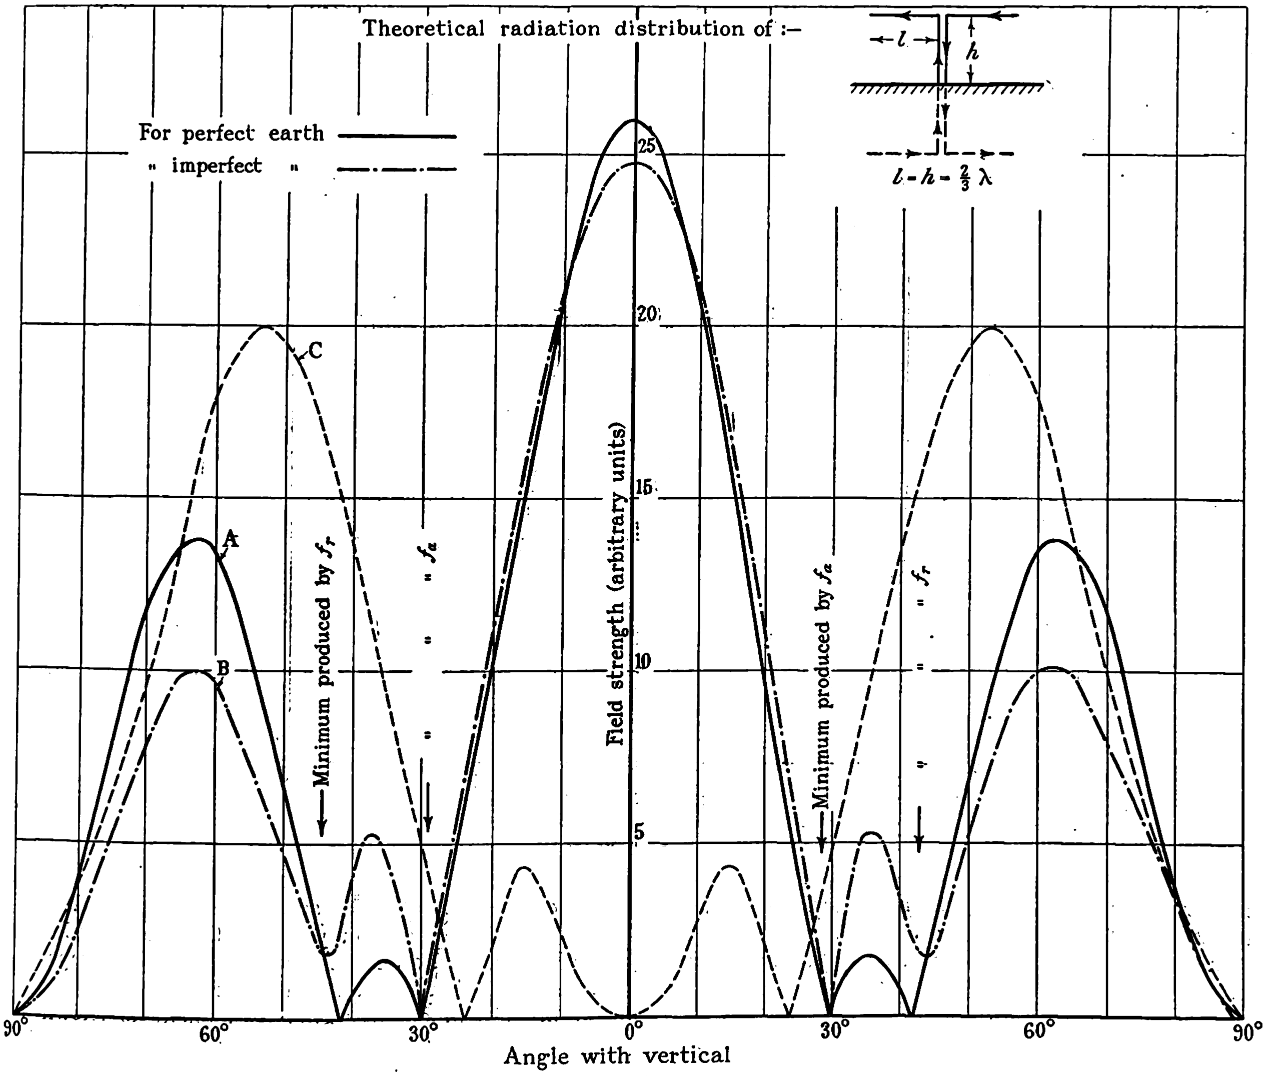

Fig. 5.

In analysing the experimental results it is essential to endeavour to discriminate between the radiation distribution due to the antenna alone (f_a) and that due to the effect of reflection in the earth (f_r). The radiation distribution in the case of a perfectly conducting earth is shown by the full line in Fig. 5, curve A. The minimum at 30° is due to f_a, while that at 41·5° is due to f_r. Mr. Barfield kindly measured the conductivity of the ground on the site of the transmitting antenna, by observing the tilt of the ground wave. He obtained values which varied between $0\cdot8 \times 10^8$ and 2×10^8 electrostatic units at various frequencies, the variation being caused, he thought, by buried conductors. Assuming that the conductivity is $1\cdot5 \times 10^8$ electrostatic units, the radiation can be calculated as explained in Appendix 2, and gives a distribution shown by the chain curve in Fig. 5 (curve B). It will be seen that the minimum due to f_a remains unaltered, while that due to f_r does not come to zero and is shifted to a slightly larger angle with the vertical. If the end-effect correction explained in Appendix 1 be applied, the curve will not be affected to a very great extent, but the minimum due to f_r will be shifted some 3° towards the vertical.

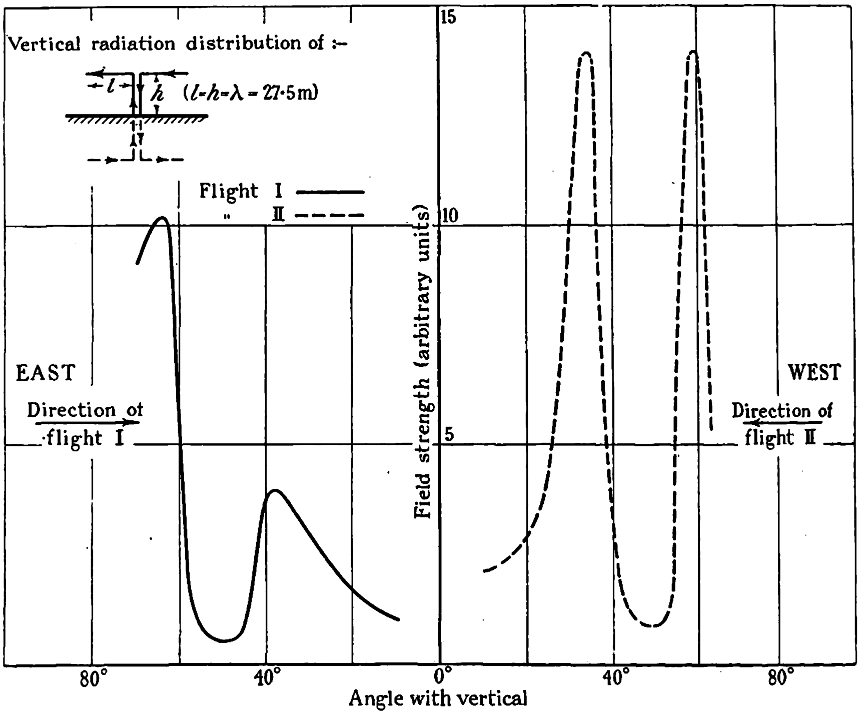

Fig. 6.

On examining Fig. 4 a number of points may be noted:

(*a*) The positions of the main maxima and minima repeat to an accuracy of less than 2°.

(*b*) The positions of the main maxima and minima are slightly different on the two sides of the transmitting antenna and occur at a greater angle to the vertical than the theory would lead one to expect.

(*c*) The signal strength on the east side is much weaker than that on the west.

The accuracy with which the results repeat leaves very little room to doubt that all the effects noted truly exist and are not merely due to experimental error. The asymmetry of the positions of the maxima and minima on either side of the antenna might be caused by some error due to synchronizing the watches. An error of 1 second might account for this, and, although the watches were thoroughly tested and were checked before and after the flights, such an error might be conceivable owing to changes of temperature in the course of the flights, which were some 2 hours in duration. It will be noted, however, that the error repeats accurately on two different days and it is difficult to imagine how such a consistent error could occur.

It was thought that some of the discrepancies between the theoretical and the experimental curves might be caused by slightly unequal excitation of the two halves of the antenna. Calculation showed, however, that this could not cause asymmetry and that its effect would only be of the second order, as it would produce a component of the radiation distribution in time quadrature with the main component. This component is shown by the broken line C in Fig. 5 and it does not appear that any satisfactory deduction can be made from it.

The minimum that should theoretically occur at 43° is the minimum produced by the interference of the antenna and its image. Experimentally it is found to occur at 36° on one side and 41° on the other, giving a mean of $38\frac{1}{2}$°. If the earth were a perfect conductor this minimum would occur at 41°. It would appear, therefore, that the minimum is shifted by the imperfection of the earth by the correct amount but in the wrong direction.

The position of the other minimum, which is produced by the antenna alone, shows a discrepancy of as much as 9° between the experimental and theoretical values.

If allowance is made for end effects, as explained in Appendix 1, this discrepancy can be reduced to 5°.

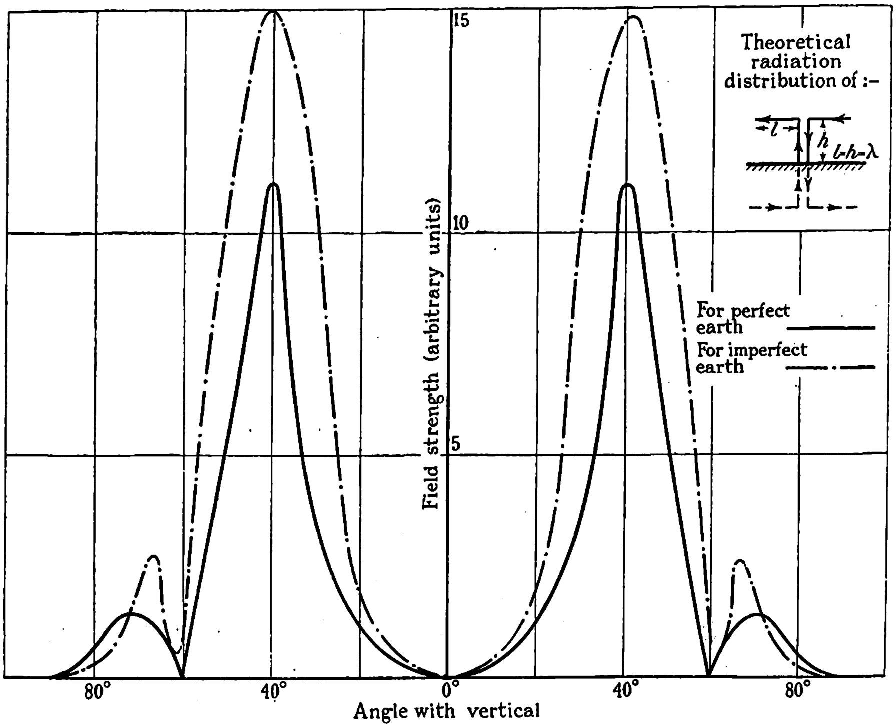

FIG. 7.

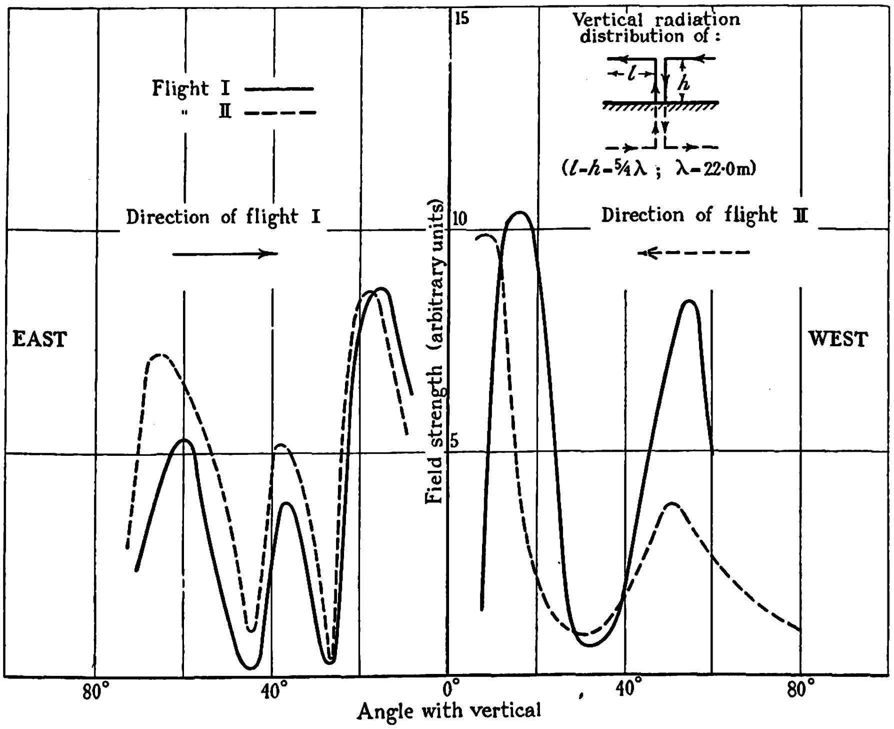

FIG. 8.

The author believes that the reason for these discrepancies may well be found in the site—buried conductors, etc.—and evidence for this will be given below.

The next experiments were carried out on the same antenna with a wavelength of 27·5 m ($h = \lambda$). The experimental results are shown in Fig. 6. In this case the flights were carried out over the antenna from both directions in the hope of eliminating the effect of the directive properties of the aeroplane itself. It will be seen later that this could not give the expected results.

The curves of Fig. 6 are to be compared with the theoretical curves of Fig. 7.

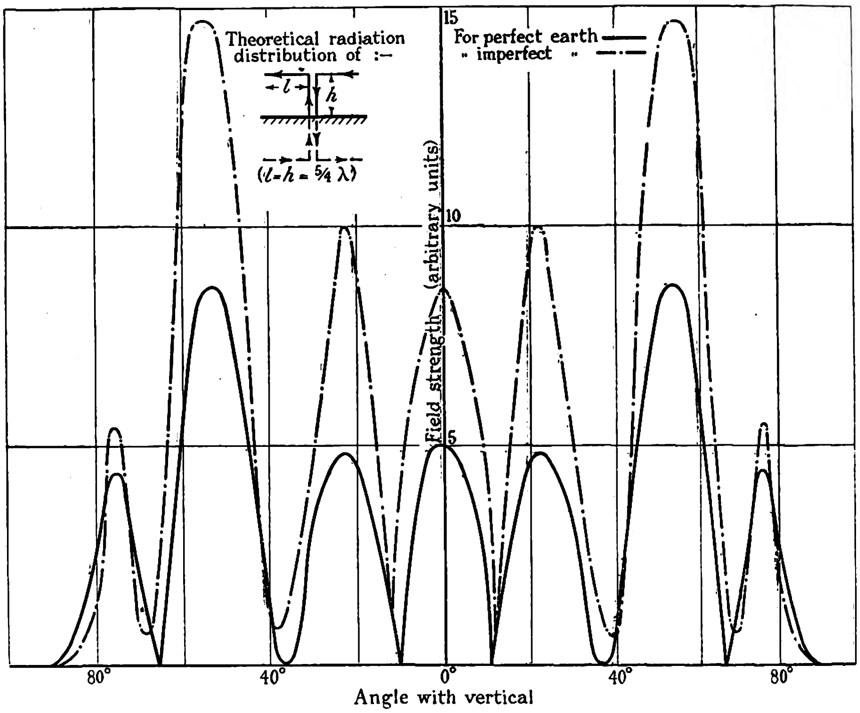

Fig. 9.

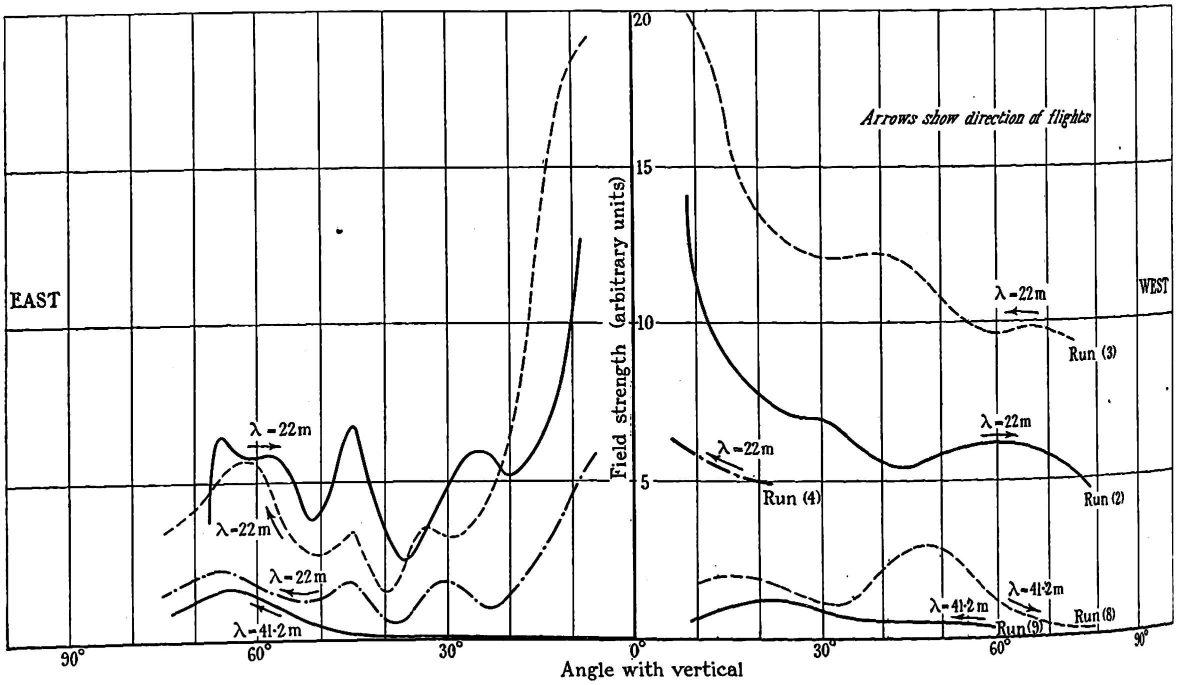

Fig. 10.—Radiation distribution with short vertical antenna.
Arrows show direction of flights.

Deductions similar to those in the previous case can be made, namely, asymmetry on the two sides of the antenna and a shifting of the minima and maxima towards the vertical as compared with the theoretical curves.

Similar tests were made with the antenna excited at a wavelength of 22 m ($h = \frac{3}{4}\lambda$). The experimental results are shown in Fig. 8, which should be compared with the theoretical curves of Fig. 9. Here, again, deductions similar to those in the two previous cases can be made.

In order to allow for the radiation distribution of the antenna on the aeroplane, the field strength received from a small vertical antenna was analysed with the aeroplane in the same way as in the case of the horizontal antenna. By a small antenna is meant an antenna not greater than $\frac{1}{8}$th wavelength in height. In order to increase the effective height of this antenna, a horizontal portion was added in the plane perpendicular to the plane of flight of the aeroplane, so that radiation from this horizontal portion might affect the result to a negligible extent. In these conditions it was thought reasonable to assume that the radiation distribution of the transmitter would be sinusoidal. That is, if the signal strength (corrected for distance) were divided by sin θ (where θ is the angle with the vertical) the result should give the radiation distribution of the aeroplane antenna. In this, however, the experiments led to disappointment. The results obtained are shown in Fig. 10.

Two wavelengths were studied (41·2 m and 22 m). The aeroplane was flown both from east to west and from west to east, so that in some cases the engine would lie between the receiving and the radiating antenna and in the other cases it would lie on the other side of the receiving antenna, and the screening effect might be expected to be different in the two cases. On examining Fig. 10, however, it will be found that the radiation distribution diagram is substantially independent of the direction of flight of the aeroplane. Yet the curves obtained are far from uniform and the signal strength on the east side of the transmitting antenna is always much stronger than that on the west. Looking back at Figs. 4, 6 and 8 we see that this result was obtained in every case. We are finally led to the

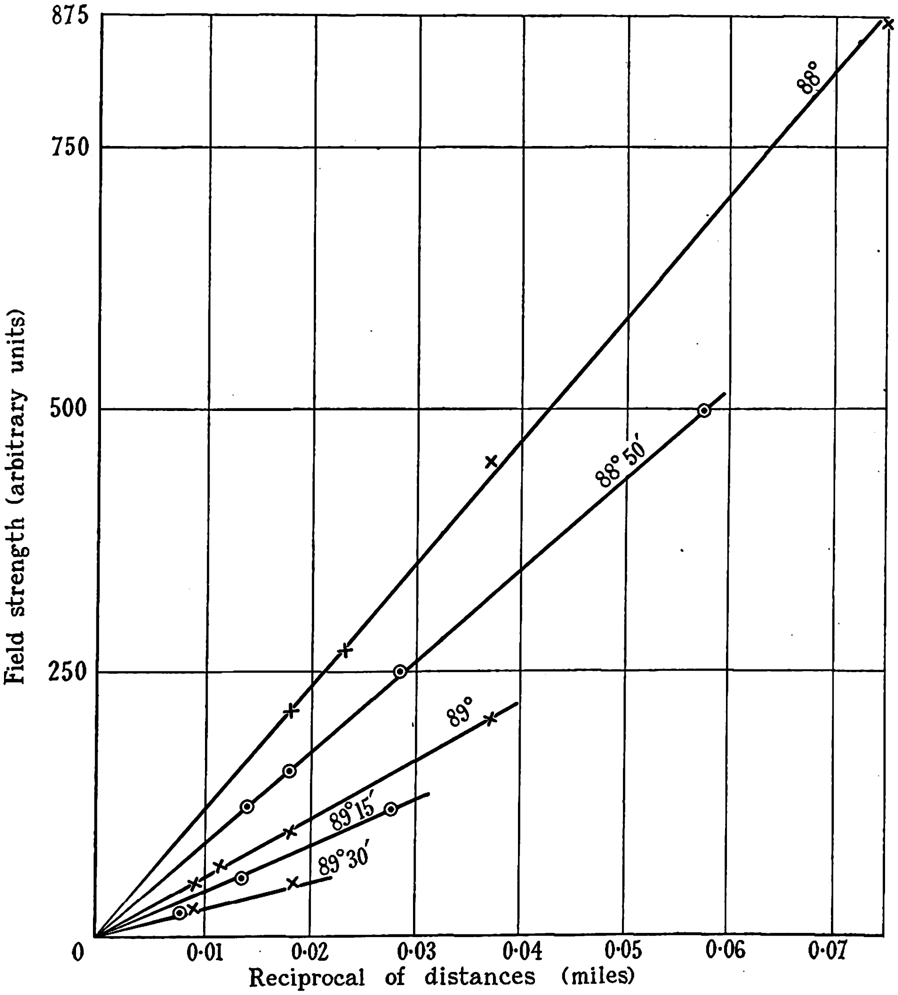

FIG. 11.—Signal strength plotted against reciprocal of distance for various inclinations to vertical. $\lambda = 185$ m.

conclusion that the radiation distribution of the aeroplane antenna may be sinusoidal and that the irregularities noted are due to the nature of the neighbouring objects around the transmitter. This result was unexpected as the site was considered to be clear of interfering obstructions. The building in which the oscillator was housed at the foot of the antenna was made of concrete without any metal, but the back of it contained electrical power generators some 60 ft. from the foot of the antenna. There were also some conductors buried in the ground. The masts were made of wood and held up by steel-rope stays, but the masts were 500 ft. apart and the antenna, held in the centre, was only 170 ft. long. There were, moreover, no trees for some considerable distance from the site. However unexpected the result may be, there does not appear to be any way of evading the conclusion that the variations shown in Fig. 10 were due to the ground or objects in the neighbourhood of the transmitting antenna. A further confirmation of this was obtained by finding the radiation distribution of the aeroplane antenna on the ground by rotating the aeroplane about a vertical axis. The signal strength during any one rotation was found not to vary by more than 5 per cent even at a wavelength as low as 15 m.

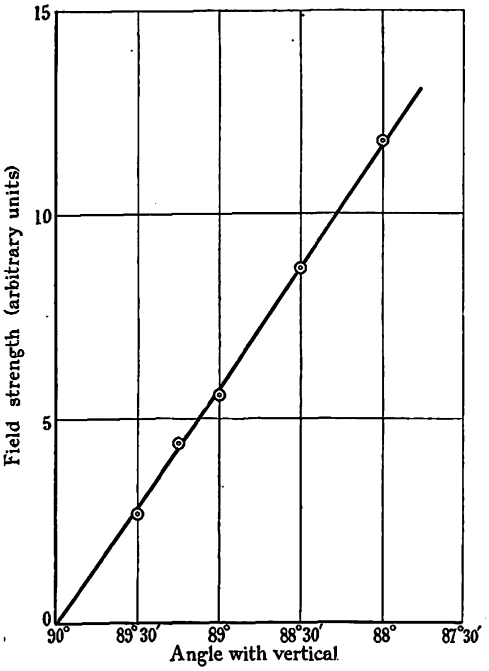

FIG. 12.—Variation of signal strength with angle to vertical. $\lambda = 185$ m.

In the calculation of the foregoing experimental curves it has been tacitly assumed that the signal strength varies inversely with the distance. While this is known to be true for comparatively short distances on long wavelengths, it is known to be false for short waves on the ground, the law in this case being very nearly inversely as the square of the distance. The author believed that this was due to the attenuation produced by the ground, but that the inverse-distance law would hold along any radius even at very small angles of elevation from the ground. Some rough experiments carried out by the author confirmed this, but far more elaborate experiments have been carried out by D. K. Martin * of the Bell Telephone Laboratories. In these experiments the signal strength was measured at various heights above the ground, travelling horizontally for a distance as great as 120 miles from the transmitter. From these results Fig. 11 has been calculated. This shows the variation of signal strength with the reciprocal of the distance along radii making various angles with the vertical. It will be noted that all the points lie on a series of straight lines to a very high degree of accuracy, thus effectively proving the inverse-distance law up to angles of 89½° with the vertical.

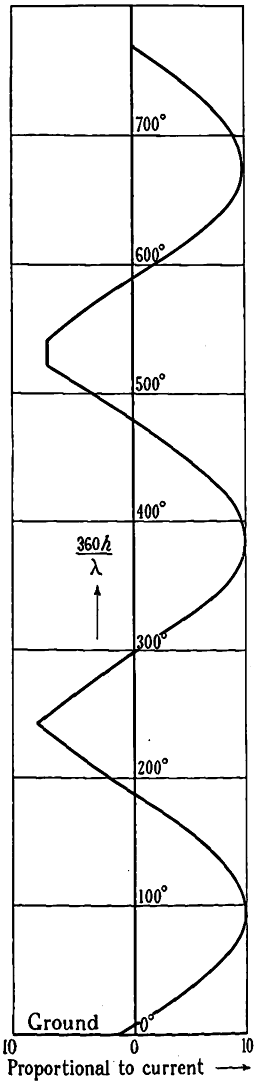

FIG. 13.—Current distribution in Australian beam antenna at Grimsby. $\lambda = 25 \cdot 9$ m.

This series of curves is very interesting in another

---

* See Reference (13).

respect. If we write $(\frac{1}{2}\pi - \delta)$ for θ in equation (3) of Appendix 2, and make δ very small (δ being the angle of elevation with the ground) we have

$$K_i - jK_i' = -\left\{1 - 2\delta\sqrt{(\sigma/f)} + 2j\sqrt{(\sigma/f)}\delta\right\}$$

The signal strength for small values of δ is, therefore, proportional to

$$2\delta\sqrt{(2\sigma/f)}$$

The gradient of the straight lines in Fig. 11 will be a measure of the field strength for various values of δ and, according to the above, this should be a linear relation. That this is so is well shown in Fig. 12. The gradient of this line depends on the conductivity of the ground and on the effective height and the current in the transmitting antenna. Knowing the latter, the conductivity of the ground could be deduced.

The linear relation of Fig. 12 is a very striking, though far from complete, confirmation of the equations (8) and (9) explained in Appendix 2. It is very interesting, however, in tending to show that only the constants of the ground in the immediate neighbourhood of the ground station affect the signal strength of the direct ray in aeroplane-to-ground communication.

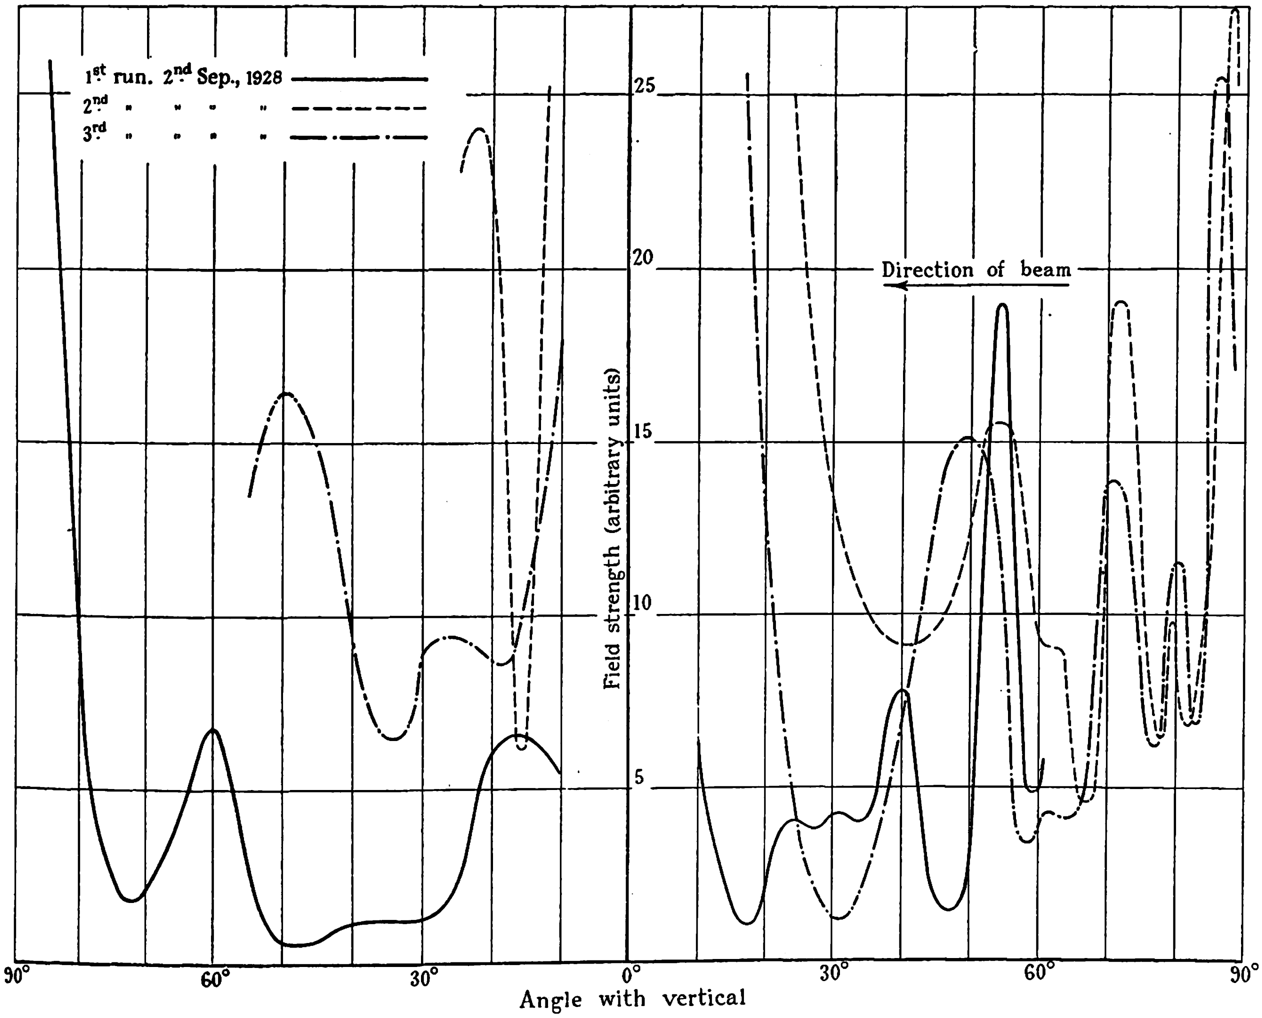

FIG. 14.—Vertical radiation distribution of Australian beam aerial at Grimsby. $\lambda = 25 \cdot 9$ m.

(4) EXPERIMENTAL RESULTS ON A BEAM ANTENNA.

With the co-operation of the Post Office, a number of flights were made over the beam antenna erected near Grimsby by the Marconi Co. for transmissions to Australia. The beam array consists of a large number of vertical wires spread over a span of 1 300 ft. Each wire is built on the Franklin system, with portions of current loops eliminated. The current distribution, on the simple sinusoidal theory, is shown in Fig. 13. The ordinates are measured in degrees instead of metres (a distance h corresponds to $360\ h/\lambda$ degrees), to simplify the calculations. In order to obtain a theoretical radiation distribution curve the current areas are divided up into a large number of small areas having a height of not more than 45°, and the distances of their centres of gravity from the ground are read off in degrees. If A is an area and h_1 the height of its centre of gravity from the ground, the field strength in a direction making an angle θ with the vertical in the case of a perfect earth will be proportional to

$$A \cos (h_1 \cos \theta)$$

The total field strength due to the whole antenna is obtained by adding all such terms. In the case of an imperfect earth the field strength has to be calculated as explained in Appendix 2.

It should be pointed out that the radiation distribution should be identical in form but not in strength in all vertical planes passing through the centre of the antenna array, if the reflector is neglected. The reflector consists of simple straight wires 960° high situated $\frac{1}{4}$ wavelength behind the transmitting array itself. This beam is so arranged as to permit of transmission either way round the earth. It was a simple matter, therefore, to find the ratio of front-to-back radiation, by simply reversing the direction of the beam, leaving the measuring receiver in the same place. The ratio on the ground of the field strength in front and behind was found to be of the order of 2 : 1, which value roughly checked with calculations based on the current measurements made on the reflectors and the transmitters, together with a rough estimate of the phase relation between them (see Appendix 2). This showed that the reflector would not affect the radiation distribution in a vertical plane to a very large extent, and, considering the errors liable to be found, it was not considered necessary to allow for it. The experimental results are given in Fig. 14 and the theoretical curve calculated for a perfect earth is shown in Fig. 15.

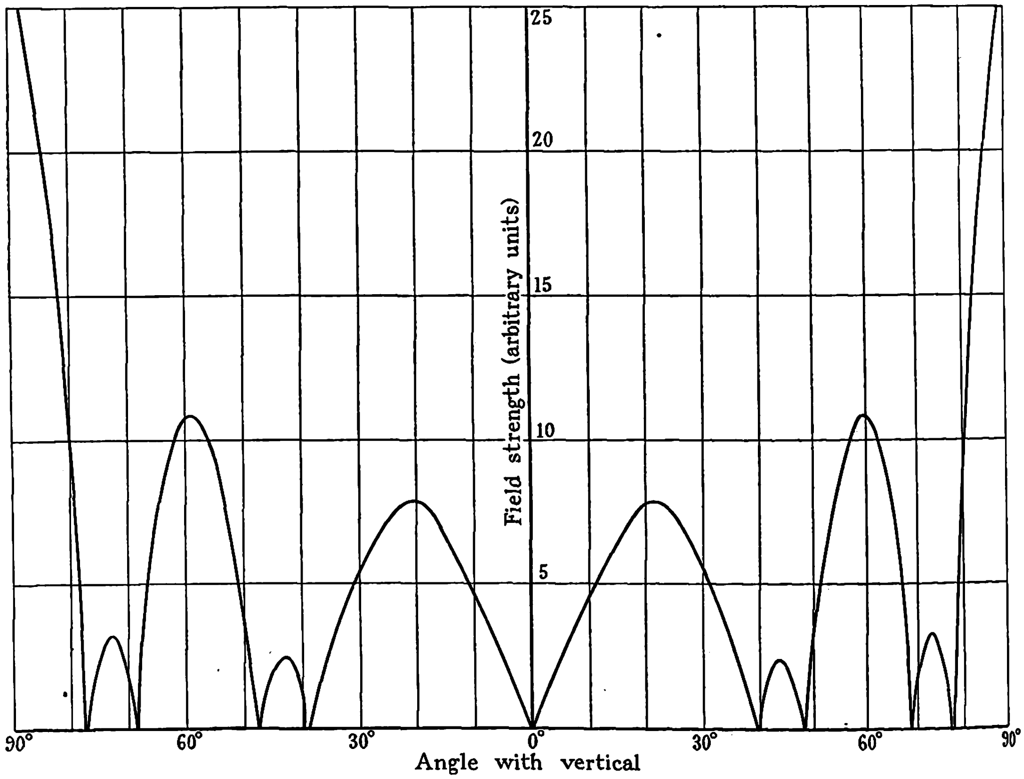

FIG. 15.—Theoretical radiation distribution from Australian beam over a perfect earth. $\lambda = 25{\cdot}9$ m.

The difficulty of investigating experimentally the radiation distribution of a beam compared with that of the simple antenna, lies in the very high directive properties of the former. Should the aeroplane fly in a plane slightly displaced from the true plane, the result would be very considerably distorted. Actually it was noted from the ground that the aeroplane flew in a plane parallel to, but slightly displaced from, the true plane. The true flight of the aeroplane was in a plane containing the main beam (i.e. perpendicular to the antenna array), and a displacement horizontally of as small an angle as 5° would reduce the signal from a strong maximum to a minimum. The size of the antenna system produced a further error, as it was not possible to reach such a height that the distance of the aeroplane from the antenna was large compared with the size of the antenna system itself. This error, however, when flying in the plane of the beam, is only of a second order. The aeroplane flight was practically a perfect straight line in space, starting at an altitude of 8 000 ft. at a horizontal distance of about 4 000 ft. behind the antenna, and ending at an altitude of some 500 ft. at a horizontal distance of about 25 000 ft. in front of the antenna. In flight 1 the signal strength was noted to be comparatively weak. This was no doubt due to the aeroplane flying appreciably out of the true plane, and it explains why the radiation distribution on this flight differs so considerably from that of the other two flights. The agreement between the other two flights is considered very satisfactory, in view of the experimental difficulties, and the results of flight 1 may, on this evidence, be discarded as untrustworthy.

The comparison of the experimental results and theoretical curves, as shown in Figs. 14 and 15, is very interesting. The large value of field strength obtained experimentally at 0° is probably due to a small asymmetry in the excitation of the beam system, and also to the fact that the aeroplane was not flying absolutely in the true plane. The first minimum between 30° and 65° is not so good. The third at 75° no doubt corresponds to the theoretical minimum at 69°, while the fourth at 82° corresponds to that at 77°. Then follows a very interesting result. Instead of increasing to reach a maximum of field strength on the ground, the field strength reaches a maximum at 86° and falls rapidly. Such an effect would be expected if the ground were not a perfect conductor. The angular position of the maximum can be used in obtaining an estimate of the conductivity of the ground. This would appear to be of the order of 4×10^8 electrostatic units. If this figure were used for correcting the theoretical radiation distribution curve given in Fig. 15, very little difference would be found except for angles greater than 82°.

(5) Conclusion.

From these results we may conclude that the experimental values are reliable but that very accurate analysis of the differences between the experimental and theoretical results is rendered impossible by the nature of the transmitting site.

There is considerable evidence that the minor irregularities seen in Figs. 4, 6 and 8 are due to ground effects and are not to be found in the transmission from the special antenna construction used. On the other hand, it seems difficult to attribute the discrepancies between the experimental and theoretical results to the same cause, although, judging from the size of the variations noted in Fig. 10, they may well be sufficient to explain all the discrepancies. In all the cases investigated with the simple horizontal antenna, the maxima and minima were all shifted towards the vertical, and this shift increased with decrease of wavelength. This occurred irrespectively of the nature of such maxima and minima, i.e. whether they were due to the antenna alone or to the interference between the antenna and its image (as explained above).

Evidence has been given that the inverse-distance law of field strength holds for angles of elevation at least as small as ½°.

The results on the beam antenna show comparatively good agreement with theory, considering the very much greater experimental difficulties of this case. It is interesting to note that the shift of the maxima and minima in this case is away from the vertical, which is the reverse of the results obtained on the simple antenna.

The final conclusion to be drawn from this is that the theory of radiation distribution is substantially correct, but, in order to examine its accuracy in great detail, it would be necessary to carry out experiments over some irreproachable site, and this might be more difficult to find than would at first appear. The necessity for this would in any case be somewhat academic, for in practice it might be difficult to find such a site for the erection of a transmitting station, and if this were not obtained the ordinary calculations would never give a very high order of accuracy. It would have been desirable to carry out a few more tests in order to confirm the deductions reached, but the author was unable to continue the experiments.

In conclusion the author wishes to thank the many workers who have helped him in carrying out this investigation. In particular, his thanks are due to the Air Ministry, who generously supplied the aeroplane for carrying out the tests; also to Squadron-Leader A. L. Gregory, Messrs. F. S. Barton, N. F. S. Hecht, T. H. Gill and members of their staff at the Royal Aircraft Establishment, who gave him all the facilities and advice that could be desired during the progress of the work.

The author has also to thank the General Post Office and in particular Colonels A. G. Lee and A. S. Angwin, and Mr. De Wardt, for permitting and giving every assistance in carrying out the measurement on the beam antenna.

Finally, and principally, he wishes to thank Flight-Lieut. Ragg, R.A.F., whose skill and patience in piloting the aeroplane were largely responsible for the unexpected accuracy of the measurements, and also Messrs. J. S. McPetrie, B.Sc., and B. J. Byrne, of the National Physical Laboratory, without whose efficiency and patience the work would not have reached its comparatively satisfactory conclusion.

This work was carried out as part of the programme of the Radio Research Board and is published by permission of the Department of Scientific and Industrial Research.

APPENDIX 1.

Correction for End Effects.

The author has shown experimentally* that in a straight vertical antenna the first half-loop of current was some 8 per cent greater in area than the half-loop of a sine wave. At the foot of the antenna the effect may be expected to depend on the length and the proximity to the ground. If the length is l and the wavelength λ, the charge per unit length near the top when the current at the centre of a loop is I will be proportional to I, while that at the foot will be proportional to $I \cos (2\pi l/\lambda)$.

The end effect is produced by a sudden discontinuity in the charge. At the top, from a value proportional to I it suddenly changes to zero, while at the foot it changes from $I \cos (2\pi l/\lambda)$ to $-I \cos (2\pi l/\lambda)$. When the foot of the antenna is in close proximity to the ground it is to be expected, therefore, that the end effect at the foot will be $2 \cos (2\pi l/\lambda)$ as large as that at the top. To simplify calculations we may, with sufficient accuracy, represent the end effects by an area 8 per cent as great as a half-loop of current concentrated at the top end, together with one $16 \cos (2\pi l/\lambda)$ per cent concentrated at the foot. The radiation distribution from such concentrated areas may be very readily calculated, and superposed on the radiation distribution calculated from a simple sinusoidal distribution.

The case of a horizontal antenna as shown in Fig. 3 is similar to that of a vertical antenna turned through 90°.

---

* See Reference (4).

The centre point C now corresponds to the foot of the antenna. It must be remembered, however, that these end effects have their images at A′, B′ and C′ in the ground.

APPENDIX 2.

MEASUREMENT OF THE PHASE RELATIONS IN ANTENNA ARRAYS.

For the purpose of measuring the phase difference between two antennæ a low-voltage cathode-ray oscillograph was used. E.M.F.'s from the two antennæ A and B (Fig. 16) whose phase difference is to be measured are induced in two coils C and D connected to the opposite plates of the oscillograph. An ellipse is obtained the size and ellipticity of which varies with the e.m.f.'s induced in C and D. These are adjusted until the axes of the ellipse bisect the line joining the plates, as shown. It can readily be shown then that, if γ is the phase angle and a and b are the axes of the ellipse,

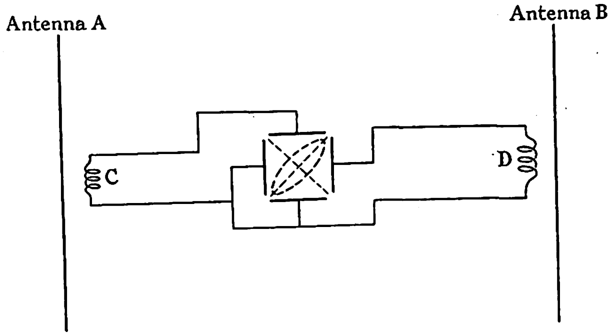

FIG. 16.

$$\tan \gamma = a/b.$$

It will be noted that an ambiguity exists, for

$$\gamma = \text{arc tan } (a/b) \quad \text{or} \quad \pi + \text{arc tan } (a/b).$$

An error may occur at very high frequencies, owing to the fact that the deflecting plates of the oscillograph are not at the same distance from the cathode. This error may be readily eliminated by interchanging the connections of the coils C and D to the oscillograph plates and taking a mean of the results.

The instrument used was placed in a metal box in which a small hole was cut for the purpose of observation. In front of the tube a number of wires were stretched at 45° to the deflecting plates. The distance between the wires was such as to show deflections in the ratio of 1: 2: 3: 4, etc., of the spot on the screen. The wires were faintly lighted by a means of a neon lamp working from the high-tension supply of the oscillograph. In this way the axes of the ellipse could be readily adjusted to the correct direction and their lengths read off. The leads and coils connected to the instrument were made as identical as possible.

Good consistency was obtained at 26 m, but considerable irregularities were found at 15 m. Such an instrument should be very valuable during the erection of a complicated beam system, but the author feels that the measurements made with it should be subjected to more thorough investigation. The phase relation between a pair of isolated, spaced antennæ can be obtained by taking measurements of the radiation distribution along the ground, and this method might be used as a check in measurements made with the cathode ray.

THE PULLING INTO STEP OF A SYNCHRONOUS INDUCTION MOTOR.*

(AN APPLICATION OF THE M.I.T.† INTEGRAPH.)

By HAROLD E. EDGERTON and FREDERICK J. ZAK.

(*Paper first received 2nd November, 1929, and in final form 24th January, 1930.*)

SUMMARY.

The problem of the pulling into step of a synchronous motor has proved very difficult to solve, since it centres about a non-linear differential equation. One solution of the equation is not enough. All possible solutions with all combinations of the coefficients need to be made and classified into two groups, those that synchronize and those that do not. Until recently this has been practically impossible because of the amount of time required to make the solutions by graphical or point-by-point methods.

The development of the integraph by Dr. Bush and his associates at the Massachusetts Institute of Technology has made it possible to solve this problem by machine integration. This integraph, which performs two successive integrations simultaneously, is particularly adapted to the solution of first- and second-order total differential equations. The solutions described in this paper were obtained by using the integraph in this way.

This paper presents the complete solution of the problem for the case of a non-salient-pole synchronous motor. The results are put in a simple form convenient for practical use. By means of these results all of the necessary relationships between field current, induction-motor torque and slip, which determine whether or not a given load of a definite flywheel effect can be brought into synchronism, are determined. An example of a practical application is given.

LIST OF SYMBOLS USED IN THE PAPER.

P_j = synchronous torque in kW per electrical degree of acceleration per second per second (at synchronous speed).
P_d = synchronous torque in kW per electrical degree of slip per second.
P_m = maximum synchronous torque from synchronous motor characteristics, kW.
P_l = synchronous load torque, kW.
$\mathbf{1}$ = Heaviside's unit function.
θ = angle between terminal voltage and the e.m.f. generated in the armature by the action of the direct field current.
k = relative damping coefficient = $P_d/\sqrt{(P_m P_j)}$.
Wr^2 = total moment of inertia of motor and load, lb.-ft.^{2}.
I = Wr^2/g in lb.-ft.-sec. units.
f = frequency, cycles per sec.
p = number of poles.
s = slip as a fraction of unity.
V = terminal voltage per phase.
E = induced voltage per phase.
X = synchronous reactance, ohms per phase.
n = synchronous speed, r.p.m.

INTRODUCTION.

A synchronous induction motor is brought up to speed as a wound-rotor induction motor. External resistance in the rotor circuit gives large starting torque with moderate line currents. As the motor comes up to normal speed the rotor resistance is gradually reduced. At the end of the starting period the rotor is short-circuited and the motor runs steadily at a small slip, the load torque being balanced by the induction-motor torque.

Now, in order to synchronize, the rotor circuit is opened and immediately connected to an exciter. This switching takes place so quickly that the motor does not slow down appreciably. Of the several methods available for connecting the exciter in the rotor circuit, the best method short-circuits all the rotor phases, the exciter armature serving to short-circuit the alternating currents in the exciter phase or phases. Such a connection gives the maximum induction-motor torque characteristics. For this reason the motor tends to supply the load at the same slip.

There is now, however, a direct current superimposed on the low-frequency rotor current. The d.c. component in the rotor circuit rises to its final value practically instantaneously when compared with the slow mechanical oscillations. Synchronous-machine characteristics are produced by this direct current in the rotor circuit. The synchronous torque thus developed tends to pull the motor into synchronism.

It is now a matter of adjustment between the various components of torque. The motor may pull into synchronism and run as a synchronous motor. It may continue to supply the load as an induction motor but with speed and current pulsations. It may revolve several times and then pull into synchronism. The desired condition is to have the motor synchronize on the first swing through the steady-state operating angle.

The inertias of the motor and of the connected load are very important in this problem of pulling into step. Energy must be supplied to the rotating parts to get them from a speed lower than synchronism up to synchronous speed. The torque available to speed up the rotor depends upon the field current and upon the angular displacement between the terminal voltage and the e.m.f. generated in the armature by the action of the direct field current. The angular displacement varies with time in a manner determined by the differential equation.

The initial angle (determined by the point at which the exciter is connected) also influences the pulling into step. If the exciter is connected at an angle which initially causes generator action, the speed of the rotor decreases. This is because the energy of the rotating parts is initially the only available source of energy. As the rotor then swings into the region of motor characteristics the motor torque must supply more energy. This is due to the fact that the rotor must be speeded up from a greater slip than if the exciter were switched at a more favourable angle.

Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† Massachusetts Institute of Technology.

The amount of field current in the rotor is the remaining important factor that influences the pulling into step. The larger the field current in practical machines the more favourable are the chances of synchronization, since more synchronizing torque is available. The synchronizing torque does not increase directly with field current, because of energy losses in the armature resistances. The practical limitation of the field current is determined by the allowable heating of the rotor.

There are two convenient ways of connecting the exciter to a 3-phase rotor. One is to connect each exciter terminal to a slip-ring and leave the other slip-ring open. The other is to connect two slip-rings to one terminal and the other ring to the other terminal of the exciter. The first method is not as satisfactory as the second from the standpoint of pulling into step, because the induction-motor characteristics are greatly influenced. Leaving one of the slip-rings open-circuited makes the rotor single-phase. Such a rotor gives a torque that is a sine-squared function of angular displacement as well as a linear function of slip. This would cause pulsations in the line currents, torque and speed. A motor with a single phase or an unbalanced rotor requires a larger slip to supply the same load. Pulling into synchronism is more difficult when one slip-ring is open-circuited. This problem is not considered in this paper.

All of the factors mentioned in the preceding paragraphs contribute to the problem of the pulling of a synchronous motor into step. Their effects have been difficult to find since the mathematical equations of the motor are not soluble by ordinary methods of analysis. Carr, Cotton, Dreyfus, Fraenckel, Böhm, Lindstrom and others have given approximate and step-by-step solutions which have been of great practical importance.[*]

The integraph, which was available to the authors, enabled them to make many transient solutions of the fundamental differential equation in a reasonable length of time. The integraph solutions, although subject to many small errors, are within engineering accuracy for this problem, i.e. within a few per cent.

STATEMENT OF THE PROBLEM.

The differential equation that characterizes the angular variations of a cylindrical-rotor synchronous machine, when in the transient conditions following the sudden introduction of a direct voltage into the rotor circuit, is generally accepted[*] to be of the following form:—

$$P_j\frac{d^2\theta}{dt^2} + P_d\frac{d\theta}{dt} + (P_m \sin\theta)\mathbf{1} = P_l \quad . \quad . \quad (1)$$

In deriving this equation it is assumed that the currents and potentials are sinusoidal, that the applied potential is constant and that the stator resistance and rotor leakage inductance are negligibly small. The first term represents the torque due to the acceleration of the moving parts of the rotor and connected apparatus. The second term represents the torque that results from the induction-motor effect. This term is used only for the portion of the slip-torque characteristic near synchronous speed. The third term represents the torque due to the synchronizing action of the motor after the field has been excited. Heaviside's unit function,[†] $\mathbf{1}$, which is zero before and unity after time equals zero, gives the boundary condition to the synchronizing term. The synchronizing torque is zero before and a sine function of angle after the exciter is connected.

Initially, before the field is applied, the load is supplied by the induction-motor torque. This gives the initial boundary conditions of the equation. The torque due to the slip, $d\theta/dt$, is just sufficient to supply the load torque. The acceleration, $d^2\theta/dt^2$, is equal to zero.

The coefficients and factors which influence the solution of the equation are listed and discussed below. The coefficients have been expressed in terms of power or synchronous torque.

P_j = coefficient which, when multiplied by the acceleration, gives the component of power due to inertia (at synchronous speed).

P_d = coefficient which, when multiplied by the slip, gives the component of power due to the induction-motor effect.

P_m = maximum power due to synchronizing action of the field current.

P_l = amount of shaft load (considered constant in the solutions).

θ_0 = initial angle between the applied stator potential and the e.m.f. generated in the stator by the action of the direct field current that exists when the exciter is connected.

The first three, which depend upon the motor that is under consideration, together with the inertia of its connected load, may be combined into one factor which has been termed the "relative damping coefficient" and has been given the symbol k. Also the load, P_l, is more conveniently expressed as a fraction of the maximum power, P_m, that is available. Both of these changes are accomplished by changing the variable, t, of equation (1) by the following relationship.

Let $$t = t'\sqrt{\frac{P_j}{P_m}}$$

where t' is a new dimensionless variable.

[*] Various authors give modifications of this equation, which take into account the effect of salient poles, unsymmetrical rotor circuits, etc. (see, for instance, Dreyfus or Cotton, *loc. cit.*). These more involved expressions can be solved on the integraph, but the number of factors is increased so that a simple, general relationship, such as has been obtained in this paper, is improbable.

V. BUSH: "Operational Circuit Analysis," p. 41 (John Wiley and Sons, Inc., New York, 1929).

Introducing this into equation (1) gives, after dividing both sides by P_m,

$$\frac{d^2\theta}{(dt')^2} + k\frac{d\theta}{dt'} + (\sin\theta)1 = \frac{P_l}{P_m} \quad . \quad . \quad (2)$$

where

$$k = \frac{P_d}{\sqrt{(P_j P_m)}} \quad . \quad . \quad . \quad . \quad . \quad (2a)$$

The relative damping coefficient, k, is a numeric, but its numerical value depends upon the unit used for measuring angles. In the solutions that follow, electrical degrees are used as the units in which angles are measured. With electrical radians the value of k would differ by the square root of $(180/\pi)$.

The factors influencing the performance of the machine are now reduced to three:—

(1) k = relative damping coefficient.

(2) P_l/P_m = ratio of the shaft load to the maximum for slowly applied load.

(3) θ_0 = angle when the exciter is connected.

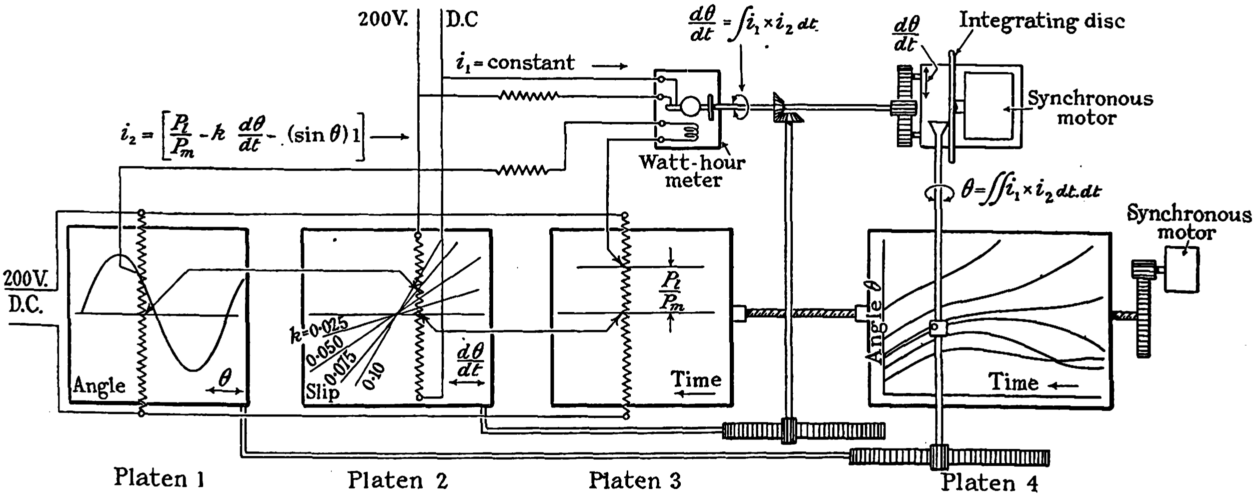

FIG. 1.—Schematic diagram of the M.I.T. integraph illustrating methods employed in solving the non-linear differential equation.

A solution of equation (2) for the angle against the dimensionless variable, t', shows how the rotor swings against time when the field is suddenly connected. The angle will either oscillate about its final steady-state value or it will continue to increase. The first type of solution indicates that the motor will synchronize, while the second shows that it will fail to pull into step.

As shown by the authors of the references that have been given, a mathematical solution of equation (2) by ordinary means is nearly an impossible task. For practical purposes many solutions are needed with different relative damping coefficients, switching angles and load ratios. Classification of these solutions would make it possible to predetermine the "pulling into step" characteristics of synchronous motors. Reduction of the solutions to the form of curves or simple equations would enable any problem connected with the pulling into step of a synchronous motor to be readily solved. For example, the minimum field current necessary to ensure that a motor with a large inertia and a certain load will always pull into step could be found.

The method of obtaining the solutions, and their practical application, are described in the succeeding sections of this paper.

INTEGRAPH SOLUTIONS.

The integraph,* produced after several years of research by Dr. Bush and others at the Massachusetts Institute of Technology, has given a method of solving the differential equation that is the basis of the pulling-into-step problem. A graphical solution of the equation is obtained as a plot of angular variation against time. From 3 to 5 minutes are required to make one solution. About 1 minute is needed between curves to "crank in the boundary conditions" and get the integraph ready for the next solution.

A diagram of the integraph is shown in Fig. 1. It consists of several platens that are free to slide. Across these are stationary potentiometers with sliding contacts that may be varied by a hand dial. Pointers indicating the positions of the contacts rest on the platens. The voltages from the potentiometers are connected together and, by the proper combination of the movements, are made to represent the values of the terms of the differential equation. A complete description of the construction and operation of the apparatus is given in the references.

Equation (2),† for solution on the integraph, is put into the integral form by transposing and integrating twice, giving

Prof. JAMES THOMSON and Lord KELVIN (then Prof. Sir William Thomson) in the *Proceedings of the Royal Society*, A (1876, vol. 24, p. 262) describe an integrating machine. On page 269 Lord Kelvin proposed "Mechanical Integration of Linear Differential Equations of the Second Order with Variable Coefficients." Present-day electrical and mechanical devices, which were not at Lord Kelvin's disposal, have made possible the construction of a practical integraph.

† L. TEPLOW solved an equation of this form on the integraph for the case of a periodically impressed torque (see *General Electric Review*, 1928, vol. 31, p. 356). Also see W. V. LYON and H. E. EDGERTON: "Transient Torque-Angle Characteristics of Synchronous Machines," *Transactions of the American I.E.E.*, 1930, vol. 49, p. 686. The latter paper dealt with the sudden-load case.

$$\theta = \int_0^{t'}\int_0^{t'}\left[\frac{P_l}{P_m} - k\frac{d\theta}{dt'} - (\sin\theta)1\right]dt'\,dt' \quad . \quad (3)$$

The integraph performs the operations indicated by the expression on the right, plotting the angular displacement as a function of t'.

The way in which this is done by the integraph is indicated diagrammatically in Fig. 1. The potentiometers over platens 1, 2 and 3 are connected in series. The voltage from the potentiometer above platen 1 is proportional to sin θ at all times because the platen moves in the same manner as the pencil recording the angular displacement on the resultant platen 4, due to the back-coupling. The person operating the integraph follows the sine curve with the pointer on the potentiometer slider. Platen 2 moves backwards and forwards under the potentiometer, its displacement being proportional to the slip, $d\theta/dt$. The value of k determines the slope of the line which the potentiometer pointer is made to follow. The voltage from this potentiometer is then proportional to the term ($k\,.\,d\theta/dt$) in the equation. The voltage from the potentiometer over platen 3 is held at a constant value proportional to the load ratio.

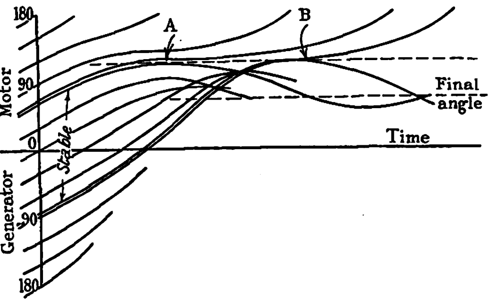

FIG. 2.—Transient angle/time curves following the connection of an exciter to a synchronous induction motor.

One of the initial conditions is that the load ratio term is equal to the slip term. The input shaft of the second integrating stage, the displacement of which is proportional to $d\theta/dt$, is initially set so that $k\,.\,d\theta/dt$ just equals the load ratio P_l/P_m, thus satisfying this initial condition. Platen 1 is set so that the potentiometer is on the initial switching angle. The pencil on platen 4 is set at θ_0 also.

When the integraph is started the pencil on platen 4 draws a line that has an initial slope which, multiplied by the relative damping coefficient, k, gives the load ratio, P_l/P_m. As the solution proceeds the influence of the sine term begins to be noticed. Its effect is to make the slope either smaller or greater as the initial angle is in the motor or generator region. The " back-coupling " moves the platens so that the angle and the change of angle with respect to time and slip are the same as those on platen 4 at all times during the solution.

The procedure used in making the solutions was to hold the relative damping coefficient, k, and the load ratio, P_l/P_m, constant, and then investigate the effects of different switching angles. The resultant solutions were of the general form, as shown by Fig. 2. For each angle at which the exciter may be connected, they show the way in which the angle subsequently varies. The initial slopes of all the curves are the same. As increasingly greater switching angles in the motor region are used, the following maximum angles reached approach a critical value, as shown in Fig. 2 at A. If, in any solution, the angle at any time reaches this critical value, it will continue to increase. Physically this means that the motor fails to synchronize during the first swing forward instead of returning to oscillate about the final steady-state angle. The critical angle, shown at A, is that which gives an unstable steady-state solution to the equation. As increasingly greater switching angles in the generator region are used an identical condition exists. The angle continues to increase instead of swinging back to the operating angle for steady-state conditions. The critical angle is the same.

From all the curves of the type shown in Fig. 2 another plot is constructed as shown in Fig. 3. The solid points are those that indicate, for the respective switching angles, that the rotor did not continue to swing forward, but that it swung back as shown by the curves (in Fig. 2) that are below the singular angle indicated by A and B. The open points are those which show that the rotor continued to swing forward. Other families of solutions similar to Fig. 2, except for different ratios of P_l/P_m, give other open and solid points in Fig. 3. The lines that are drawn are the approximate boundary of the different areas containing the points. The unstable range of angle becomes smaller as the load ratio is reduced, and finally becomes a point where the motor pulls into step for all switching angles. The angle at the point on Fig. 3 marked C is the most unfavourable angle of switching, and this point is the one of interest in this problem.

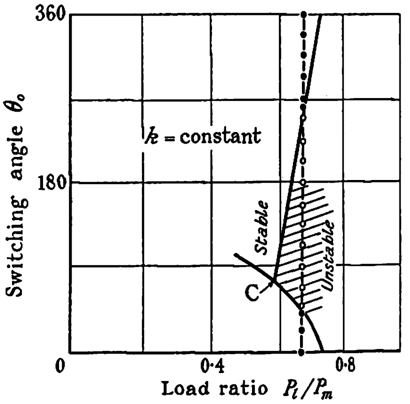

FIG. 3.—Chart for classifying switching angles and corresponding load ratios into stable and unstable regions.

The point C on Fig. 3 is now entered on the final chart, Fig. 4, together with corresponding points from other plots similar to Fig. 3, but with other relative damping coefficients. Fig. 4 is a plot of these critical load ratios against their corresponding relative damping coefficients. The determination of a single point on Fig. 4 requires many families of solutions such as Fig. 2 and then the results from these must be compiled in a curve such as Fig. 3, in order to find the point C where the load is small enough always to synchronize. Actually, however, the procedure is not as lengthy as this. After a little experience with the integraph it is quite easy to determine the important regions, A and B in Fig. 2, rather quickly, possibly from 6 to 10 solutions being sufficient to locate the boundary angle between the stable and unstable synchronizing characteristics. Four or five different values of load ratio are sufficient to determine the critical load at the point C in Fig. 3.

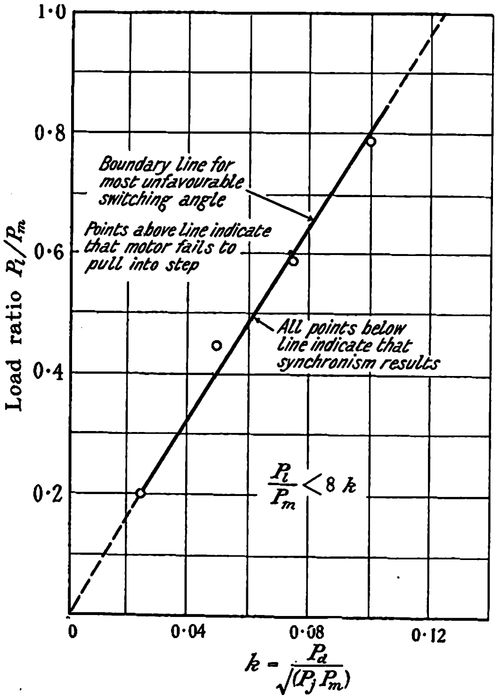

FIG. 4.—Chart for plotting the load ratio and corresponding relative damping factor for worst switching angle.

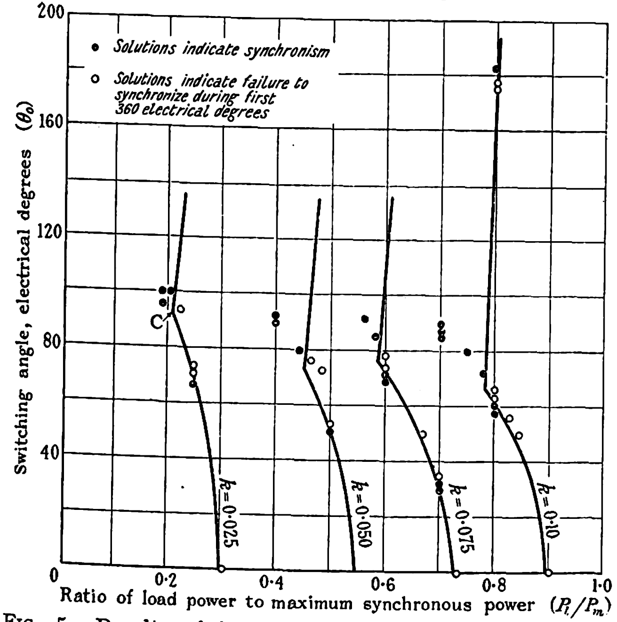

FIG. 5.—Results of integraph solutions for four relative damping coefficients.

The four points in Fig. 4 are those that were obtained by the method outlined. Fig. 5 shows the plot similar to Fig. 3, which contains the data from the integraph solutions. Only sufficient of the solutions are plotted to show how the curves bound the stable and unstable regions. If the lower part of the curve be extended upward beyond point C, it forms the boundary between two sorts of stable solutions. The region below this extension represents solutions in which synchronism is reached on the first swing, while those above correspond to synchronization after a swing of approximately 360 electrical degrees. The points in the region of switching angles from zero to 90° were the easiest to solve on the integraph. Within the limits of error of the integraph the points in Fig. 4 indicate that a straight-line relationship exists between the relative damping coefficient and the load ratio.

The following relationship then represents the " pulling into step " characteristics of synchronous motors:—

$$\frac{P_l}{P_m} < \frac{8P_d}{\sqrt{(P_m P_j)}} \quad . \quad . \quad . \quad . \quad . \quad (4)$$

The above expression, if written with an equality sign, is the equation of the straight line of Fig. 4. In words, the inequality states that the load ratio must be less than 8·0 times the indicated function of the three coefficients in order that a motor shall pull into step on the first swing. *Thus the original differential equation* (1) *represents a motor which will synchronize for all switching angles if its coefficients satisfy the condition above, i.e. expression* (4).

A more convenient form of (4) is secured by substituting in it the factors that determine the coefficients. In terms of synchronous kilowatts, electrical degrees and seconds the coefficients are:—

$$P_j = 18 \cdot 6\frac{(Wr^2)f}{p^2}10^{-6} \text{ kW/elec. deg./sec.}^2 \quad . \quad (5)$$

where Wr^2 = inertia, in lb.-ft.^{2},
f = frequency, in cycles per sec., and
p = number of poles.

$$P_d = \frac{P_l}{360\,fs} \text{ kW/elec. deg./sec.} \quad . \quad . \quad . \quad (6)$$

where P_l and s are taken from the slip-torque curve,
P_l = load, in synchronous kilowatts,
s = corresponding slip as a fraction of unity, and
f = frequency.

$$P_m = \frac{3VE}{1\,000X} \text{ kW}$$

where V = applied stator potential per phase,
E = induced stator e.m.f. per phase due to field current, and
X = synchronous reactance per phase (for a 3-phase motor).

Using the values for P_j and P_d and solving (4) for P_m gives the minimum synchronizing power that will just pull a motor into step when switching conditions are the worst.

$$P_m > 0 \cdot 0374\frac{s^2 f^3 (Wr^2)}{p^2}$$

or, since $\frac{f}{p} = \frac{n}{120}$ (n = speed in r.p.m.),

$$P_m > 2 \cdot 6\, s^2 f n^2 (Wr^2) \times 10^{-6} \text{ kW} \quad . \quad . \quad (7)$$

Knowing the characteristics of a synchronous motor, the field current that is necessary to enable the motor always to pull into synchronism may be determined.

Solving for the slip also gives a convenient form of the expression

$$s < \frac{620}{n} \sqrt{\left[\frac{P_m}{f(Wr^2)}\right]} \quad . \quad . \quad . \quad . \quad (8)$$

This gives the maximum value of slip at which the motor will always pull into step. If the induction-motor torque is not sufficient to bring the motor to the speed corresponding to this slip, the motor will fail to synchronize when the field is applied.

The previous expressions giving the conditions necessary for a synchronous motor always to pull into step are pessimistic, because they are taken for the most unfavourable switching conditions. The curves of Fig. 5 show that approximately 25 per cent more favourable synchronizing conditions result if the switching angles chance to be in the region of small angular displacement.

It must be remembered that the above solution is made on the assumption that a linear speed-torque relationship holds for the induction-motor action. This is not justified if the slip exceeds 2 or 3 per cent in most motors. The transient slip variation after the exciter is connected may easily be double the initial slip. Therefore the limiting slip equation (8) should not be taken as exact for values of slip exceeding 1·5 per cent. A margin should be allowed for cases where the initial slip is larger than about 1·5 per cent, to compensate for the change of slope of the induction-motor speed-torque curve.

NUMERICAL EXAMPLE.

This example uses the same data as those given by Carr.* These data were used also by Cotton † for two step-by-step solutions. The following calculation agrees with the two solutions given by Cotton, and shows the utility of equations (4), (7) and (8).

$\mathbf{T}_m = 2\,000$ lb.-ft.
$\mathbf{T}_l/\mathbf{T}_m = 0 \cdot 5$
$\mathbf{I} = 200$ lb.-ft.-sec. units
$(Wr^2) = \mathbf{I} \times 32 \cdot 2$ lb.-ft.^{2}
$p = 10$ poles
$s = 0 \cdot 025$ for 1 000 lb.-ft. (Cotton)
$f = 50$ cycles per sec.
$n = 600$ r.p.m.

More than sufficient data are given above. In case it is desired to find the maximum synchronizing torque in order to ensure synchronism for all conditions of switching, equation (7) gives

$$P_m > 2 \cdot 6\, s^2 f n^2 (Wr^2) \times 10^{-6} \quad . \quad . \quad . \quad (7)$$
$$> 2 \cdot 6\, (0 \cdot 025)^2\, 50\, (600)^2\, (200 \times 32 \cdot 2) \times 10^{-6}$$
$$> 188 \text{ kW}$$

so $$\mathbf{T}_m > \frac{188}{0 \cdot 746} \cdot \frac{33\,000}{2\pi \times 600} = 2\,210 \text{ lb.-ft.}$$

Thus if the field current is increased so that the maximum synchronizing torque is 2 210 lb.-ft. the motor will always synchronize. Cotton, in two step-by-step solutions, shows that with a maximum synchronizing torque of 2 000 lb.-ft. the motor will and will not synchronize if the switching angle is respectively 0 and 180 degrees. The relative damping coefficient and the load ratio can be calculated for the case used by Cotton.

$$k = \frac{P_d}{\sqrt{(P_m P_j)}} = \frac{0 \cdot 189}{\sqrt{(170 \times 0 \cdot 0598)}} = 0 \cdot 0592$$

[from equation (2a)]

since $$P_m = \frac{\mathbf{T}_m 2\pi n \times 0 \cdot 746}{33\,000} = 170 \text{ kW}$$

$$P_d = \frac{P_m(\mathbf{T}_l/\mathbf{T}_m)}{360\, fs} = \frac{170 \times 0 \cdot 5}{360 \times 50 \times 0 \cdot 025}$$
$$= 0 \cdot 189 \text{ kW/deg./sec.}$$ [from equation (6)]

$$P_j = 18 \cdot 6 \frac{(Wr^2) f}{p^2} \times 10^{-6} = \frac{18 \cdot 6 (200 \times 32 \cdot 2) 50}{10^2} \times 10^{-6}$$
$$= 0 \cdot 0598 \text{ kW/deg./sec.}^2$$ [from equation (5)]

With this relative damping coefficient of 0·0592 and the load ratio $P_l/P_m = 0 \cdot 5$, Fig. 5 may be used to show that the two points calculated by Cotton are approximately in the stable and unstable regions respectively, within the limits of interpolation and the errors of the integraph and the step-by-step calculation. This point, located on Fig. 4, is just above the boundary line in the unstable region.

In case the heating of the field definitely limits $\mathbf{T}_m$ to 2 000 lb.-ft. and the motor must always synchronize, then the load ($\mathbf{T}_l$) must be reduced until the initial slip satisfies expression (8).

$$s < \frac{620}{n} \sqrt{\left[\frac{P_m}{f(Wr^2)}\right]} = \frac{620}{600} \sqrt{\left[\frac{170}{50\,(200 \times 32 \cdot 2)}\right]}$$
$$= 0 \cdot 0238 \text{ or } 2 \cdot 38 \text{ per cent}$$

The corresponding load for this slip is 1 000 (2·38/2·50) = 950 lb.-ft. The motor will always synchronize if the load on the shaft is less than 950 lb.-ft. The two step-by-step solutions given by Cotton show that, with a load of 1 000 lb.-ft., synchronization will not result when the exciter is switched at 180 degrees.

ACKNOWLEDGMENT.

The authors wish to acknowledge many helpful suggestions during this investigation by Prof. W. V. Lyon, Dr. V. Bush and Mr. H. L. Hazen. They also wish to thank Mr. P. L. Alger of the General Electric Co. of America and Mr. H. W. Taylor of the British Thomson-Houston Co. for their helpful advice. Mr. T. S. Gray and Mr. J. B. Russell, Jun., aided in the manipulation of the integraph. Mr. Charles Gewertz, in his thesis for the degree of Master of Science from the Massachusetts Institute of Technology in 1928, gave the first integraph solutions for a numerical case. These were of great assistance to the authors in generalizing the problem.

THE RADIANT EFFICIENCY AND HEAT DISTRIBUTION OF ELECTRIC FIRES.*

By Professor S. PARKER SMITH, D.Sc., Member.

(*Paper first received 25th October, 1929, and in final form 19th February, 1930.*)

SUMMARY.

The paper details an attempt to measure the amount and distribution of the heat radiated from electric fires, employing the "Leeds" method already largely used for gas fires. A number of types of fire were tested, the radiant efficiency as measured lying generally within the limits of 55–70 per cent, with an average of about 60 per cent. The results are fairly reliable for comparative purposes, and the error in the radiant efficiency determination is probably well within 5 per cent.

INTRODUCTION.

As a converter of electric energy into heat, the electric fire may be said to have an efficiency of 100 per cent, but for many purposes it is desirable to know what part of this heat appears as radiant heat and in what manner it is distributed. This information is particularly desirable in view of the great variety of fires now on the market and the new designs developed year by year. Although it would be impracticable to test all available fires it was found that by selecting a suitable number of types a fair idea of the radiation from any given fire could be obtained. For the purposes of the test, fires were selected mainly from two large British manufacturers.

In the following tests, measurements of the radiant efficiency were taken by a modification of the "Leeds" method, which has been extensively used for measuring the radiant efficiency of gas and coal fires.

Owing to the approximate nature of some of the assumptions on which the method is based, a high degree of accuracy is not possible, but the results obtained are a sufficient guide for practical purposes.

METHOD OF MEASURING RADIATION.

The "Leeds" method for determining radiant efficiency was evolved in 1907 by a joint committee appointed by the University of Leeds and the Institution of Gas Engineers for the testing of gas fires. It has the advantage of giving both the radiant efficiency and the heat distribution. The two main assumptions on which the method rests are that all the radiant heat from the fire passes through a hemisphere, Fig. 1, which has its centre at the fire centre, and that the fire may be considered as a point source. Though neither of these assumptions is strictly correct, the errors introduced are not serious for commercial purposes. An idea of the amount of heat radiated from the back of the fire, i.e. away from the hemisphere, was obtained from measurements. These, together with other confirmatory tests, justify the neglect of this source of loss.

The underlying idea of the "Leeds" method is to determine the relation between the amount of radiation R passing through the whole area of the hemisphere and the amount r passing through the central equatorial area. This relation is called the distribution factor D, where $D = R/r$. By measuring the radiant heat h passing through the central equatorial area, the total radiant heat thrown off from the fire is then $H = h \times D$. The percentage of the energy input to the fire which this represents gives the radiant efficiency of the fire.

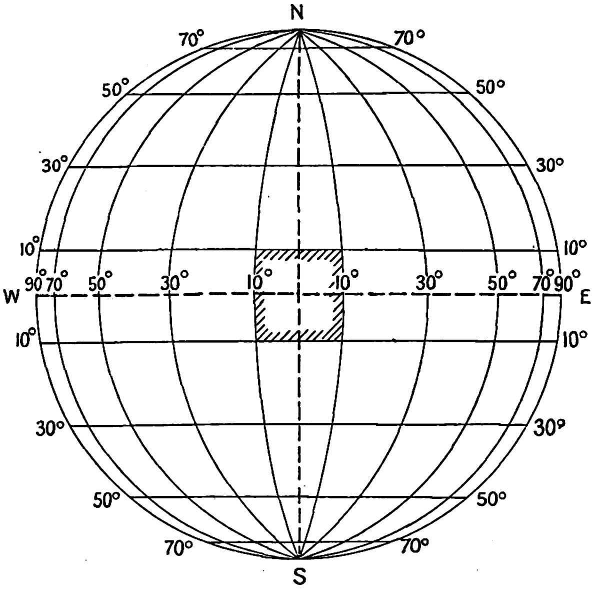

FIG. 1.—Division of hemisphere into 81 areas.

MEASUREMENT OF HEAT DISTRIBUTION.

In order to obtain the heat distribution, an imaginary hemisphere was chosen such that, when divided up by lines of latitude and longitude 20° apart, the centre equatorial area was 1 sq. ft. For this, the semi-circumference was 108 in., giving a radius of 34·4 in. The 9 lines of latitude and of longitude 20° apart divide the hemisphere into 81 areas. A thermopile in conjunction with a millivoltmeter was used to measure the heat radiated in each area. It was generally assumed that the thermopile readings taken at the centre of each area represented the mean radiant energy over that area. Particular care, however, was taken to ensure that a good approximation to the mean was obtained for the central equatorial area, a number of additional readings being taken where necessary. Since the 81 thermopile positions do not refer to the same surface area, the readings were weighted according to the area concerned, the correction factor being the cosine of the angle to the horizontal subtended by the thermopile.

---

* The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

The use of a thermopile may introduce certain sources of error. Provided that the test conditions are such that the errors affect all readings alike, the results will not be vitiated, since the thermopile readings are used solely for comparison in determining the distribution factor, etc. The chief errors may be due to:—

(*a*) *Selective Absorption of Glass Screen.*—The waveband of radiation received by the thermopile is filtered by the glass screen used for protection against air currents, so that the scale of wavelengths received by the hot junctions will differ in quality from that impinging on the screen. The effect of this would, for comparative purposes, be of no account if the radiating bodies were of the same temperature. In general, the range of temperatures of the fires tested lay within 750–900° C., as measured by an optical pyrometer. An investigation carried out on a single fire over this range showed that the distribution factor was within 2½ per cent of a constant mean value throughout. Hence the variation of distribution factor due to selective absorption is not likely to be greater than that due to other factors.

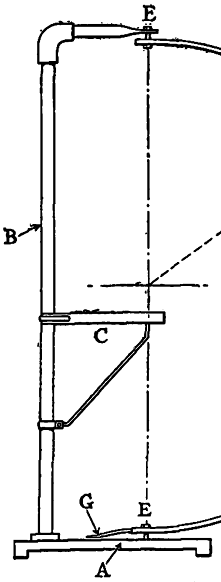

FIG. 2.—Apparatus used for taking thermopile readings.

(*b*) *Assumption of Proportionality between Radiated Energy and Thermopile Readings.*—Tests showed that over the experimental range the cold junctions maintained an even temperature; and it can be considered that practically all the radiation passing through the screen was absorbed by the black junctions for the small temperature range in question. It can therefore be assumed that the thermopile reading is proportional to the radiated energy.

After the cosine correction for variation of area with latitude had been applied, the sum of the 81 readings gave a figure H proportional to R, the total radiation passing through the hemisphere. In the same way the central reading h was proportional to r, so that the distribution factor D was found by dividing the corrected sum by the central reading. A radiometer of the Richmond type described below was used to determine the absolute value of the central thermopile reading, and this, multiplied by the distribution factor and expressed as a percentage of the energy input to the fire, gave the radiant efficiency.

DESCRIPTION OF TEST APPARATUS.

A sketch of the apparatus used for obtaining the thermopile readings is shown in Fig. 2. It consisted of a heavy cast-iron base A carrying a vertical post B to which was fitted an adjustable table C. A semicircular mild-steel hoop D was pivoted at EE so that it could move about a vertical axis. This hoop was marked off at 20° intervals. A sliding carrier F into which the thermopile fitted was attached to the hoop, the radius of the hoop being such that the elements of the thermopile were at a distance of 34·4 in. from the centre. The pointer G moved over a brass plate fixed to the base, the plate being marked off by radial lines 20° apart. Longitudinal positions of the hoop and the 9 lateral positions of the thermopile made it possible for the 81 required readings to be taken.

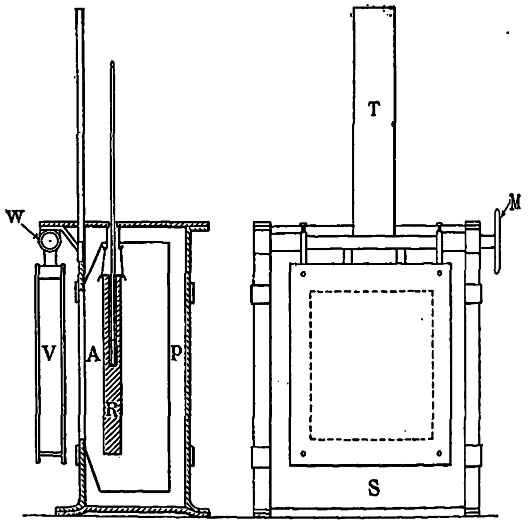

FIG. 3.—Radiometer.

The thermopile used was of the large-surface type constructed on a system devised by Dr. Moll. It consisted of 80 elements arranged in three rows in a circle of 2 in. diameter. The thermopile was mounted in a heavy brass cylinder closed on one side by an ebonite plate to which the two terminals were attached, and on the other side by a heavy brass lid into which a glass plate was fixed and which also carried a conical reflector. A polished brass disc, insulated from the body of the thermopile, was mounted at the back of the conical reflector to prevent the body of the thermopile from absorbing radiant heat. High sensitivity and rapidity of action were the features of the thermopile.

The millivoltmeter used in conjunction with the above instrument had an evenly graduated scale of 0–120 millivolts. Its resistance was 500 ohms.

A sketch of the Richmond radiometer used is given in Fig. 3. It consisted of a rectangular block of brass R, 6¾ in. × 6¾ in. × ¾ in., highly polished and having one side painted with a dull black paint. This absorbing block was suspended in an enclosure formed by a double metal case P. The air in the enclosure was maintained at a constant temperature by the circulation of a steady stream of water through the case. A polished sheet of brass S, having an opening A, 6 in. × 6 in., cut in it, was clamped to the front of the case. This opening was protected by a screen V formed by two sheets of polished brass spaced 1 in. apart, and pivoted at W so that by turning the handwheel M the screen could be removed and the blackened face of the block exposed to the source of radiation. A small hole drilled in the centre of the block along a vertical axis contained the thermometer bulb. The hole was filled with mercury to ensure good heat contact. The projecting stem of the thermometer was shielded by the vertical strip of polished brass T. The back and sides of the case were enamelled white. The thermometer was graduated in tenths of degrees C. from 10° C. to 20° C., and readings were taken by aid of a telescope.

Some difficulty was experienced in obtaining a suitable paint for the radiometer block, i.e. one which would give a dead black surface with no reflection. The paint finally employed was made from finely powdered drop-black bound with gold size. This was reduced to a thin paste by means of amyl acetate and applied to the brass block with a brush. After consulting various authorities and taking into account various sources of error, it was decided to assume an emissivity factor of unity for the blackened surface.

To avoid fluctuations of the voltage, the supply to the fires was taken from a small direct-current motor-generator set, a field rheostat being used to maintain the voltage at the required value. The input to the fire was measured on a combination voltmeter and ammeter set having substandard accuracy.

A draught-proof cubicle, approximately 9 ft. × 9 ft. in plan, was erected and all tests were carried out within this cubicle.

MODE OF CONDUCTING TESTS.

The tests were carried out in the following manner:—

The fire under test was placed on the platform, which was adjusted until the centre of the fire coincided with that of the hoop. The radiometer, with the water circulating through it, was placed in position in front of the fire, the screen being down. The distance of the radiometer from the fire was such that the centre of the brass block was 34·4 in. from the centre front of the fire. The supply was switched on and a period of time varying from ¾ hour to 1¼ hours, according to the type of fire, was allowed to elapse to ensure that conditions were steady before the readings were started.

Half-minute readings of the radiometer thermometer were then observed over a period of 6 minutes, the screen still being down. The screen was then lifted and the half-minute readings were continued for another 6 minutes. The screen was again lowered and the readings continued for a further 6 minutes.

The radiometer was then removed and the 81 thermopile readings were taken, care being taken that the thermopile was not kept too long in the regions of high intensity. At the end of the test the radiometer readings were repeated to confirm constancy of conditions.

TEMPERATURE-RISE OF RADIOMETER BLOCK.

The calculations are as follows:—

The radiometer thermometer readings are plotted to a base of time, Fig. 4. The gradient of the part AB gives the temperature-change θ_1 in deg. C. per minute before the screen is raised, while the gradient of the part DE gives the temperature-change θ_2 in deg. C. per minute after the screen is lowered. At the instant T_1 the screen is raised. The mean apparent temperature of the block at the instant T_2 when the screen is lowered is obtained by producing ED to cut in C the ordinate of time at T_2, thus giving the temperature t_2. If the temperature of the block when the screen is raised be t_1, then the apparent temperature-rise is $(t_2 - t_1)$ deg. C. In connection with this, two corrections must be considered, viz. the stem correction and the cooling correction.

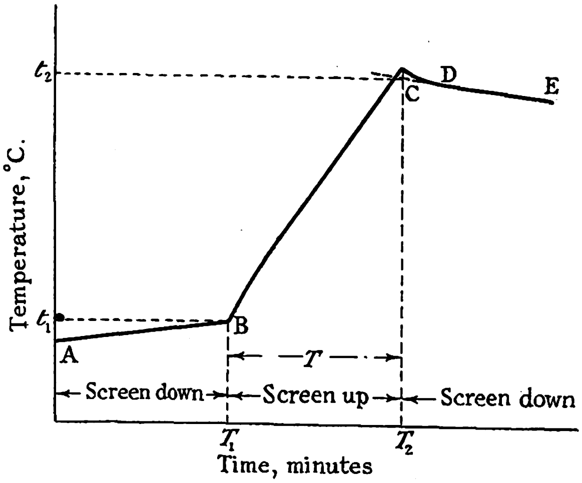

FIG. 4.—Typical temperature/time curve of radiometer block.

The *stem* correction was found in all cases to be negligible.

The *cooling* correction is applied to the apparent temperature-rise to take into account the temperature-rise of the block due to sources other than absorption by the blackened surface. If θ_1 is the temperature-rise in deg. C. per min. due to outside sources before the screen is raised, and θ_2 is the temperature-rise in deg. C. per min. after the screen is lowered, then the average temperature-rise due to such sources during the time the screen is opened is $-\frac{1}{2}(\theta_1 + \theta_2)$ deg. C. per min. The cooling correction is therefore $-\frac{1}{2}(\theta_1 + \theta_2)T$ deg. C., where $T = (T_2 - T_1)$ is the number of minutes the block is exposed.

Thus the final *corrected* temperature-rise θ_c is given by

$$\theta_c = (t_2 - t_1) - \tfrac{1}{2}(\theta_1 + \theta_2)T \text{ deg. C.}$$

HEAT ABSORBED BY THE BLOCK.

The heat passing into the block is given by $h = Ms\theta_c$ calories, where M = mass of block in grammes, including the mercury and the glass of the thermometer reduced to equivalent weight of brass, and s = specific heat of brass. The composition of the brass being known, its specific heat was found by interpolation of the values given by Griffiths and Griffiths in the "Dictionary of Applied Physics," vol. 1, p. 37. From these it was found that, between 10° C. and 20° C., $s = 0{\cdot}0918$.

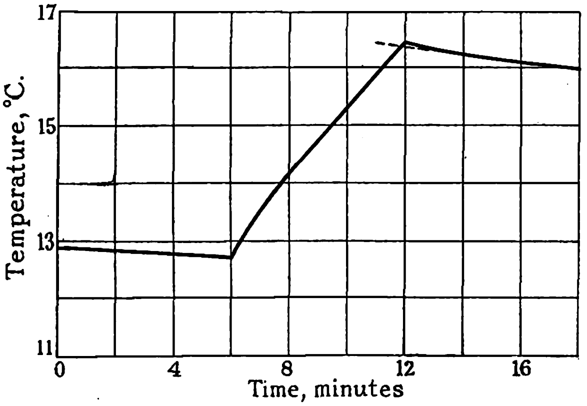

FIG. 5.—Temperature/time curve for example in Table 1.

The mass of the block was found to be 4 549·6 grammes. The equivalent weight of mercury and of glass was taken as 0·46, and the volume of mercury to fill the hole was 3·59 cm^3. Hence, equivalent weight of glass and mercury = $3{\cdot}59 \times 0{\cdot}46/0{\cdot}0918 = 18{\cdot}0$ grammes (of brass).

Thus $M = 4\,549{\cdot}6 + 18{\cdot}0 = 4567{\cdot}6$ grammes.

Since the exposed area of the radiometer block was $\frac{1}{4}$ sq. ft., the heat per square foot passing through the centre area is obtained by multiplying the heat absorbed by the block by 4. The absorption factor for the black paint used was taken as unity, as previously explained.

Thus
$$h = 4\,Ms\theta_c \text{ calories per sq. ft.}$$
$$= 16{\cdot}8\,Ms\theta_c \text{ joules per sq. ft.}$$

CALCULATION OF RADIANT EFFICIENCY.

The total radiant heat passing through the hemisphere in time $T = (T_2 - T_1)$ during which the block is exposed is

$$H = hD = 16{\cdot}8\,Ms\theta_c D \text{ joules,}$$

and the input during this period = $IVT \times 60$ joules, where I is the current and V the voltage.

Hence

$$\text{Radiant efficiency} = \frac{16{\cdot}8\,Ms\theta_c D}{60\,IVT} \times 100 \text{ per cent}$$
$$= K\frac{\theta_c D}{IVT} \times 100 \text{ per cent}$$

where K is a constant for the radiometer and is

$$K = \frac{16{\cdot}8\,Ms}{60} = \frac{16{\cdot}8 \times 4\,567{\cdot}6 \times 0{\cdot}0918}{60} = 117{\cdot}3$$

Thus

$$\text{Radiant efficiency} = 117{\cdot}3\,\frac{\theta_c D}{IVT} \times 100 \text{ per cent.}$$

ILLUSTRATIVE EXAMPLE.

To illustrate the application of the method, the results of the 3-unit fire "B" are worked out in Table 1.

Input:—Voltage = 250 volts, current = 12·0 amperes.

TABLE 1. *Illustrative Example.*

	Thermopile readings									Total	Cosine correction for variation of area	Corrected total
	To "West"					To "East"						
	80°	60°	40°	20°	0°	20°	40°	60°	80°			
80° North	5·0	7·0	8·6	10·6	11·9	11·5	10·0	8·0	6·0	78·6	0·174	13·7
60° North	9·8	22·0	36·3	44·0	47·1	45·0	38·5	25·6	12·5	280·8	0·500	140·4
40° North	15·3	40·4	61·0	74·5	79·9	77·0	64·5	44·0	18·5	475·1	0·766	365·8
20° North	14·0	50·8	73·0	84·0	88·0	85·1	75·0	54·0	17·5	541·4	0·940	508·9

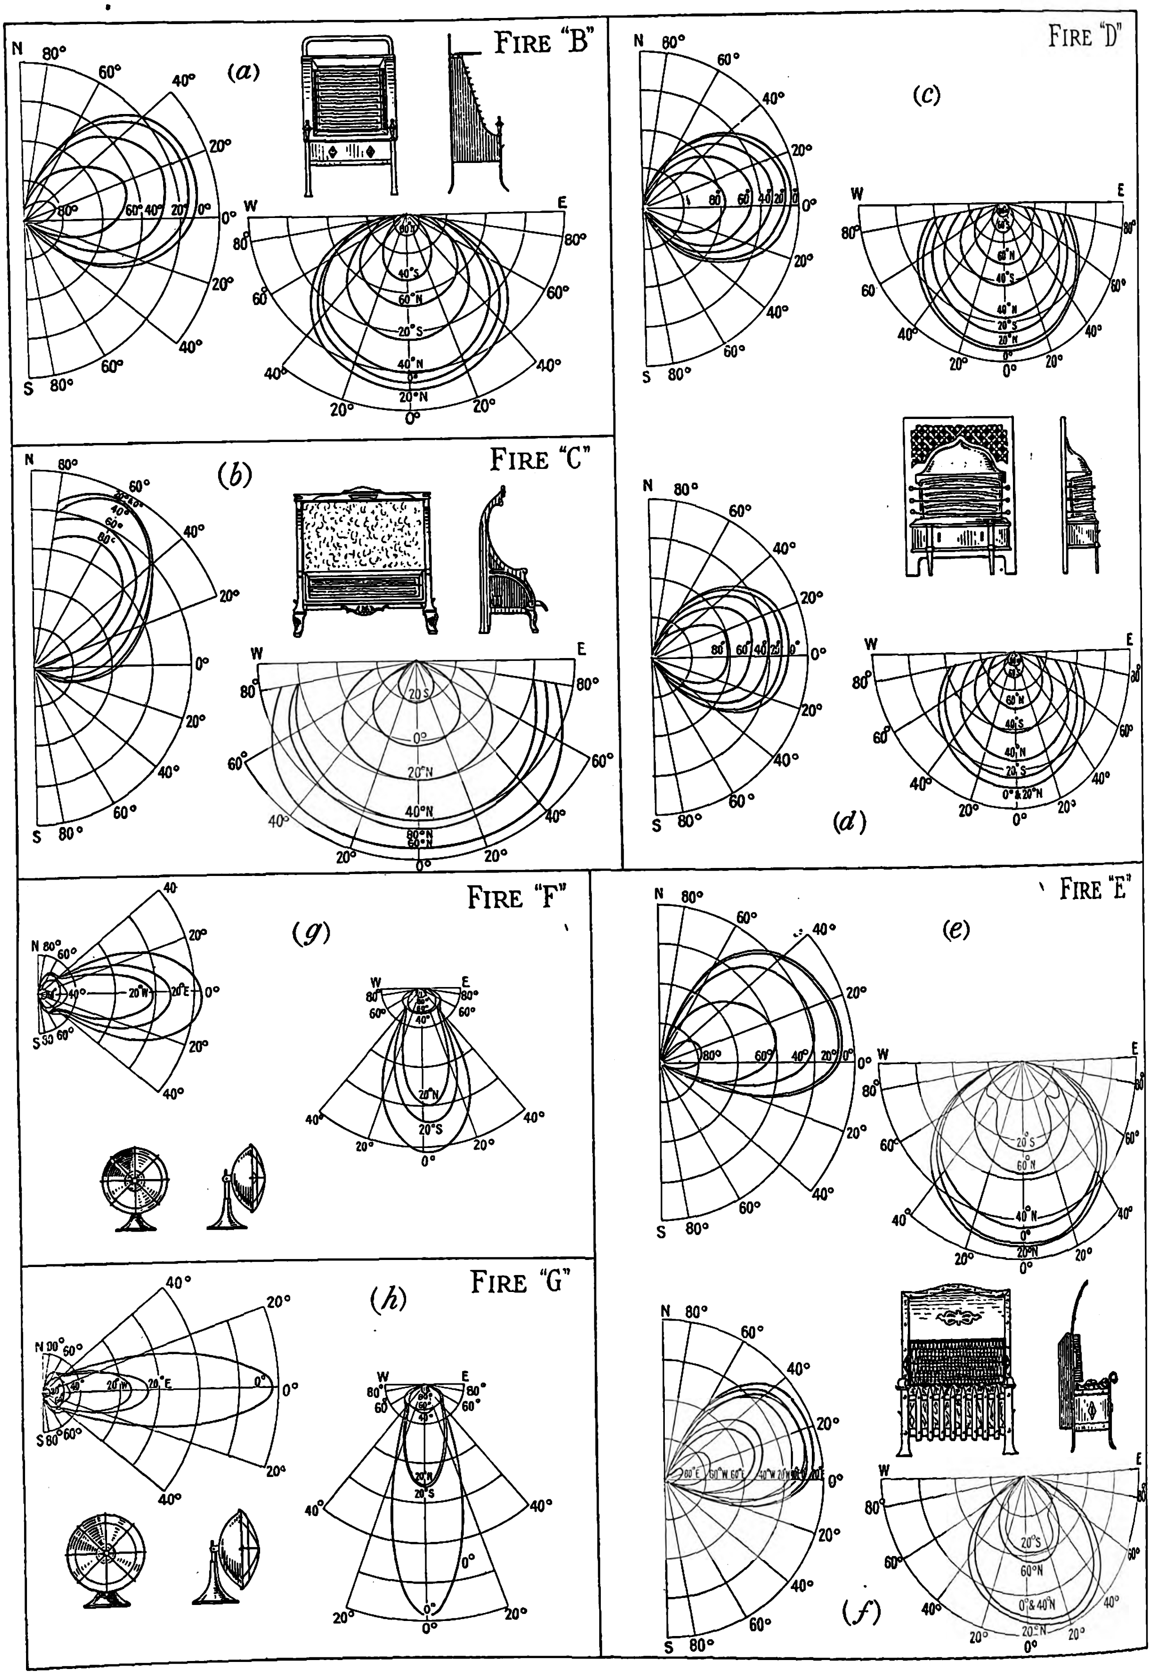

Fig. 6.—Radiant-heat distribution charts.
N–S = vertical distribution; W–E = horizontal distribution.

Cooling Correction.—The thermometer readings are plotted to a base of time in Fig. 5.

From this graph the following are obtained:—

$$\theta_1 = -0\cdot030 \text{ deg. C. per min.}; \ \theta_2 = -0\cdot062 \text{ deg. C. per min.}; \text{ time of exposure } T = 6 \text{ minutes.}$$

$$\begin{aligned}\theta_c &= (t_2 - t_1) - \tfrac{1}{2}(\theta_1 + \theta_2)T \\ &= (16\cdot37 - 12\cdot72) - \tfrac{1}{2}(-0\cdot030 - 0\cdot062)6 \\ &= 3\cdot65 + (0\cdot046 \times 6) = 3\cdot93 \text{ deg. C.}\end{aligned}$$

HEAT-DISTRIBUTION CHARTS.

Two charts were drawn for each fire—a horizontal distribution and a vertical distribution. The tabulated thermopile readings were used, curves being drawn through points in corresponding latitudes for the horizontal distribution and through points in corresponding longitudes for the vertical distribution.

SUMMARY OF RESULTS.

The results of 36 tests taken on electric fires are summarized in Table 2. All fires were tested at 250 volts. Typical examples of radiant-heat distribution have been selected for reproduction. These are shown in Figs. 6, 7 and 8. All radiometer exposures T were 6 minutes, except in tests 35 and 36, where T was 2 and 3 minutes respectively.

DISCUSSION OF RESULTS.

The results show that the radiant efficiency of various electric fires tested varies from 55 to 70 per cent, the comparatively low efficiency of 40 per cent in fire "E" being due to the presence of a particularly massive guard. When this guard is removed the radiant efficiency rises to 56 per cent. Ordinary electric fires are seen to have a radiant efficiency of about 60 per cent, while bowl types reach about 70 per cent. It is also seen that the switching off of one or more elements had not much influence on the radiant efficiency—in some cases the radiant efficiency was slightly greater, in others slightly less, than with the complete fire switched on.

It is interesting to note that the firebar element "A" —test 1—has a slightly lower radiant efficiency when mounted free than when built into fire "B" (test 2, etc.). This is no doubt due to convection, owing to the air current being less restricted.

Effect of Back Reflector Plate.—Fires "B" and "D" were fitted with back reflectors in the form of a sheet of highly polished metal fixed to the back plate of the fire and exposed to the backs of the elements. The effect on the radiant efficiency of removing this reflector is seen by comparing tests 2 and 5 and tests 11 and 12. In the first fire the radiant efficiency was reduced by 1·7 per cent and in the second by 0·4 per cent. The reflector on the first fire was fairly close up against the elements while, owing to the shape of the second fire, its reflector was a considerable distance away from the elements. This, no doubt, accounts for the difference in the effect of the reflectors. Though the reflector plate has not much effect on the radiant efficiency, the back of the fire is appreciably cooler when the plate is fitted.

Effect of Guards.—The effect of guards in front of the elements is more marked. The case has already been mentioned where the removal of a guard makes an increase of over 16 per cent in the radiant efficiency (see tests 17 and 18). This is an exceptional case; the guard consisted of an expanded-metal trellis mounted in a rectangular cast-iron frame, the trellis obscuring a considerable area of the elements. The trellis also had the effect of making the distribution unsymmetrical, since from a viewpoint about 40° E. the thickness of the metal only was visible, but from a point about 40° W. the breadth—equal to twice the thickness—was visible. Thus an object placed west of the fire only received about two-thirds of the radiation received by an object placed at a similar angle east of the fire. The heat distribution chart for this fire shows this graphically [see Figs. 6 (*f*) and 6 (*e*)]. In the other fires tested (see tests 11, 13; 21, 22; and 25, 26) the effect of the lighter guards was not so great, the increase in radiant efficiency due to the removal of the guard being of the order of 2 to 3 per cent. Any advantage gained by the addition of a back reflector is more than offset by the addition of a front guard. The design, and more especially the placing, of guard bars in front of a fire is therefore seen to be of sufficient importance to merit attention. The use of a hob is seen to reduce the radiant efficiency by about 1·6 per cent (compare tests 2 and 4).

Convection Currents.—In fire "J" (see tests 31 and 32) a lamp was placed at the head of an air passage which passed behind the elements. This was a 250-watt orange-sprayed lamp, and served to give appearance to the fire and also to induce a convection current. The backs of the elements were shielded from this current by a metal shield which was also designed to prevent any current due to the elements themselves being formed at the back. This shield was not polished. A comparison between tests 31 and 32 shows that convection due to the lamp apparently reduced the radiant efficiency by about 5 per cent, but in the complete fire it must be remembered that the lamp input has to be taken into account and its effect is considerable.

In general, it would seem that attempts at producing convection by directly increasing the amount of warmed air are not very successful, to judge from the fairly constant value of the radiant efficiency.

Bowl Fires.—Apart from the higher radiant efficiency of bowl fires, it would seem that at the normal working temperatures the radiant efficiency is not much influenced by the design. The effect of the design of the fire is seen in the radiant distribution [Figs. 6 (*g*) and (*h*)]. Since the total thermal efficiency of an electric fire as a heater is 100 per cent, and in most designs very little heat is emitted by conduction, it follows that practically all energy that is not radiated appears as convected heat.

Reflector Fires.—In the case of the two reflector fires "L" and "M" (tests 37 to 40, Table 3) it was found that a modification of the method was necessary because the intensity of radiation along the equator was so low that the resultant temperature-rise of the radiometer block was too small to be measured with any degree of accuracy. In order to estimate the efficiency of these fires the following procedure was adopted.

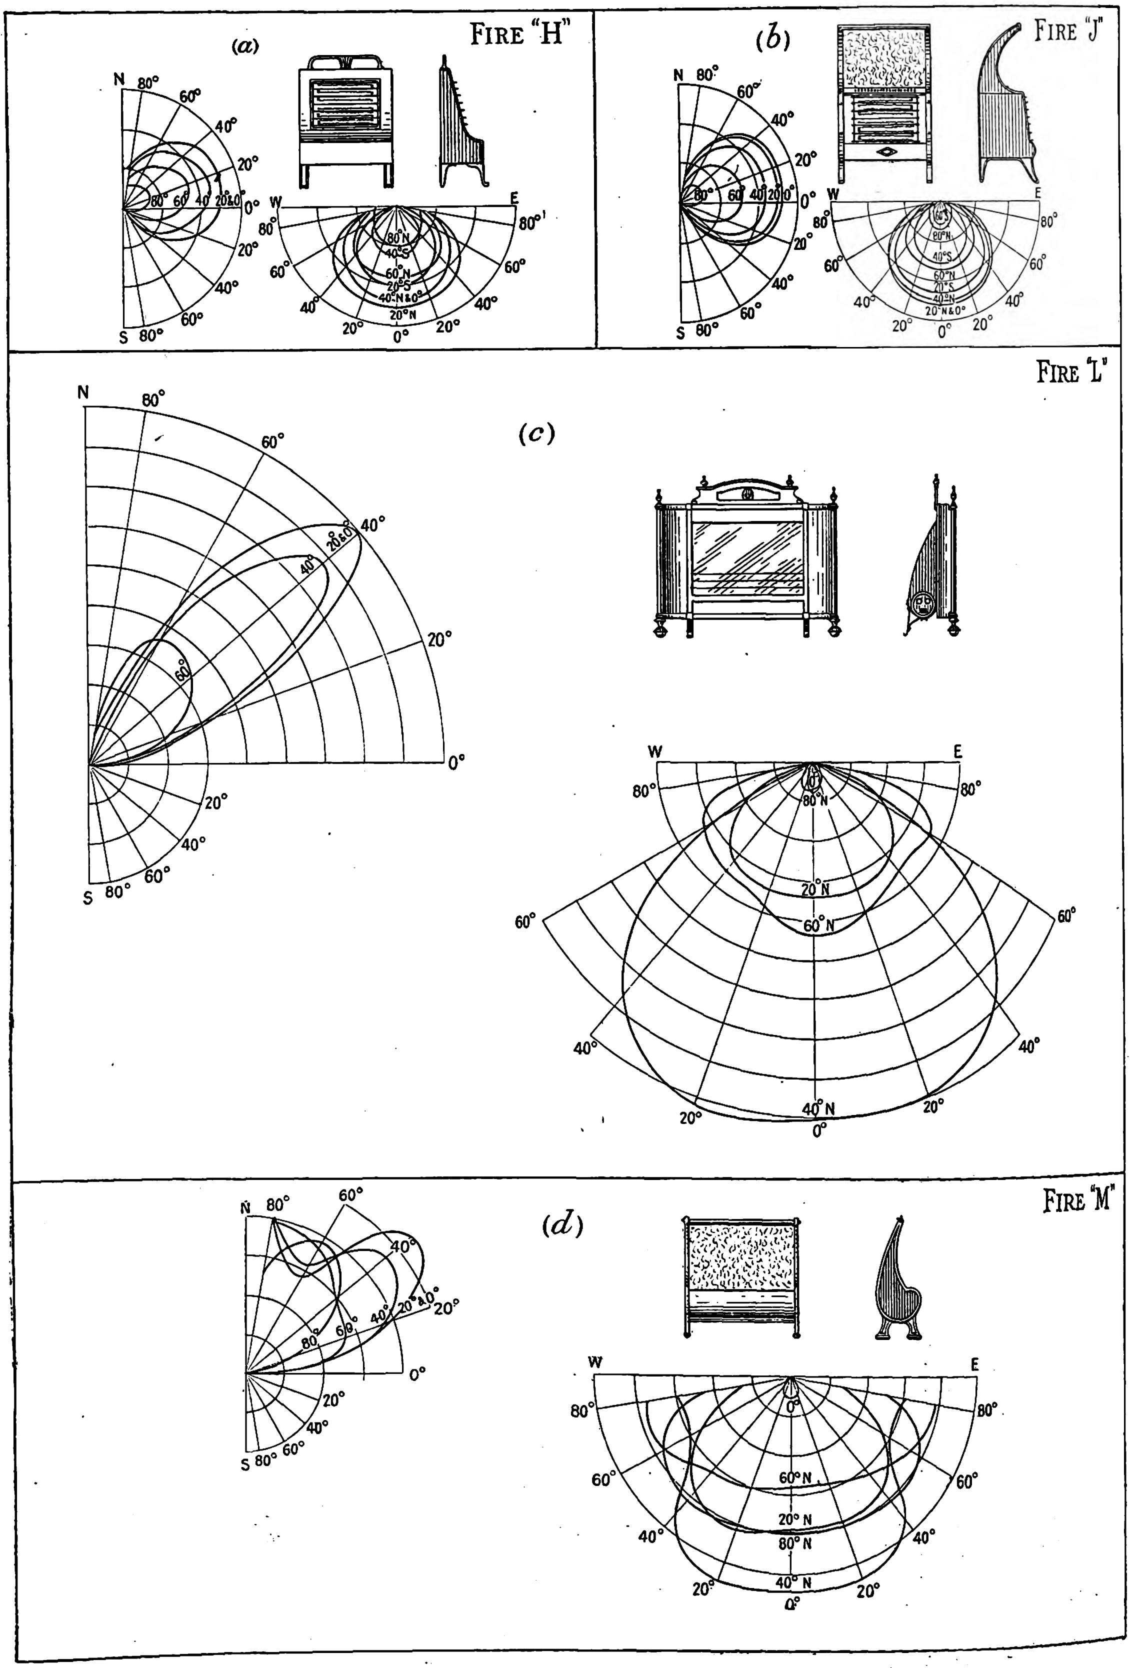

FIG. 7.—Radiant-heat distribution charts.
N–S = vertical distribution; W–E = horizontal distribution.

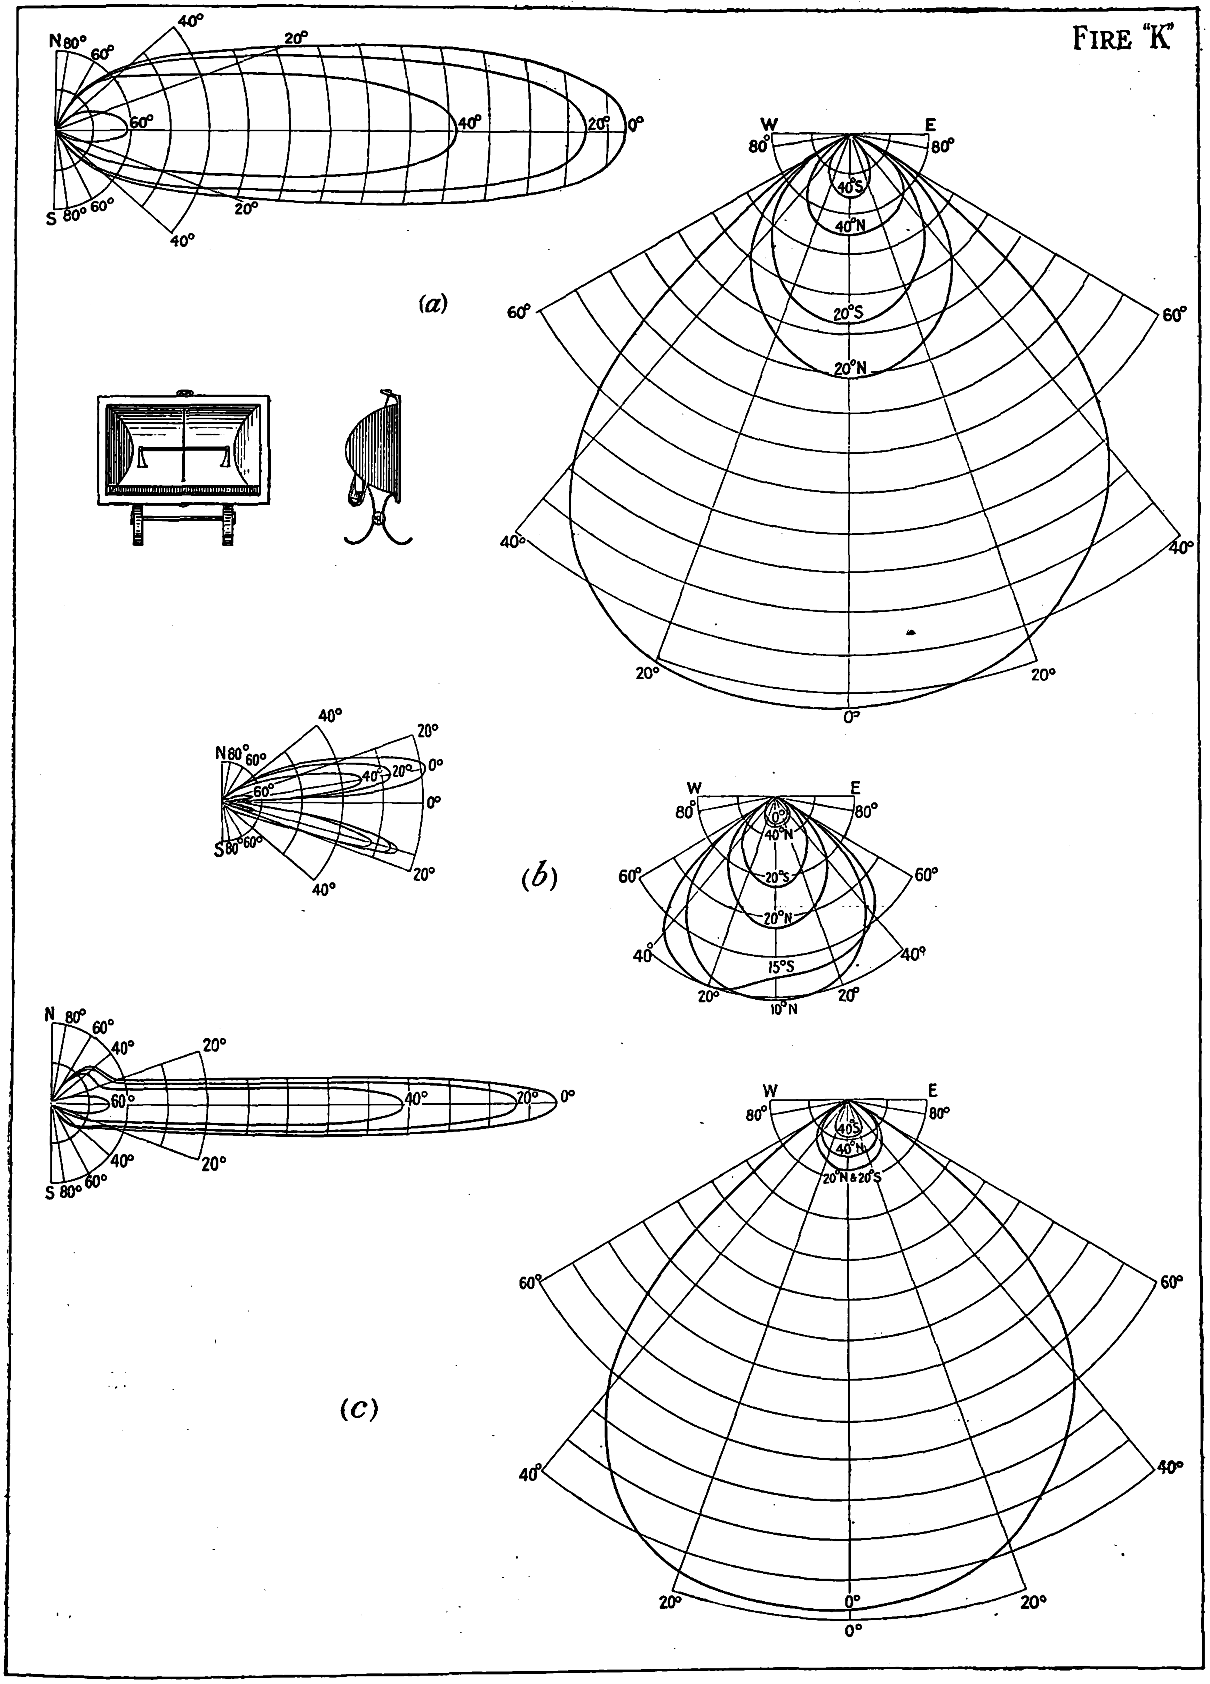

FIG. 8.—Radiant-heat distribution charts.

N-S = vertical distribution; W-E = horizontal distribution.

From the results of tested fires with fairly flat distribution curves about the "equator," an auxiliary curve was drawn of corrected temperature-rise θ_c of the radiometer block for 6 minutes to a base of central thermopile reading. This proved to be a straight line. On the distribution chart of the reflector fire an area was then taken such that the shape of the distribution curve at that area was similar to the shape of the distribution curves at the areas where the readings were taken from which the auxiliary curve was drawn. The thermopile reading h' at the centre of such an area was noted, and from the curve was obtained the corrected temperature-rise θ'_c which would have occurred in the radiometer block after 6 minutes had it been placed at that area.

The distribution factor with respect to this area is then $D' = H/(h' \times c)$, where H = total weighted sum of 81 readings and c is the cosine correction for the latitude in which the chosen area lies. The corresponding temperature-rise at the chosen area will be $c\theta'_c$ deg. C., and

$$\text{Radiant efficiency} = 117\cdot3 \times \frac{c\theta'_c \times H/h'c}{IVT}$$

$$= 117\cdot3 \times \frac{\theta'_c \times H/h'}{IVT}$$

Thus the cosine correction for latitude disappears from the final expression.

Example.—Reflector fire "M."

$$\text{Voltage} = 250\ \text{V, current} = 11\cdot5\ \text{A.}$$
$$H = 1\ 555\cdot8.$$

Taking the area at 40° N., 60° E.: $h' = 59\cdot0$.

From the auxiliary curve $\theta'_c = 2\cdot75$ deg. C.

$$\therefore\quad H/h' = 1\ 555\cdot8/59\cdot0 = 26\cdot4$$

Radiant efficiency

$$= 117\cdot3 \times \frac{2\cdot75 \times 26\cdot4}{250 \times 11\cdot5 \times 6} \times 100 \text{ per cent}$$
$$= 49\cdot5 \text{ per cent.}$$

TABLE 3.

Radiant Efficiency of Electric Fires.

			amps.		per cent	
37	L	High heat	11·9	1 482·0	45	7 (*c*)
38		Low heat	5·89	774·8	51	—
39	M	High heat	11·5	1 555·8	49	7 (*d*)
40		Low heat	5·63	740·0	52	—
41	C	Top and bottom firebars off	4·0	589·0	58	—
42		Bottom firebar off	8·0	1 070·9	53	—

* *Types of fire:* L and M = Reflector; C = Ordinary glow.

The radiant efficiency was calculated in this way for as many areas as suited the conditions, and a mean was taken.

The above method was also used to obtain the efficiencies for the two lower heats of fire "C," and the accuracy attained can be judged by comparing the efficiencies thus found (tests 41 and 42, Table 3) with that obtained by the direct method (test 9, Table 2).

In the case of the low heat of the glow-bar fire "K," Fig. 8 (*b*), it was found to be impracticable to apply this modification since no part of an available distribution chart could be found suitable for comparison with the actual distribution chart.

It would seem that reflector fires such as the first two in Table 3 convect relatively more heat than the other types of fires, and are therefore better suited where a warm current of air is needed.

RADIATION, CONVECTION AND VENTILATION.

When judging the merits of an electric fire, the radiant efficiency must not be the sole consideration. While it is true that, with ample radiant heat, a room may be comfortable with an air temperature some 10 deg. F. lower than with convected heat only, yet extremes must be avoided. On a calm, cold day with strong sunshine, it may be agreeable to sit out-of-doors, but corresponding conditions do not exist indoors—a fire does not irradiate the body like the sun. For comfort in a room heated by an electric fire, the air temperature should not fall below, say, 50 to 55° F. The fire itself should therefore provide convection air-currents in addition to those produced by objects in the room receiving direct radiant heat.

Closely connected with convection is the question of ventilation. As a general rule, the creation of a draught up a flue by placing an electric fire in an ordinary fireplace is neither satisfactory nor economical. Where possible, means should be provided for admitting cool, fresh air, while the warmed air should escape near the ceiling; but even where no special ventilating arrangements have been made it is often not difficult to obtain satisfactory results. Advantage can be taken of the fact that with electric fires draughts through windows and under doors are not so strong as with coal fires, sufficient air movement and ventilation being obtained without discomfort or stuffiness.

It is not easy to make a close comparison between electric and gas fires. The latter must be fixed below a flue, and the flue heat can be made to produce ventilation. Portability is an asset of which the electric fire has a virtual monopoly. It has been seen that the radiant efficiency of electric fires varies from 55 to 70 per cent. The deficit from 100 per cent can be considered to be due to the heat emitted by convection, and, provided a suitable scheme of ventilation be arranged, practically the whole heat of the fire can be utilized. Tests carried out by the author on 5 modern types of gas fire showed that the radiant efficiency varied from 40 to 50 per cent. Of the remaining heat a large part escapes as flue heat, the balance being convection.

More knowledge is required concerning the factors which influence radiation. The hotter the elements the greater will be the amount of heat radiated, but the precise relation between power input and radiation must be separately determined for each type of fire. For example, suppose an " element " or firebar be supported in free air and supplied with a definite power, then, according to the inclination of the face of the element, so the relative proportions of convected and radiated heat will vary. If both conduction and convection are largely prevented, as in certain cases of ceiling-panel heating, the heat must escape chiefly by radiation and the temperature must rise; whereas floor and wall panels both assist convection. Experiment has shown that raising the temperature of the elements of a fire by over-running may not increase the amount of radiation in proportion to the increased rating, on account of a more rapid increase in convection, while from the physiological point of view a very brightly glowing body is harmful to the eyes.

Experience would seem to indicate that, in the electric fires now available, practical requirements regarding both radiation and efficiency are fairly well met.

ACKNOWLEDGMENTS.

This investigation was begun 4 to 5 years ago and much preliminary work had to be done before the research proper could be commenced. The majority of the apparatus was made in the Electrical Engineering Department of the Royal Technical College, Glasgow. Valuable aid in the early measurements was given by Mr. G. Shearer, B.Sc., Mr. N. M. MacElwee, B.Sc., and Mr. J. A. Cowan. The measurements in the paper were taken by Mr. J. Sorbie, B.Sc., and it is desired to acknowledge a grant by the Institution from the War Thanksgiving and Research Fund. Much valuable criticism was obtained from members of the staff of the Research Laboratories of the General Electric Co., Wembley.

THE MEASUREMENT OF HIGH VOLTAGES, WITH SPECIAL REFERENCE TO THE MEASUREMENT OF PEAK VOLTAGES.*

By R. Davis, M.Sc., G. W. Bowdler, M.Sc., and W. G. Standring, M.A.

[From the National Physical Laboratory.]

(*Paper received* 13*th March*, 1930.)

Summary.

Two methods of measuring peak voltage have been investigated. In the one method a condenser divider is used, and the voltage on the low-voltage arm of the divider is rectified. In the other the current through a condenser connected across the voltage to be measured is rectified, and the mean current so obtained is a measure of the peak voltage across the condenser. The accuracy of the methods is considered theoretically for different wave-forms, results arrived at by the two methods are compared, and agreement to about 2 parts in 1 000 is obtained.

Introduction.

For the measurement of high voltage, i.e. voltages between 10^5 and 10^6, the sphere gap has been largely used. The flash-over value of the gap has generally been determined either experimentally by means of a third winding on a suitably designed supply transformer, or by calculation. The accuracy claimed, however, is only of the order of 1 or 2 per cent.

The design of suitable instruments for the direct measurement of high voltages provides a difficult problem. This is being studied by the Bureau of Standards, which is developing the absolute electrometer for the purpose.

Measurements would be greatly simplified by the provision of some accurate form of potential divider. For use at high voltages the usual resistance form involves great difficulty, owing to capacity troubles and the large amount of power wasted, and for very high voltages is impracticable. A capacity divider offers much less difficulty, and it is possible to design a high-voltage condenser the capacity of which can be known or measured with reasonable accuracy. In this paper the authors consider the use of a condenser divider for the measurement of effective and peak voltages.

The knowledge of the peak value of the applied voltage is of importance in insulation testing, as it is this, rather than the applied R.M.S. voltage, which determines breakdown or flash-over. This paper is consequently largely devoted to the study of two methods of measuring peak voltage. In the first method considered a fraction of the applied voltage, as obtained from a condenser divider, is rectified, thus giving a measure of the peak, and in the second the current through a condenser connected across the supply voltage is rectified and measured on a direct-current ammeter, this current giving a measure of the peak voltage on the condenser.

The Condenser Potential-Divider.

Some preliminary experiments were made to investigate the use of the condenser divider as a potential divider, using the circuit illustrated in Fig. 1. By means of the switch S the supply voltage, about 200 volts (R.M.S.), could be applied either to the resistance or the condenser divider. It was found that the electrostatic voltmeter did not always read the appropriate R.M.S. voltage $C_1V/(C_1 + C_2)$. The explanation was found to be that when the supply to the condenser divider was removed, condensers C_1 and C_2 each received a charge depending on the point in the voltage wave at which the supply was interrupted. Then if one of the condensers was discharged, or if its charge leaked away at a quicker rate than the charge on the other, the voltmeter V_2 indicated, on the re-application of the voltage to the condenser divider, the alternating voltage $C_1V/(C_1 + C_2)$ plus a steady voltage which was proportional to the difference of the charges on C_1 and C_2, at the instant of the application of V, divided by $(C_1 + C_2)$.

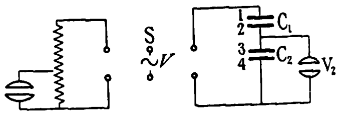

Fig. 1.

Thus, if Q be the quantity of electricity bound on C_1 and on C_2 when the supply is removed, and V_1 and V_2 be the potentials to which the condensers are raised by these charges, then $Q = C_1V_1 = C_2V_2$.

If condenser C_2 be discharged and the voltage V applied to the divider, the voltmeter connected across C_2 indicates the R.M.S. value $C_1V/(C_1 + C_2)$ plus the direct voltage $C_1V_1/(C_1 + C_2)$, since the condensers are now connected in parallel with respect to the quantity of electricity C_1V_1. This was confirmed experimentally.

The conclusion to be drawn is that the measuring arm of the condenser divider will indicate correctly the R.M.S. voltage applied to it, provided that neither condenser has an initial charge. In practice a transformer winding will be connected permanently across the divider, so that equal and opposite charges will not be bound on plates 1 and 4 of the divider system. A suitable leak connected across one arm will dissipate any charge on plates 2 and 3 and make the divider read correctly.

* The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

APPLICATION OF THE CONDENSER DIVIDER TO THE MEASUREMENT OF PEAK VOLTAGE.

The use of a thermionic valve in conjunction with an electrostatic voltmeter for the measurement of peak voltage is well known and was described * by Sharpe and Doyle in 1916. The circuit is illustrated in Fig. 2, where D represents the thermionic valve rectifier and V the electrostatic voltmeter. A condenser connected in parallel with the voltmeter acts as a reservoir for the charge passed by the rectifier, and is an essential addition to the circuit. The general principles of the method are too well known to warrant any further description here.

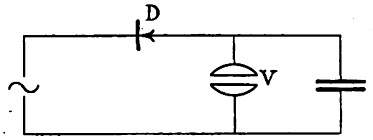

FIG. 2.

For the measurement of very high peak-voltages by this method a valve capable of withstanding twice the peak value must be used, a requirement clearly prohibitive, so that some potential-dividing device must be adopted. Fig. 3 (*a*) illustrates a circuit which might be used, in which this method of measuring peak voltage is used in conjunction with a potential divider. This circuit was investigated experimentally, and it was found that, if C_3 acquired a charge, the plates 2 and 3 of the condenser divider acquired an equal and opposite charge. This was demonstrated by removing the supply from the condenser divider, connecting electrodes 1 and 4 together to neutralize the equal and opposite charges acquired by these electrodes at the moment of switching off, and short-circuiting the rectifier D, whereupon voltmeter V_3 (and voltmeter V_2) indicated zero.

Let V_3 be the voltage acquired by condenser C_3. Then the charge on C_2 equals $-V_3C_3$ and the direct voltage acquired by C_2 equals $-V_3C_3/(C_1+C_2)$. The voltage V_3 will increase until it is equal to

$$\frac{k\,.\,VC_1}{C_1+C_2}-\frac{V_3C_3}{C_1+C_2}$$

where kV is the peak value of the applied R.M.S. voltage V. The voltmeter V_2 connected across C_2 should read, therefore, the voltage

$$\left[\left(\frac{VC_1}{C_1+C_2}\right)^2+\left(\frac{V_3C_3}{C_1+C_2}\right)^2\right]^{\frac{1}{2}}$$

and the voltmeter V_3 connected across C_3 should read

$$V_3=\frac{kVC_1}{C_1+C_2}-\frac{V_3C_3}{C_1+C_2}$$

i.e.

$$V_3\left(1+\frac{C_3}{C_1+C_2}\right)=\frac{kVC_1}{C_1+C_2}$$

i.e.

$$V_3=\frac{kVC_1}{C_1+C_2+C_3}$$

These conclusions were tested experimentally, using a voltage supply having a wave-form approximating to a sine curve in which k was assumed to be 1·41. Table 1 gives a typical result.

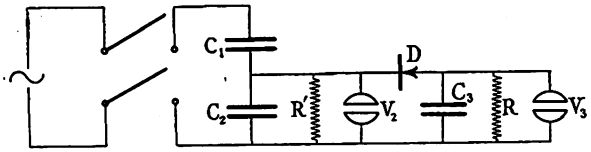

FIG. 3 (*a*)

The disagreement between the theoretical and observed values of V_3 (54·7 and 54·1) is presumed to be due to error in assuming a value for k of 1·41.

TABLE 1.

C_1	C_2	C_3	V	V_2	V_3	$\frac{1{\cdot}41\,VC_1}{C_1+C_2+C_3}$	$\left[\left(\frac{VC_1}{C_1+C_2}\right)^2+\left(\frac{V_3C_3}{C_1+C_2}\right)^2\right]^{\frac{1}{2}}$
μF 1	μF 1	μF 2	153·0	94·2	54·7	54·1	94·1

This preliminary investigation indicated the necessity for a modification of the circuit, to enable the charge built up on C_2 to be dissipated before the voltmeter V_3 could build up to the peak value. This can be done by shunting the condenser C_2 by a resistance, R′. The effect of this resistance on the divider ratio is determined from the following expression, in which V is the total voltage applied to the divider, V_2 the voltage on the measuring arm, C_1 and C_2 the high- and low-voltage arms of the divider respectively, R' the resistance across C_2, and $\omega = 2\pi \times$ frequency.

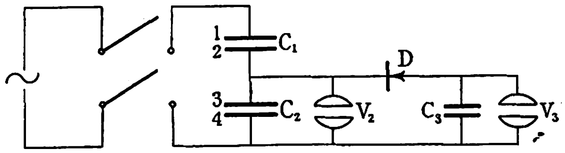

FIG. 3 (*b*).

$$\frac{V}{V_2}=\frac{C_1+C_2}{C_1}\left[1-\frac{1}{2\{\omega R'(C_1+C_2)\}^2}\right]$$

For a condenser divider for 10^6 volts, C_1 might be 10 μμF and C_2 10^5 μμF. The error introduced by a resistance of 1 megohm at a frequency of 50 cycles per sec. would be less than 3 in 10^4.

DETAILED CONSIDERATION OF THE ACTION OF THE PEAK VOLTMETER.

The necessary conditions for the peak voltmeter accurately to record the peak value of a periodic voltage wave, assuming that the charge on the measuring arm of the divider is destroyed, are:—

(1) There should be no capacity across the valve.

(2) The electrostatic voltmeter with its associated condenser should have perfect insulation.

(3) The plate-voltage/plate-current characteristic of the rectifying valve should be such that with no voltage between the plate and the negative end of the filament no plate current should flow, and for negative voltages between plate and filament no reverse current should flow.

Condition (1). *Effect of Valve Capacity, and Consideration of Values of Divider and Peak-Voltmeter Capacities.*—The capacity between the valve electrodes is negligibly small, but to one side are connected a filament battery and leads to the peak voltmeter and the peak condenser, and to the other a lead to the condenser divider. Thus the effective capacity across the valve may be appreciable and its effect must be considered.

Let K be the value of this capacity,

C_1 and C_2 the capacities of the high- and low-voltage arms of the condenser divider,

C_3 the capacity of the peak condenser,

V the applied voltage,

V_1, V_2, V_3 and V_K the instantaneous voltages on C_1, C_2, C_3, and K respectively, and

V_m, etc., the maximum values of V, etc.

When equilibrium is established the valve will no longer pass current at any time (neglecting any small current due to leakage on the peak condenser), and the various capacity currents will be those produced by the alternating voltage V in the capacity network C_1, C_2, C_3, K. Thus the voltage on C_2 will be

$$\frac{VC_1}{C_1 + C_2 + (C_3K/C_3 + K)}$$

provided that no charge is allowed to collect on C_2.

The total charge on the connected plates of C_3 and K must be constant, giving the relation

$$V_3C_3 - V_KK = (V_3)_mC_3$$

or, substituting $V_2 - V_3$ for V_K,

$$\begin{aligned} V_3(C_3 + K) &= (V_3)_mC_3 + V_2K \\ &= (V_2)_mC_3 + V_2K \end{aligned}$$

Squaring and taking mean values we obtain

$$[V_3^2]\,(C_3 + K)^2 = \left\{(V_2)_mC_3\right\}^2\left(1 + \frac{[V_2^2]}{(V_2)_m{}^2}\cdot\frac{K^2}{C_3^2}\right)$$

where the mean value is indicated by the square brackets.

Taking the square root and neglecting second-order quantities, this reduces to

$$\begin{aligned} \sqrt{[V_3^2]} &= \frac{(V_2)_mC_3}{C_3 + K} \\ &= V_m\frac{C_1C_3}{(C_3 + K)\left(C_1 + C_2 + \dfrac{C_3K}{C_3 + K}\right)} \\ &= \frac{V_mC_1}{C_1 + C_2}\left[\frac{C_3}{(C_3 + K)\left\{1 + \dfrac{C_3K}{(C_3 + K)(C_1 + C_2)}\right\}}\right] \\ &= \frac{V_mC_1}{C_1 + C_2}\left(1 - \frac{K}{C_3} - \frac{K}{C_1 + C_2}\right) \end{aligned}$$

This is the value obtained from the voltmeter reading and it shows that the use of the simple formula $V_mC_1/(C_1 + C_2)$ would involve two errors, which may be made negligible by giving the divider and peak-voltmeter capacities sufficiently large values.

TABLE 2.

Plate voltage	Plate current	
	Mullard DU.5	Osram DEP.240
volts	μA	μA
0	33·0	0·70
− 100	− 0·2	− 0·01
− 200	− 0·7	− 0·03

The two errors were investigated experimentally with various values of K, C_2 and C_3, with results closely agreeing with the formula.

If C_1 be infinite, the formula becomes $V_m\{1 - (K/C_3)\}$ and is applicable to the rectification of the whole voltage. This is in accordance with the conclusions of Paterson and Campbell.*

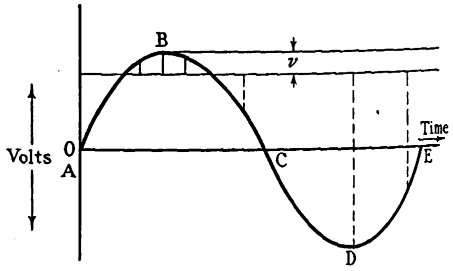

FIG. 4.—Voltage wave applied to measuring arm of capacity divider.

Conditions (2) *and* (3). *Effects of the Valve Characteristic and of the Imperfect Insulation of the Peak Condenser.*—In practice the insulation of the peak condenser is not perfect. Consequently when the peak voltmeter receives a charge a current which tends to discharge the voltmeter flows through the resistance associated with the voltmeter and its condenser.

---

* *Philosophical Magazine*, 1919, vol. 37 p. 301.

Further, the behaviour of the valve does not fulfil condition (3) above. The characteristics of two valves were investigated and the results are given in Table 2.

The characteristics of the DEP.240 valve approach more closely to the ideals required, and this valve was used for subsequent work.

When the voltmeter indicates a steady value V the net quantity of electricity passed by the valve in a cycle equals the charge dissipated via the leak across the voltmeter. If R be the value of the leak, this quantity equals $360V/R$ ampere electrical degrees (abbreviated to ampere-degrees). This equilibrium current V/R flows through the resistance R′, say, which is connected across the condenser C_2, the measuring arm of the divider. The measuring arm consequently acquires a direct voltage $(V/R)R'$ which depresses the whole of the applied voltage-wave by this amount, leading to an error of this value on the peak-voltmeter reading. The value of the resistance R' should be as small as is consistent with the expression $1/2[\omega R'(C_1 + C_2)]^2$ being negligible.

The effect on the peak-voltmeter reading of supplying the quantity 360 V/R ampere-degrees per cycle may be investigated in the following way. Let ABCDE, Fig. 4, represent the voltage wave applied to the measuring arm of the divider. Assume that the error on the peak voltmeter due to the passage of electricity through the valve is $-v$, so that the voltage on the valve at the peak of the wave is $+v$. The voltage on the valve at any other instant in the cycle can either be determined from the equation of the curve ABCDE, or graphically. From this voltage the current passing through the valve at any instant can be determined. In the figure the vertical lines indicate the voltages on the valves at different instants; the broken lines represent negative, the unbroken, positive values. A current/time curve for the valve over a period of a cycle can now be constructed, and by measuring the area of this curve the net quantity of electricity passed by the valve in a cycle can be determined. The quantity so determined is passed for an error $-v$. By repeating this process for different values of error, a curve relating the error to the quantity passed by the valve can be constructed. This relation between quantity and error for a particular rectifier is illustrated by the curves in Fig. 5 (*d*) for the case of a sinusoidal voltage-wave having maxima of 50, 100 and 200 volts, respectively.

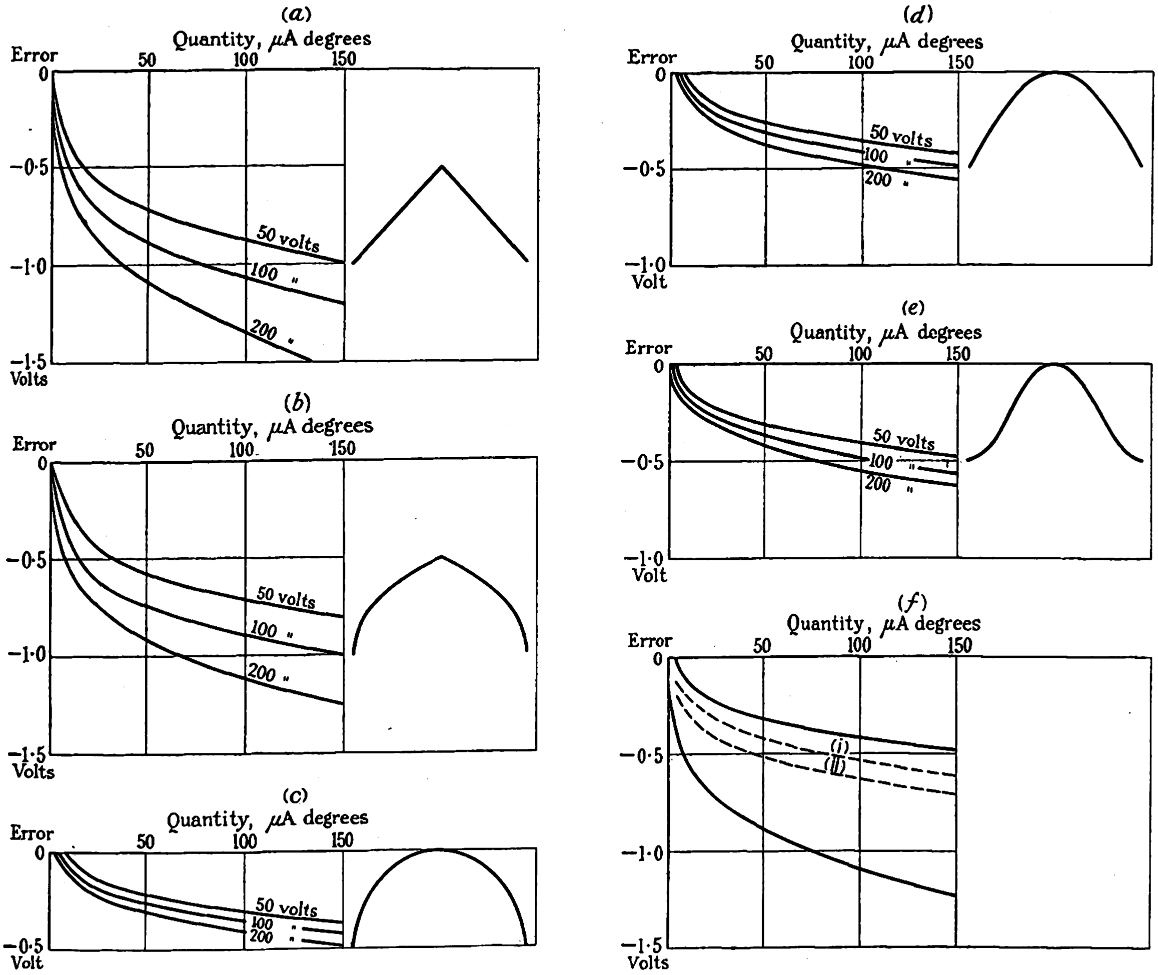

FIG. 5.—" Quantity/error " curves for a rectifier, obtained by applying various voltage waves.

In determining the quantity for different errors the quantity of electricity passed in the reverse direction has been neglected. This quantity was estimated to be about 5 microampere-degrees for an applied sinusoidal wave with a maximum of 100 volts. The effect of this constant error on the "quantity/error" curve is negligible. Further, in determining the voltage on the valve at any instant in the cycle the effect of the increase in the voltage on the peak condenser, due to the acquisition of a charge during the period of positive conduction of the valve, is negligible.

EXPERIMENTAL INVESTIGATION OF THE RELATION BETWEEN ERROR AND PEAK-CONDENSER LEAKAGE.

An Osram 3-electrode valve working at a filament current of 0·4 ampere (the condition under which the valve was calibrated) was used in the tests. The plate and the grid of the valve were connected, and the plate voltage was applied between the plate and the negative end of the filament. The circuit diagram is illustrated in Fig. 3 (*b*). The condensers C_1, C_2 and C_3 were of nominal capacities, 1·0, 1·0 and 2·0 μF, respectively. The value of the resistance *R′* was 0·1 megohm, and the error on the divider due to this resistance was less than 2 in 10^4. R consisted of sealed liquid resistances which were constant in value for voltages up to 1 000.

TABLE 3.

V_2	V_3	R	$360\frac{V_3}{R}$	Error due to quantity $360\frac{V_3}{R}$	Error $\frac{V_3}{R}R'$	E_2
volts	volts	megohms				volts
69·25	100·5	5 500	6·6	0	0	100·5
69·25	99·5	63	570	−0·8	−0·2	100·5
69·25	99·4	46	780	−0·9	−0·2	100·5
69·25	99·2	35	1 020	−1·0	−0·3	100·5
69·25	98·8	22	1 616	−1·2	−0·5	100·5
69·25	98·5	14	2 530	−1·4	−0·7	100·6
69·25	97·5	7	5 015	−1·8	−1·4	100·7

The peak voltage of a supply, the wave-form of which approximated to a sine curve, was determined for different quantities of electricity passed by the valve per cycle. The variation in the quantity was obtained by varying the value of *R*. Let V_3 be the equilibrium voltage on the peak voltmeter. On removing the supply voltage the peak condenser begins to discharge via the resistance R. By timing the rate of loss of charge the value of *R* can be determined by the well-known condenser leak method. Then the quantity of electricity passed per cycle by the valve is $360\ V_3/R$ microampere-degrees, where V_3 is in volts and *R* in megohms. The error for this quantity can then be determined from one of the curves in Fig. 5, or by interpolating between two of the curves if the maximum of the wave under examination lies between 100 and 200 volts or between 50 and 100 volts.

The error due to the direct-current charge on the condenser divider is $-\ (V_3/R)R'$.

The results obtained are given in Table 3, where

V_2 = R.M.S. voltage on condenser C_2 (volts),
V_3 = peak voltmeter reading (volts),
R = resistance in parallel with C_3 (megohms),
R' = 0·1 megohm,
E_2 = corrected peak voltage.

The agreement as shown in the last column is sufficiently close to justify the considerations on which the corrections are based. They would also indicate that the errors given in the fifth column apply closely to waves which are not accurately sine waves. The ratio of the peak value to the R.M.S. value, for the wave-form used in the test, works out to be $1{\cdot}45_0$ instead of 1·414—the value of this ratio for a sine curve. Further consideration will be given to the question of wave-form in the next section.

EFFECT OF WAVE-FORM.

The relation between the quantity of electricity passed by the rectifier and the error in the peak-voltage reading has been theoretically determined for the following voltage waves, which are illustrated in Fig. 5:—

$$(a)\ \begin{cases} e=E\left(\frac{4}{T}\right)t \text{ from } t=0 \text{ to } t=\frac{1}{4}T \\ e=E\left(\frac{4}{T}\right)\left(\frac{T}{2}-t\right) \text{ from } t=\frac{1}{4}T \text{ to } t=\frac{1}{2}T \end{cases} \qquad \frac{E}{V}=1{\cdot}732$$

$$(b)\ \begin{cases} e=E\left(\frac{4}{T}\right)^{\frac{1}{2}}t^{\frac{1}{2}} \text{ from } t=0 \text{ to } t=\frac{1}{4}T \\ e=E\left(\frac{4}{T}\right)^{\frac{1}{2}}\left(\frac{T}{2}-t\right)^{\frac{1}{2}} \text{ from } t=\frac{1}{4}T \text{ to } t=\frac{1}{2}T \end{cases} \qquad \frac{E}{V}=1{\cdot}414$$

$$(c)\ e=E\sin^{\frac{1}{2}}\frac{2\pi}{T}\cdot t \qquad \frac{E}{V}=1{\cdot}252$$

$$(d)\ e=E\sin\frac{2\pi}{T}\cdot t \qquad \frac{E}{V}=1{\cdot}414$$

$$(e)\ e=E\sin^2\frac{2\pi}{T}\cdot t \qquad \frac{E}{V}=1{\cdot}633$$

in which

e = instantaneous value of the voltage,
V = R.M.S. value of the voltage,
E = maximum value of the voltage,
t = time,
T = periodic time.

The negative half of the wave is supposed to be similar to the positive half.

The quantity/error curves have been constructed for values of *E* of 50, 100 and 200 volts, respectively. These are illustrated by the curves in Fig. 5. The shape of the wave has been illustrated in each case.

From these curves Table 4 has been constructed showing the relation between the leak across the peak condenser and the error in the peak-voltmeter reading, for the voltage waves given by equations (*a*) to (*e*).

Table 4 shows that when the leakage resistance across the condenser is high (5 000 megohms or more) the error in the worst case is only about 0·5 per cent. In practice it will be almost impossible to realize this worst possible case—that of a triangular wave with a definite point at the peak. Excluding this case, therefore, the uncertainty in the peak-voltmeter reading is only of the order of 0·2 per cent for the family of curves dealt with above.

In the case of wave-shapes which are irregular the shape near the crest alone is of importance. Thus, for waves with subsidiary peaks, these peaks will not affect the error appreciably unless they are within 0·5 per cent of the maximum of the highest peak, for otherwise they occur in that portion of the cycle when the valve is non-conducting.

For any given voltage wave a curve connecting quantity and peak-voltmeter reading can be determined experimentally. By comparing the shape of this curve with that of the quantity/error curves in Figs. 5 (*a*) to 5 (*e*), and by comparing an oscillogram with the corresponding wave-forms, it is possible with some reliability to convert the experimental curve into a quantity/error curve. An illustration of this is given in Fig. 5 (*f*). Curves (i) and (ii) are experimental ones inserted between curves for a sine wave and a triangular wave. Figs. 6 (*a*) and 6 (*b*) are oscillograms of the corresponding voltage wave-forms. The errors appear to be nowhere more than 0·2 per cent different from those associated with a sine wave-form. For a sharp but rounded peak the shape of a sine wave with the time scale reduced 20 times the errors would be approximately the same as for a triangular wave. Thus most voltage supplies should be measurable to 0·5 per cent and, with sufficient care, to 0·1 or 0·2 per cent.

TABLE 4.

SUMMARY OF ERRORS IN THE CONDENSER-DIVIDER METHOD OF MEASURING PEAK VOLTAGE.

Using the nomenclature of Fig. 3 (*b*) and calling the peak-voltmeter reading V_3, the following are the errors in the peak-voltmeter reading:—

(1) The shunting effect of R' on C_2 introduces an error

$$-V_3\frac{1}{2[R'\omega(C_1+C_2)]^2}$$

(2) The capacity (K) across the valve introduces errors

$$\text{(i)}\ -V_3\cdot\frac{K}{C_1+C_2}\quad\text{and}\quad\text{(ii)}\ -V_3\cdot\frac{K}{C_3}$$

(3) The leakage resistance (R) across the peak condenser introduces

(i) an error $-V_3\cdot\dfrac{R'}{R}$

and (ii) an error depending on V_3, on the valve characteristic and on the wave-form of the supply voltage.

All these errors can be determined when accurate measurements are required, or the circuit may be so arranged that most of them are negligible.

For satisfactory working R must not be too large, or the peak voltmeter will not respond to a drop in the supply voltage. The response depends on the product RC_3. To reduce errors 2 (ii) and 3 (i), however, it is desirable to have both R and C_3 large. If the various errors are each to be limited to, say, 1 part in 1 000 then C_3 must be 1 000K, $C_1 + C_2$ must be 1 000K, R' must be 1 000R, and $2[R'\omega(C_1 + C_2)]^2$ must be 1 000. These conditions dispose of all the errors except that depending on the valve characteristic. The Osram DEP.240 has been found to be a satisfactory type of valve, but from the curves in Fig. 5 it may be seen that, if the leakage resistance R is not sufficiently high, there may be an appreciable error. For example, if V_3 be 50 volts and R be 120 megohms (corresponding to 150 microampere-degrees), this error is 0·8 per cent.

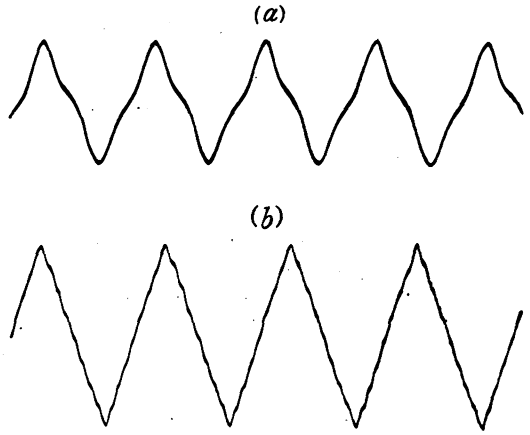

FIG. 6.

The results of some measurements at high voltages by the two methods described in this paper are compared later. In the voltage rectification method the values of C_1, C_2, etc., were C_1 = from 10 to 45 $\mu\mu$F, $C_2 = 0{\cdot}2\ \mu$F, $C_3 = 0{\cdot}2\ \mu$F, K = (about) 100 $\mu\mu$F, R = 6 000 megohms, and R' = 1 megohm.

Here the error involving the valve characteristic was only about 1 in 1 000. All the other errors together came to a similar amount.

THE MEASUREMENT OF PEAK VOLTAGE BY RECTIFICATION OF A CONDENSER CURRENT.

In this method of measuring peak voltage, which was described by Chubb and Fortescue,* the voltage is applied to a condenser in series with a pair of diode rectifiers connected in parallel. The rectifiers are so arranged that one of them carries the positive, and the other the negative portion of the current. A d.c. microammeter or galvanometer measures the current flowing through either of the rectifiers. The circuit is illustrated in Fig. 7, where the switch S may be connected to either terminal of the microammeter A.

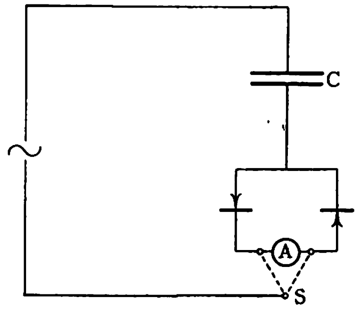

FIG. 7.

If the impedance of the rectifiers be small compared with that of the condenser the current i is given by the equation $i = C(de/dt)$, where e is the instantaneous circuit voltage and C is the capacity of the condenser.

Then in a cycle the total charge flowing through each rectifier is $\int idt = C\int de$, where the integration is carried out over that part of the cycle for which de/dt is positive in the case of one rectifier, and negative in the case of the other. For a sine wave of voltage in which $e = E \sin 2\pi ft$, f being the frequency, the charge flowing through each rectifier in a cycle is $2\pi fCE\int_{3/(4f)}^{1/(4f)} \cos 2\pi ft\,.\,dt$, which equals $2CE$. The mean current at a frequency f is consequently $2CEf$.

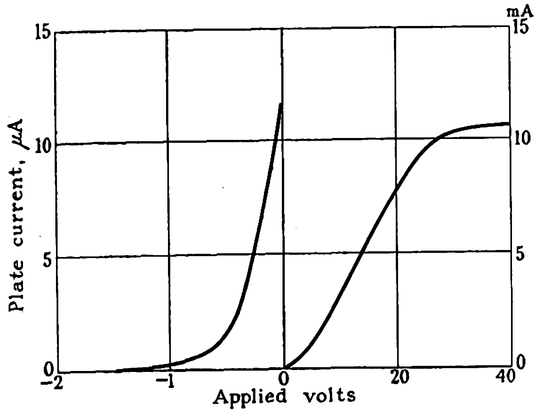

FIG. 8.—Characteristics of rectifying valves.

For a sine wave of voltage the method will give the true peak voltage provided that:—

(1) The impedance of the rectifier is negligible compared with that of the condenser.

(2) All the positive current passes through one rectifier and all the negative through the other.

(3) The measuring instrument (ammeter or galvanometer) correctly indicates the mean current.

The conditions (1) and (2) are controlled by the characteristics of the rectifying valves. These are illustrated by the curves in Fig. 8, where the current and voltage scales are magnified for negative values of applied voltage in order to reveal the point on the characteristic at which the valves were used. Three-electrode valves were used, and the grid and plate were connected together.

At the instant when the condenser current is zero, the voltage on the valve is zero, for which voltage the rectifier current is 11 μA. Consequently the valve will pass a quantity of electricity greater than that passed by the condenser. The error due to this can be reduced to negligible proportions by so arranging the circuit that at zero condenser-current the voltage on the valves shall be negative and not zero. For the present tests the connections to the filament circuits of the valves were made at points 1 volt negative with respect to the negative ends of the filaments.

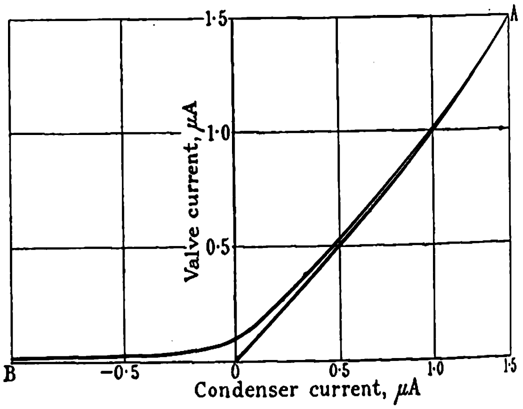

FIG. 9.—Curve showing relation between current through one valve and condenser current.

From the valve characteristic a curve showing the relation between the current through one valve and the condenser current can be derived. This is illustrated in Fig. 9. Condition (2) assumes that the relation is represented by the lines OA and OB. Only the region near zero condenser-current is drawn, for as the condenser current increases the excess of the valve current over the condenser current gets smaller. From a value of about 1 μA up to about 10 mA, which is the saturation current of the valve, the difference between the two is indistinguishable. The error introduced in the case of a sine wave of condenser current can be determined quantitatively as follows:—

Let $i = I \sin \theta$ represent the condenser current. When i is small

$$i = I\theta$$

---

* *Transactions of the American I.E.E.*, 1913, vol. 32, p. 739.

Let i_1 = the excess current through the galvanometer at any instant.

The total excess in a cycle = $\int i_1 d\theta$, where the integration is carried out over the cycle.

$$\int i_1 \,.\, d\theta = \frac{1}{I} \int i_1 \,.\, di$$

The value of $\int i_1 \,.\, di$ as determined from the valve characteristic was equal to 0·14 (microamperes)^2.

$$\text{The true quantity} = \int_0^\pi I \sin \theta d\theta = 2I.$$

Hence the error = $0 \cdot 14/(2I^2)$, where I is in microamperes.

For an error of 1 in 1 000, I equals 8·4 μA, which is equivalent to a mean current in the galvanometer of 2·7 μA, a low value which can easily be exceeded in practice. For example, 10^6 volts will supply, through 1 $\mu\mu$F, about 140 μA at 50 cycles.

The impedance of the rectifiers is of the order of 10^4 ohms, so that for a current of 200 μA the voltage-drop on the rectifiers is 2. As this is in quadrature with the voltage on the condenser, for a voltage of 50 on the latter the error due to the valve impedance is less than 1 in 1 000.

The microammeter used was a moving-coil instrument of the pointer type and was calibrated with direct current. A similar instrument was calibrated with rectified alternating-current by comparison with measurements made with a potentiometer and a differential galvanometer.* In no case did the calibration differ from that on direct current—even when the frequency was raised to 4 000 cycles per second—by more than 1 part in 1 000. Consequently condition (3) may be regarded as being accurately fulfilled. In some later measurements the current was measured on a potentiometer instead of the microammeter, in order to obtain greater sensitivity.

THE EFFECT OF WAVE-FORM.

Since the charge flowing through the rectifier equals $\int C \,.\, de$, where the integration is taken during the cycle when de/dt has one sign only (positive for one rectifier and negative for the other), the average current in the galvanometer for the wave-shape of applied voltage illustrated in Fig. 10 (*a*) would be proportional to $E_1 + E_2$, and for the wave-shape illustrated in Fig. 10 (*b*) it would be proportional to $E_1 + E_2 + E_1' + E_2'$. Therefore for wave-shapes having different positive and negative peaks this method would only give the average. For waves with subsidiary peaks, since the method gives only one relation between the quantities E_1, E_2, E_1', E_2', it will not avail to determine E_1 and E_2.

It is concluded that the method of measuring peak voltage by the valve rectification of a condenser current is satisfactory for all wave-shapes with the exception of (1) wave-shapes with different positive and negative maxima, and (2) wave-shapes with more than one peak in each half-cycle.

To ascertain whether the peak value of a given voltage wave can be determined by this method the wave-shape can be examined visually by means of oscillograms. The electrostatic oscillograph has been found useful for this purpose.

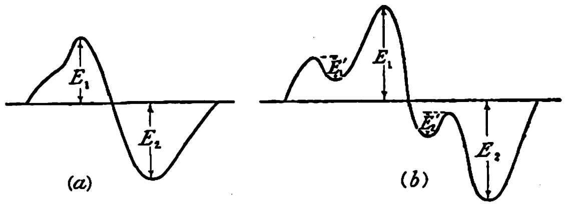

FIG. 10.—Wave-shapes of applied voltage.

COMPARISON OF RESULTS OBTAINED BY THE TWO METHODS.

Tests were made to compare the results obtained by the two methods described in the previous sections. The condenser used in the current rectification method constituted the high-voltage arm of the divider, so that any uncertainty in the absolute value of the capacity was common to the two methods. The apparatus was so arranged that by means of a switch the low-voltage plate of this condenser could be connected either to the low-voltage arm of the divider or to the current-rectifying apparatus. This connecting lead was shielded, and its capacity together with that of the electrostatic voltmeter across the low-voltage arm of the divider, etc., was taken into account in determining the capacity of this arm. The current in the current-rectification method was measured on a potentiometer.

The results obtained by the two methods are given in Table 5.

TABLE 5.

Capacity of high-voltage condenser	Capacity of low-voltage condenser	Peak voltage by:—	
		Voltage rectification	Current rectification
$\mu\mu$F	μF	kV	kV
45·30	0·2011	$213\cdot_{2}$	$213\cdot_{4}$
29·91	0·2011	$279\cdot_{0}$	$278\cdot_{5}$
25·51	0·2011	$426\cdot_{3}$	$426\cdot_{5}$
18·52	0·2011	$694\cdot_{5}$	$695\cdot_{0}$
10·07	0·2011	101_{9}	101_{9}
10·07	0·2011	118_{4}	118_{1}

Peak-condenser capacity = 0·2 μF.

Table 5 shows that the agreement between the methods is of the order of 0·2 per cent. This agreement is very satisfactory as important sources of error in the current rectification method would tend to make the reading high, whereas the errors in the other method would generally tend to make the reading low. It does not, however, necessarily signify a corresponding accuracy in the absolute values of the peak voltage measured, as the high-voltage condenser used was incompletely shielded and was affected by the stray capacitance to high-voltage conductors, etc., in the building.

---

* G. W. BOWDLER: *Journal of Scientific Instruments*, 1930, vol. 7, p. 151.

CONCLUSION.

The result of the work shows that under suitable conditions and with proper precautions an accuracy of the order of 1 or 2 parts in 1 000 is obtainable in the measurement of peak voltages up to 10^6, by the rectification of voltage from a condenser divider or by the rectification of the charging current of a condenser.

The authors wish to thank Dr. E. H. Rayner, M.A., D.Sc., Member, for the interest which he has taken in the work.

DISCUSSION ON

"SUMMARY (TO 1925) OF EUROPEAN AND AMERICAN DATA ON INTERFERENCE BETWEEN POWER AND COMMUNICATION CIRCUITS.*

Mr. R. K. Honaman (*communicated*): In the discussion of acoustic shocks, notably on page 590 and again on page 599, it is pointed out that acoustic shock arises when only one of the two voltage discharge-gaps associated with a metallic circuit is operated by induction, or when one of the two discharge-gaps operates in advance of the other. While such a condition would undoubtedly result in acoustic shock, it would be of interest to point out that the occurrence of acoustic shock does not necessarily require this difference in time of initiation of the discharges on the two sides of the line. The protectors used on telephone lines in the United States are air discharge-gaps between carbon electrodes. Even if the discharge of these gaps takes place at the same instant—and in most cases this is true at least within an extremely small fraction of a second—nevertheless the discharge characteristics of the gaps on the two sides of the line are not symmetrical, that is, there is a difference in the impedance of the discharge path while currents are passing. This dissymmetry in the discharge impedances gives rise to the voltage between wires which most commonly causes acoustic shock. Inasmuch as this dissymmetry lasts during the entire interval while the discharge is taking place, the acoustic shock also lasts for the same interval. Contrary to a belief commonly held, the effect of this time on the intensity of acoustic shock is important. While the so-called "initial crack" is usually very severe, the prolonged effect of the shock through the interval while the gaps are discharging is also very important. Much effort has been expended in an endeavour to provide spark-gaps which would combine adequate protection for the circuits with features providing for symmetry of discharge of two units. It has not been found practicable, however, up to the present time to modify the gaps in any way to reduce substantially this dissymmetry in the discharge impedances, without at the same time making unjustifiable sacrifices in the protective characteristics of the over-voltage protectors.

PROCEEDINGS OF THE INSTITUTION.

797TH ORDINARY MEETING, 9TH JANUARY, 1930.

Colonel Sir Thomas F. Purves, O.B.E., President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 19th December, 1929, were taken as read and were confirmed and signed.

The President announced that the Council had elected Sir Richard T. Glazebrook, K.C.B., D.Sc., F.R.S., Past-President, an Honorary Member of the Institution.

The following list of donors to the Library was taken as read, and the thanks of the meeting were accorded to the donors.

Donors to the Library.—American Institute of Electrical Engineers; American Telegraph and Telephone Co.; The Astronomer Royal; Messrs. Blackie and Son, Ltd.; D. J. Bolton, M.Sc.; British Engineering Standards Association; British Insulated Cables, Ltd.; Cable Research; Cambridge University Press; Canadian Engineering Standards Association; Central Electricity Board; Messrs. Crosby Lockwood and Son; Department of the Interior, Canada; A. T. Dover; Captain P. P. Eckersley; Electricity Commissioners; J. J. Fahie; The Fanfare Press; Franklin Institute; E. Garcke; B. Hague, D.Sc., Ph.D.; Industrial Transport Publications, Ltd.; Prof. A. E. Kennelly, D.Sc.; G. H. Lake; Librairie Payot et Cie; Lincoln Engineering Society; London and Home Counties Joint Electricity Authority; Messrs. P. Lund, Humphries and Co., Ltd.; Prof. E. Mallett, D.Sc.(Eng.); H. G. Massingham; Mines Department; Captain W. Morecombe, R.E., B.Sc.(Eng.), National Illumination Committee of Great Britain; W. H. Patchell; O. Pedersen; Messrs. Sir Isaac Pitman and Sons, Ltd.; St. G. Lane Fox Pitt; A. R. Rubin; Safety in Mines Research Board; Schweizerischer Elektrotechnischer Verein; E. Kilburn Scott; Siemens-Schuckert-Werke, G.m.b.H.; Prof. S. Parker Smith, D.Sc.; W. Hanneford Smith, F.R.S.E.; G. W. Stubbings, B.Sc.; Surveyor-General of India; Prof. W. M. Thornton, O.B.E., D.Sc., D.Eng.; S. Velander; Verein Deutscher Ingenieure-Verlag; R. A. Watson Watt; W. J. White; "World Power."

A list of candidates for election and transfer, approved by the Council for ballot, was taken as read and was ordered to be suspended in the Hall.

The President announced that, during the month of December, 35 donations and subscriptions to the Benevolent Fund had been received, amounting in the aggregate to £120. A vote of thanks was accorded to the donors.

A paper by Messrs. T. W. Ross and H. G. Bell, M.Sc. Tech., Associate Members, entitled "Recent Developments in the Protection of Three-Phase Transmission Lines and Feeders" (see page 801), was read and discussed.

The meeting terminated at 8 p.m. with a vote of thanks to the authors, which was moved by the President and carried with acclamation.

798TH ORDINARY MEETING, 23RD JANUARY, 1930.

Colonel Sir Thomas F. Purves, O.B.E., President, took the chair at 6 p.m.

The President having reported the death of Dr. S. Z. de Ferranti, F.R.S., Honorary Member, who held the office of President of the Institution from 1910 to 1912, and was awarded the Faraday Medal in 1924, the members rose in silence as a mark of their sympathy and regret.

The minutes of the Ordinary Meeting held on the 9th January, 1930, were taken as read and were confirmed and signed.

The President announced that the Council had made the ninth award of the Faraday Medal to Sir Ernest Rutherford, O.M., F.R.S.

Messrs. H. W. Hartridge and A. E. Kennard were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the President reported that the members whose names appeared on the lists (see page 522) had been duly elected and transferred.

A paper by Mr. L. C. Grant, Member, entitled "The Breaking Performance of High-Power Switchgear and of a New Form of Quenched-Arc Switch" (see page 1089), was read and discussed.

The meeting terminated at 7.50 p.m. with a vote of thanks to the author, which was moved by the President and carried with acclamation.

799TH ORDINARY MEETING, 13TH FEBRUARY, 1930.

Colonel Sir Thomas F. Purves, O.B.E., President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 23rd January, 1930, were taken as read and were confirmed and signed.

Messrs. H. J. Neill and H. C. Wilkinson were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the President reported that the members whose names appeared on the lists (see page 655) had been duly elected and transferred.

The President announced that, during the month of January, 2 327 donations and subscriptions to the Benevolent Fund had been received, amounting in the aggregate to £1 344. A vote of thanks was accorded to the donors.

A paper by Prof. J. Hartmann, Dr.Tech., Member, entitled "The Jet-Wave Rectifier: the Experimental and Theoretical Basis of its Design" (see page 945), was read and discussed. The paper was illustrated by a cinematograph film.

The meeting terminated at 7.50 p.m. with a vote of thanks to the author, which was moved by the President and carried with acclamation.

INSTITUTION NOTES.

National Certificates and Diplomas in Electrical Engineering (England and Wales).

The undermentioned colleges have been approved under the scheme drawn up by the Board of Education and the Institution:—

Approved for Ordinary Grade Certificates (Senior Part-time Course).

West Ham Municipal College.

Approved for Higher Grade Certificates (Advanced Part-time Course).

Acton Technical Institute.
Bournemouth Municipal College.
West Ham Municipal College.

Graduateship Examination Results: May, 1930.

On the last page of the cover of this issue of the *Journal* will be found particulars of certain publications, etc., which are on sale on behalf of the Fund.

Proceedings of the Meter and Instrument Section.

11TH MEETING OF THE METER AND INSTRUMENT SECTION, 21ST MARCH, 1930.

Mr. E. W. Hill, Chairman of the Section, took the chair at 7 p.m.

The minutes of the meeting held on the 7th March, 1930, were taken as read and were confirmed and signed.

The Chairman drew the attention of the members to the arrangements which had been made for the holding of a Summer Meeting at Leamington Spa on the 24th May.

An informal discussion then took place, the subjects being as follows:—

(1) " To Meter or not to Meter " (opened by Mr. A. J. Gibbons).
(2) " Whether or not Prepayment Meters should be Earthed " (opened by Mr. C. B. Green).
(3) " Whether or not Prepayment Meters should be Stamped and Sealed " (opened by Mr. W. Lawson).
(4) " The Use of 1-amp. Secondaries in Current Transformers in special circumstances, as against 5-amp. Secondaries " (opened by Mr. E. Fawssett).
(5) " Formula for the Merit-Factor of a Meter " (opened by Mr. G. F. Shotter).
(6) The Chairman also raised two minor points which had been submitted in writing by Mr. S. Garbutt.

The meeting terminated at 9.42 p.m. with a vote of thanks to those members who had introduced the subjects for discussion.

12TH MEETING OF THE METER AND INSTRUMENT SECTION, 4TH APRIL, 1930.

Mr. E. W. Hill, Chairman of the Section, took the chair at 7 p.m.

The minutes of the meeting held on the 21st March, 1930, were taken as read and were confirmed and signed.

A paper by Messrs. E. H. Rayner, M.A., Sc.D., Member, W. G. Standring, M.A., R. Davis, M.Sc., and G. W. Bowdler, M.Sc., entitled " Low Power-Factor Measurements at High Voltages " (see page 1132), was read and discussed.

The meeting terminated at 9.8 p.m. with a vote of thanks to the authors, which was moved by the Chairman and carried with acclamation.

THE STEAM AND ELECTRIC POWER PLANT OF IMPERIAL CHEMICAL INDUSTRIES, LTD., AT BILLINGHAM.

By H. A. Humphrey, Member, D. M. Buist, Member, and J. W. Bansall, Associate Member.

(*Paper first received* 18*th November*, 1929, *and in final form* 29*th January*, 1930; *read before* The Institution 13*th March*, *before the* North-Eastern Centre 24*th March*, *before the* North Midland Centre 25*th March*, *before the* North-Western Centre 1*st April*, *before the* Tees-side Sub-Centre 2*nd April*, *before the* Scottish Centre 8*th April*, *and before the* South Midland Centre 14*th April*, 1930.)

Summary.

This paper describes a large pulverized-fuel, high-pressure, high-temperature, industrial power plant erected by Imperial Chemical Industries, Ltd., for the supply of steam and electrical energy to the Billingham-on-Tees factory of Synthetic Ammonia and Nitrates, Ltd.

Apart from its size, this plant possesses the following features, and these features alone are described, all reference to standard boiler and power plant practice being omitted wherever possible:—

(1) A maximum pressure of 800 lb. per sq. in. gauge and a maximum temperature of 856° F.
(2) The world's largest high-pressure pulverized-fuel boiler plant, containing special constructional features for the high pressure and temperature.
(3) An unusually large distillation plant.
(4) A 7-stage feed-heating system, with feed-pumps specially designed for high pressure and temperature.
(5) High-pressure pass-out turbines of unique design.
(6) The first system of its kind of automatic frequency control, automatic steam-pressure control, and automatic feed-pump regulation, together with automatic synchronizing.
(7) Unusual lay-out features for the accommodation of pipework and cables.

Table of Contents.

Introduction.
  (*a*) Boiler plant.
  (*b*) Turbo-alternators.
  (*c*) Costs.

  (*e*) Lay-out.
Section (1). General Arrangement of the Plant.
  (*a*) General lay-out.
  (*b*) Boiler and pulverizer houses.
  (*c*) Distillation bay.
  (*d*) Feed-heating bay.
  (*e*) Pipe bay.
  (*f*) Turbine bay.
  (*g*) Switch house.
Section (2). Flow Sheet.
Section (3). Description of Individual Parts of the Plant.
  (*a*) Boiler plant.
  (*b*) Pipework.
  (*c*) Turbines.
  (*d*) Feed-heating and distillation plants.
  (*e*) Switchgear.
Section (4). The Automatic Regulation of Steam Pressure and Station Frequency.
  (*a*) Stability of operation.
  (*b*) Co-ordinated control of the boiler plants and power plant.
  (*c*) Mode of operation of automatic scheme.
  (*d*) Description of automatic scheme.
Section (5). Other Special Features.
  (*a*) Alternative auxiliary supply system.
  (*b*) Automatic synchronizing.
  (*c*) Automatic control of feed pumps.
  (*d*) Battery-booster control scheme.
  (*e*) Neutral earthing scheme.
  (*f*) Special instruments.
Conclusion.
Appendix 1. Efficiency Calculations.
Appendix 2. Increase in Thermal Efficiency Due to Feed-Heating and Raising the Initial Temperature and Pressure.
Appendix 3. Technical Data.

Introduction.

The conditions governing the design of the power plant described in this paper differ essentially from those relating to a public electricity supply station.

The extension programme of Synthetic Ammonia and Nitrates, Ltd., at Billingham, called for 6 930 tonnes * of steam per day delivered for process purposes, and 37 500 kW distributed as electrical energy to the works. The quantity of steam in the first item is approximately double the amount of steam required to generate the electrical energy of the second item, and so the boiler-plant capacity is three times that of a purely electric power station.

Then again, the load factor of a chemical works approaches closely to 100 per cent, and continuity of supply is of the utmost importance. A cessation of power supply not only causes loss of output but disorganizes the steady conditions of temperatures and pressures upon the maintenance of which satisfactory operation depends throughout a very complicated process. The power station, therefore, must have sufficient stand-by plant and means of bringing such plant rapidly into operation, whilst, further, the lay-out, methods of control, size of units, etc., must all be considered on the lines of "safety first."

In designing a plant for an annual output as great as that of the largest electricity station in the country, great attention must be paid to all possibilities for securing economy in generating costs. The balance has to be struck between simplicity and reliability on the one side, and maximum attainable economy on the other. Unproved designs involving apparatus of an experimental nature had to be avoided, and the consulting engineer had to steer his way through some rather conflicting considerations in order to obtain the best *commercial* results.

---

* One tonne = 1 000 kg = 2 204 lb.

Another matter influencing design was the existence of a large powdered-fuel-fired boiler plant and also the fact that a contract for a bulk supply at 11 000 volts, 40 periods, from the adjacent North Tees power station continues until 1941.

(*a*) *Boiler Plant.*—The existing boiler plant provides the steam used in the factory at 290 lb. absolute * and 653° F., and the necessity of paralleling with these conditions made their adoption for the new plant almost imperative. The first problem, therefore, was how best to raise steam at some higher pressure so that after some of its energy had been converted to electrical energy it could be passed on as steam to process. Calculations showed that if steam were raised at such a pressure that it entered the primary turbines at 645 lb. per sq. in. and 833° F. its expansion down to 290 lb. would provide steam at 653° F., these being the steam conditions of the existing boiler plant.

A study of the superheater problem showed that, to gain the economy due to high velocity of flow in the superheater tubes, a large resistance pressure-drop had to be faced, and the normal working pressure at the boilers therefore became 715 lb. and was finally fixed at 815 lb. as a maximum.

By adopting still higher pressures a slightly greater calculated efficiency would have been possible, but in view of the fact that 856° F. was considered to be the highest safe temperature for ordinary steel superheaters, and that such high temperatures have a greater influence on economy than super-high pressures, any temptation to adopt still higher pressures was readily rejected. Especially was such a decision made easy because a pressure of 1 200 lb. per sq. in., for example, would have entailed reheating the steam after expansion, in order to reach existing boiler-plant conditions, and the small additional economy was not worth the added complication and expense thus involved. Further, we have yet to learn a great deal about creep stresses at 856° F., and such stresses are proportional to pressure. Considerations of safety after prolonged use therefore suggested the wisdom of not exceeding the 815 lb. maximum boiler pressure adopted.

High-pressure boilers must have distilled-water feed. Unfortunately, only 60 per cent of the steam would be condensed and returned from process, and so 2 512 tonnes per day of raw water, obtained from Billingham Beck, had to be distilled and the distillate added to the "make-up" feed. This involved the erection of an unusually large distillation plant, with its attendant de-aerators.

(*b*) *Turbo-Alternators.*—Careful consideration of the possible degree of economy to be obtained by progressive feed-heating led to the adoption of separate feed-heating turbines from which the steam is bled to heat the feed water. Here, again, a commercial maximum economy, rather than a theoretical maximum, was aimed at, and no attempt was made to bleed the primary turbines. These unusual pieces of apparatus were advisedly kept simple and comparatively small, and the consulting engineer insisted, in the interests of flexibility, on their being mechanically independent of other units.

By passing all the steam required as such, plus that required for conversion to electrical energy, through two primary turbines, 23 800 kW would be obtained, so that two units of 12 500 kW each would provide the working units and one was to be added as a spare. A corresponding set of feed-heating turbines would give 9 500 kW output for two units working, and these were fixed at 6 000 kW each on the generator side.

Lastly, condensing sets had to be provided because the proportion of steam energy to electrical energy distributed to the works was liable to vary, and condensing sets were necessary to meet such variation within the required limits and to make up the balance of the electrical output. One working condensing set to produce 10 200 kW would meet the then known conditions, another machine being kept as spare. These were made capable of 12 500 kW each in view of unknown requirements, and provision was made for a third set, should this be required in the future.

Naturally, some complicated calculations were involved in correlating the output and input of all the plant units, and in the end the steam to be raised by the new boilers was found to be 11 700 tonnes per day, and the electrical energy required was augmented to 43 500 kW in order to cover all the internal requirements of the plant plus the outside load.

(*c*) *Costs.*—In granting the authors permission to read this paper, the directors of Imperial Chemical Industries, Ltd., have reserved from publication all questions of cost, but it may be stated that the estimated cost of electric energy at the busbars of the station is well below the unit cost of any electric generating station in the world depending on coal as fuel. This is due to the use of high-pressure and high-temperature steam, to the use of primary turbines passing a greater quantity of steam than would be available in an ordinary central station, to the low cost of coal in the locality, to the high load factor, to the abundant supply of cooling water, and to the many economies which have been introduced into the designs.

(*d*) *Erection.*—The station was erected in record time. Tenders were invited in December 1927, contracts were placed in February 1928, excavations were commenced in May 1928 and by February 1929 the station was erected with sufficient plant to commence operation and give an external supply to the factory.

(*e*) *Lay-out.*—The general lay-out of the power plant was the subject of quick decisions, made even before contracts were placed and adhered to during the subsequent settlement of details with the main contractors. In reviewing the lay-out now that the plant is built, no radical improvement therein can be suggested. The governing decisions were:—

---

* Except where otherwise stated, all subsequent pressures mentioned in this paper are absolute pressures.

(1) To dispose the plant so that the flow from boilers to high-pressure turbines, thence to the feed-heating and the distillation plants and finally back to the boilers, constituted a simple ring with a tee-off to the condensing sets and one to the factory for process purposes.

(7) To provide on the electrical side, as on the steam side, a separate bay in the switch house for all cables, consisting of a vertical gallery fed from the basement and feeding two horizontal steel-floored races under the main switchgear and under the control room respectively.

(8) To place the majority of the generating plant next to the switch house for convenience and economy of heavy cable runs.

(9) To place the switch house external to the main buildings to facilitate exit of the large number of feeders; and, for the same reason, to place the main switchgear on a level with the cable bridges.

The above short introduction gives an outline of the plant, the details of which the engineering staff of Synthetic Ammonia and Nitrates, Ltd., had to work out with the co-operation of the contractors. The great care applied to the many problems involved renders the detailed solutions worthy of study, and it is felt that the members of the Institution would welcome, as a model, the most complete data ever published concerning a modern power station.

This preliminary review will enable members to appreciate the leading features now to be described in detail.

Section (1). GENERAL ARRANGEMENT OF THE PLANT.

(*a*) *General Lay-out.*—The power station is situated adjacent to the River Tees, from which an ample supply of cooling water is obtained from a large pump house on the riverside containing four 36-in. pumps driven by 2 200-b.h.p. 6 600-volt motors. This pump house is one of two built for the general factory supply. Excellent railway facilities for the supply of coal were already in existence for the general requirements of the factory. As will be seen from the site plan (Fig. 1) the boiler and power plants are separated by a chimney bay. The boiler plant consists of a north and a south boiler house between which lies the pulverizer house, the general arrangement being clearly shown in the end elevation in Fig. 2.

The power plant is accommodated in the following five bays: Distillation bay; feed-heating bay; pipe bay; turbine bay; and switch house. The last named has several floors and accommodates house transformers, motor-convertors, reactances, switchgear, control room and various offices. The power plant is further divided into three complete units, which are interconnected at various points on the steam and on the electrical side, each unit extending across the entire five bays. The general arrangement of the power plant will be seen from the end elevation in Fig. 2, which also shows the type of steel structure employed, the construction being similar to that of the other plant buildings throughout the factory. The structural steelwork throughout both plants weighs 6 500 tons.

(*b*) *Boiler and Pulverizer Houses.*—The schematic arrangement of the boiler and pulverizer plants is depicted diagrammatically in Fig. 3. The north and south boiler houses each contain four multi-drum boilers normally generating 215 000 lb. of steam per hour at 715 lb. per sq. in. The intervening pulverizer house contains six 15-ton roller mills and four 15-ton ball mills together with their attendant bunkers, conveyors, cyclones, exhausters, feeders, etc.

Raw coal is brought in by rail and dropped into underground bunkers from which it is raised by skip hoists to overhead belt conveyors which carry it past magnetic separators to overhead steel bunkers (lined with concrete applied by means of compressed air) in the pulverizer house. The raw coal falls through chutes to the weighers and from there to the mill hoppers.

From the mills the pulverized coal is carried to an overhead cyclone separator by an air stream circulated by exhauster fans. From the cyclones the pulverized coal drops through rotary air locks to screw conveyors, which distribute it to the pulverized-coal bunkers of which there is one to each boiler. From these bunkers the powder passes through feeders driven by variable-speed motors, from which it is picked up by the air stream from the primary air fans and fed to the burners. The air for combustion is supplied by forced-draught fans, being first of all brought to a temperature of about 500° F. by air preheaters.

The flue gas is discharged into the stacks by induced-draught fans which draw the gas through economizers, air preheaters and de-dusters, the grit, together with the ash from the combustion chamber, being discharged into ash sluices along which it is washed into a slurry whirl pit. A centrifugal slurry pump raises the ash and water to an ash settling pit where the water drains off from the ash. An overhead grab raises the ash and drops it through a chute into buckets on an aerial ropeway by which the ash is conveyed to barges at the riverside for dumping at sea.

(*c*) *Distillation Bay.*—The distillation bay (Fig. 4) comprises three complete sets of feed-heating distillation plants, two of which are normally working, the remaining set being spare.

Each set consists of a range of four evaporators, a feed-water heater (2nd stage feed-heater), a raw-water heater, a condensate de-aerator (1st stage feed-heater), a raw-water de-aerator, an air ejector and four flash boxes. The steam-and-water-flow through the distillation plant will be seen from the detailed flow sheet (Fig. 13). The three condensate storage tanks and the two raw-water storage tanks are mounted on the north wall of the distillation bay, the reserve in the former being sufficient to maintain the normal feed-water supply for nearly three hours if one of the distillation plants should fail.

(*d*) *Feed-Heating Bay.*—The feed-heating bay (Fig. 5) contains the three 6 000-kW feed-heating turbines, exhausting into their respective distillation plants, together with their attendant feed-heaters, feed-pumps and extraction pumps, arranged on the separate drain-pump system. Each set of bleeder heaters (3rd-, 4th-, 5th- and 6th-stage feed-heaters) is adjacent to its turbine to facilitate operation. The three final-stage heaters are grouped together in line with the final boiler feed-pumps, whilst the intermediate feed-pumps are accommodated in a line between the latter and the feed-heating turbines.

The emergency heater and feed-pumps are situated

in the north-east corner of the distillation bay, from which the auxiliary boiler feed-line passes across the distillation bay to the boiler plant. All heater extraction pumps are on the ground floor below their respective heaters.

The sealing pumps, supplying gland-sealing water to all pumps in the distillation and feed-heating bays, are also on the turbine floor behind the centre main feed-pump (see Fig. 5).

(*e*) *Pipe Bay*.—Between the feed-heating and the turbine bays is situated the pipe bay (Fig. 6) which contains the high-pressure (primary) receivers, desuperheaters (secondary receivers) and reducing valves, together with the entire collecting and distributing system of high- and intermediate-pressure pipework.

The accommodation of the pipework in one bay around a symmetrically placed receiver system facilitates control of the steam flow by means of valve tables mounted on the turbine floor-level, immediately above the receivers. The lay-out of the pipework associated with this compact arrangement gives complete flexibility, as will be seen from Fig. 16.

All valves are provided with extended spindles for hand operation, with the exception of the three motor-operated reducing valves on the turbine floor-level. The latter can also be operated by hand.

(*f*) *Turbine Bay*.—This bay (Fig. 7) contains the main generating units—three 12 500-kW high-pressure, pass-out, or primary, turbines and two 12 500-kW intermediate-pressure condensing turbines. Provision has been made for a third condensing machine should this be required at a future date. The turbines run at 2 400 r.p.m. and are direct-coupled to 13 750-kVA alternators generating 3-phase, 40-cycle current at a pressure of 6 600 volts.

The condensing machines are provided with duplicate extraction pumps driven by a.c. and d.c. motors respectively, the former operating normally. In the event of a failure of the a.c. supply the d.c. motor-driven pump automatically starts up.

(*g*) *Switch House*.—As will be seen from Fig. 2, the switch house has a top floor, above the turbine floor-level, which accommodates the control room, battery room, battery booster room, model room and various offices. The general arrangement of this floor is shown in Fig. 8.

The first floor (Fig. 9) houses all the main e.h.t. switchgear and the auxiliary 400-volt a.c. and 460-volt d.c. switchgear. These two boards are both arranged for hand operation and are accordingly placed in a gallery facing the main turbine room, immediately over the transformers and convertors respectively.

On the ground floor (Fig. 10) are placed the four 1 500-kVA station transformers, from which the 400-volt auxiliary a.c. supply is derived; the three 2 000-kW motor-convertors, which provide the 460-volt auxiliary d.c. supply; and the bus-section reactors, station-feeder reactors and the auxiliary e.h.t. switchgear and neutral-earthing switchgear. Provision has also been made for a workshop on this floor, adjacent to the railway entrance to the building.

Below the ground floor there is a cable basement extending underneath the main turbine bay and terminating in three cable ducts leading under the pipe bay to the feed-heating turbo-alternators. In addition, vertical and horizontal cable galleries are provided in the switch house which allow of clean unimpeded cable-runs to the various portions of the switchgear and to the control room. This unorthodox feature is clearly revealed in Fig. 2. The extra building cost incurred was amply recovered in the consequent facility of erection, quite apart from the simplicity and the neatness of the runs and the accessibility afforded for speedy repairs. Furthermore, it permitted the erection of a bay the exact duplicate of the feed-heating bay in width, height and design of structural steelwork.

Section (2). FLOW SHEET.

Fig. 11 illustrates in simple diagrammatic form the feed-heating cycle and steam distribution.

The general heat-flow in the boiler and power plants is illustrated diagrammatically in Fig. 12, while the complete quantitative flow sheet is given in detail in Fig. 13.

Steam is normally generated at a pressure of 715 lb. per sq. in., the maximum working pressure being 815 lb. per sq. in. and the temperature 856° F. On leaving the superheaters the steam passes into the high-pressure steam receivers (primary receivers), where its pressure is in the neighbourhood of 650 lb. per sq. in. As will be described later, in Section 3 (*b*), these receivers function as equalizers and distributors.

The high-pressure steam from the primary receiver system is distributed to the reducing valves and the primary turbines, being admitted to the latter at 645 lb. per sq. in. and 833° F. Under normal operating conditions the reducing valves remain closed while each of the two high-pressure turbines running takes some 244 tonnes of steam per hour and generates 11 900 kW at an overall efficiency of 74 per cent. Steam exhausts at 290 lb. per sq. in. from the primary turbines into the de-superheaters or secondary receivers where the superheat is maintained constant at 243° F., corresponding to a total temperature of 653° F., by means of a thermally-regulated water spray. Under certain conditions of steam load and electrical load, steam is automatically diverted from the high-pressure turbines and passes from the primary to the secondary steam receiver system through one or more of the reducing valves. From the secondary receiver system the steam is distributed to the following points: Process plants; condensing turbines; feed-heating turbines; 7th-stage feed-water heaters; and distillation plant air ejectors and soot-blowers.

The process plants normally consume 6 930 tonnes of steam per day, which represents very nearly 60 per cent of the boiler output. Of this quantity 3 994 tonnes per day are returned in the form of condensate to the feed-water storage tanks in the power station, so that the net consumption to be replaced by distillate amounts to 2 936 tonnes per day, or 42 per cent of the total quantity delivered by the three outgoing steam mains.

The condensing turbine under normal operating conditions takes 1 130 tonnes of steam per day and gives an output of 10 200 kW at an overall efficiency

feed-heating turbines. The steam for the next four heaters is bled from the feed-heating turbines, the bleeding points occurring immediately after the 6th, 12th, 18th and 24th (exhaust) stages of each machine. The last heater in the feed-water heating system is supplied with live steam direct from the secondary receivers, so that accurate adjustment of the final feed-water temperature may be obtained once the feed-heating turbine and its attendant distillation plant and heaters have settled down to steady operating conditions. This being the case, the two feed-heating turbines (normally running) each take 1 310 tonnes of steam per day from the secondary receiver system, whilst their corresponding final-stage feed-heaters each account for a further 400 tonnes per day from the same source. Under these conditions each turbine generates 4 750 kW at an overall efficiency of 70 per cent, exhausting to its distillation plant at a pressure of 12·73 lb. per sq. in. and a temperature of 205° F., whilst the net quantity of raw water distilled and passed into the feed line as "make-up" feed-water then amounts to 1 138 tonnes per day from each of the two distillation plants.

An examination of the steam and water quantities so far given reveals that the amount of distillate gained from the two feed-heating distillation sets is insufficient to compensate for the steam consumed by the process plants and for boiler blow-down losses and gland leakage in the high-pressure turbines. It was, therefore, necessary to install three further distillation sets deriving their steam supply from the factory's low-pressure steam main. Two of these sets can make up the deficit of 860 tonnes per day by the evaporation of raw water. The final resultant steam and water balance is shown in Table 1.

The power balance is given in Table 2, whilst from the figures in Table 3 it will be seen that the anticipated overall thermal efficiency of the power station is 24·2 per cent. Table 4 shows the increase in thermal efficiency due to raising the pressure and temperature of the steam at the turbine stop-valves and also that due to the adoption of regenerative feed-heating.

The calculations involved in the determination of the quantities in Tables 3 and 4 are detailed in Appendices 1 and 2 respectively, whilst Appendix 3 contains general data relating to the various parts of the installation.

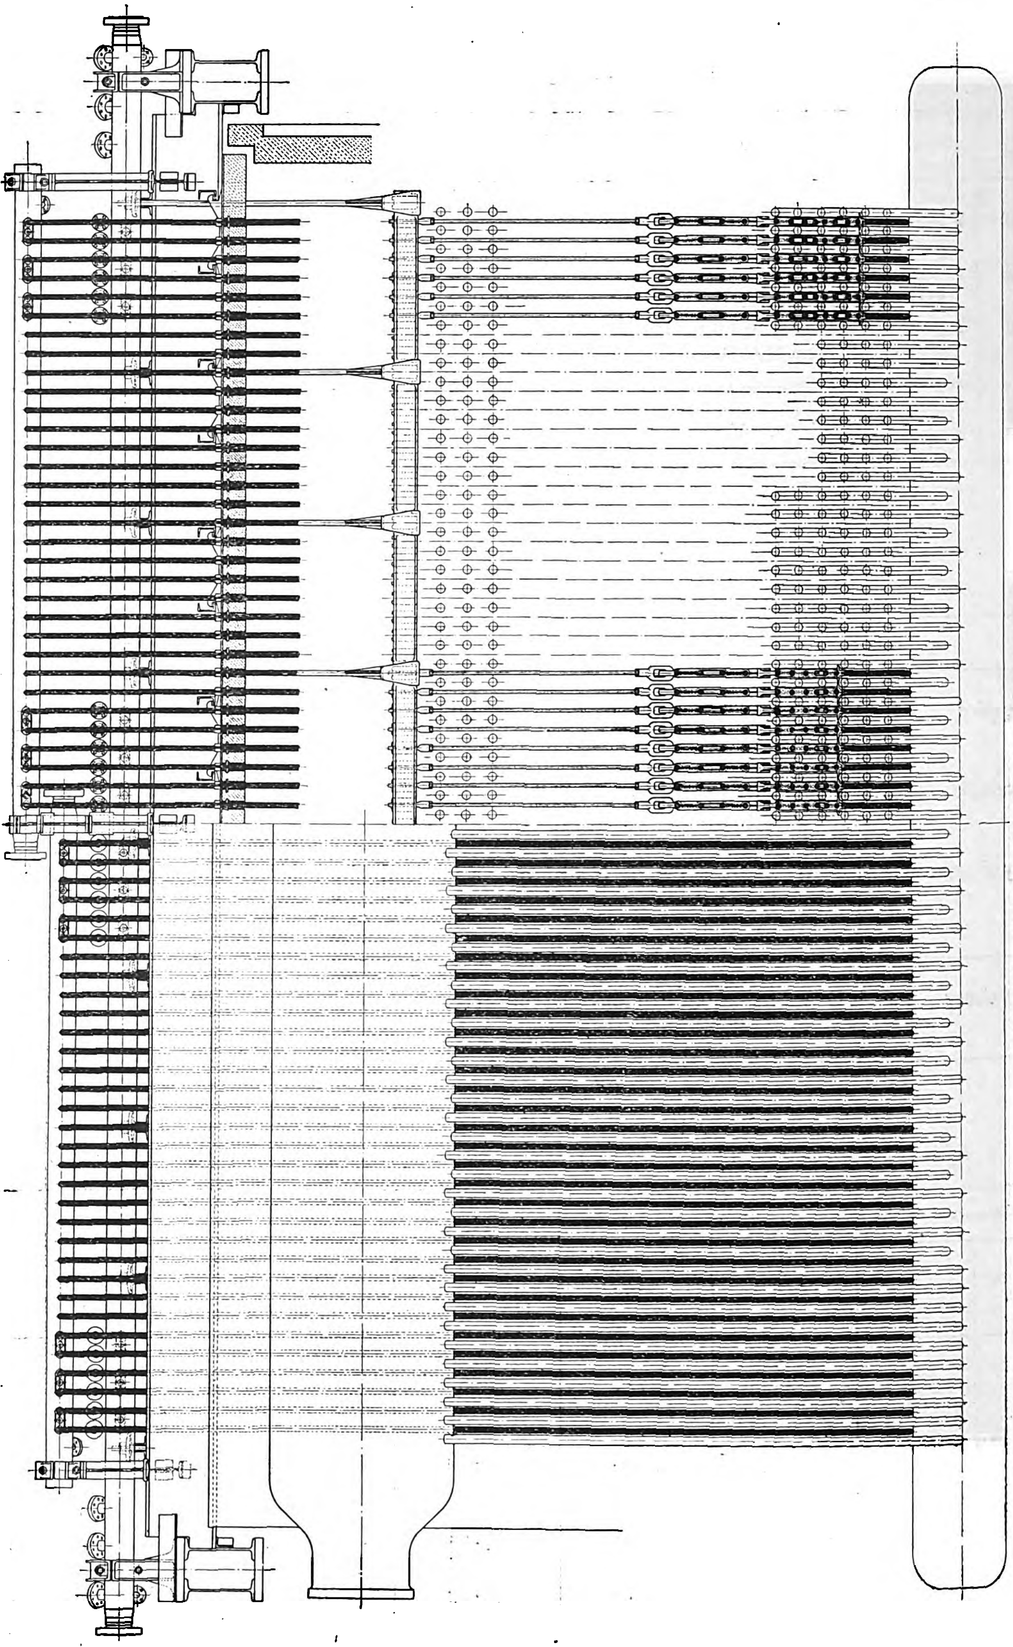

FIG. 14.—Method of boiler drum suspension.

Section (3). DESCRIPTION OF INDIVIDUAL PARTS OF THE PLANT.

(a) *Boiler Plant.*

The general arrangement of the boiler plant has already been described in Section (1) in conjunction with the pictorial flow-sheet of Fig. 3. Space precludes a detailed description of the entire plant, but mention will be made of its more important features and of certain details in which it differs from usual high-pressure boiler-plant practice.

In the first place it is noteworthy that the two boiler houses are isolated from the pulverizer house by means of brick walls, whilst the raw-coal bunker floor at the top of the pulverizer house (Fig. 2) has been made dust-tight to keep the lower floors clean. In addition, the symmetrical location of the 10 pulverizing mills permits the coal dust from the vents of the mill systems to be discharged into the boiler combustion chambers by means of the primary air fans. This feature eliminates a great deal of the dust nuisance from the pulverizer house.

The flue gas de-dusting equipment consists of two falling-water-film type units to each boiler. River water from the condenser circulating-water outlet main is pumped to the de-dusters and to a number of sluice channels in the boiler-house floor which convey the ash and water to settling pits, via slurry pumps.

Boilers.—The steam-generating plant consists of 8 multi-drum boilers, each having a normal rating of 215 000 lb. per hour and a maximum rating of 270 000 lb. per hour.

The general construction of the boilers is clearly illustrated in the end elevation of the plant given in Fig. 2. The main upper drums are both suspended from the boiler structure, whilst the boiler as a whole is largely dependent upon the tubes for its support (Fig. 14).

A considerable portion (about 30 per cent) of the boiler heating surface is exposed to the radiant heat of the combustion chamber. The available heating surface in the combustion chamber is 3 000 sq. ft., which includes the fin-tube water walls, water screens and front rows of boiler tubes, whilst the convection tubes of the boiler account for 7 000 sq. ft., which makes a total of 10 000 sq. ft. for the boiler heating surface. The evaporation obtained averages from 22 to 28 lb. per sq. ft. per hour, exclusive of the steam which is generated by the cast-iron gilled steel-tube economizer. It has been calculated that the latter will generate about 30 per cent of the total steam when operating under normal load conditions. This reduces the average amount of steam generated by the boiler tubes to approximately 17 lb. per sq. ft. of heating surface per hour, an effective evaporation which is very much in excess of that obtaining in average practice to-day.

Boiler Drums.—The manufacture of these drums was entirely outside the scope of the ordinary boiler shops and presented quite a problem to large forging makers. When it was realized that 32 drums were required and that each drum would take more than 6 months to complete, it was clear that if any trouble were experienced in obtaining satisfactory and uniform forgings at regular intervals the completion of the plant would be seriously delayed.

The question of choosing a suitable type of boiler was one of considerable difficulty in view of the many new conditions which had to be faced. In December 1927 it was decided that high-pressure boilers should be installed. Early in 1928 the design work was commenced, and after the size of the plant and the capacity of the boiler units had been determined it was obvious that the design and manufacture of the large 800-lb. pressure, forged-steel boiler drums would require careful consideration to ensure perfect forgings and to obtain them in time to meet the steam demands.

After due consideration of all the factors involved it was decided not to adopt the lighter alloy-steel forgings but to use ordinary mild steel having an ultimate tensile strength of little more than 26 tons per sq. in. and a yield stress of not less than 13 tons per sq. in. The length of the main steam drums is 43 ft., the internal diameter 4 ft. 6 in. and the shell thickness 4½ in. The finished drum weighs 56 tons and was machined from a 150-ton ingot. Allowing for the following stresses:—

Hoop stress due to pressure;
Longitudinal stress due to pressure;
Radial stress due to pressure; and
Longitudinal stress due to the bending moment resulting from concentrated and uniformly distributed loads, which amount to over 200 tons in the case of the main steam drums,

and using a formula combining the results of each separate stress, the drum thicknesses were obtained by limiting the working stresses in the forgings to 5·2 tons per sq. in., which gives a safety factor of 2·5 on the yield stress.

Superheaters.—Special precautions had also to be taken in the design of the superheaters, on account of the very high normal superheat temperature of 850° F., whilst during periods of fluctuating load this figure might be exceeded so that temperatures lying within the region of low limiting creep stress might be reached in the tube walls. At the time the superheaters were being designed, several classes of special alloy-steel appeared to be suitable from the point of view of withstanding the high temperature; but when other factors were taken into account it was found that the most satisfactory material was mild steel of exceptionally good quality, with a very low sulphur content. This material was decided upon after very careful consideration of both cost and reliability.

In each boiler the superheater is suspended between the tubes (Fig. 15) and is partly exposed to the radiant heat of the furnace. The weight of the whole superheater is carried from the boiler structure in such a way that none of the weight of the elements is imposed upon any of the pressure parts of the boiler.

The superheaters are of the locomotive return-bend type, the saturated steam inlet flanges and superheated steam outlet flanges being at opposite sides so that there is an even distribution of steam flow throughout the superheater.

In each superheater the headers, four in number, are turned from solid mild-steel forgings, being left blank at one end and provided with heavy steel flanges at the other end. The superheater elements are made from solid-drawn steel tubing, the material for which has received special attention through all the stages of its manufacture. The finished material has a tensile strength of from 21 to 23 tons per sq. in. and an elongation of not less than 28 per cent. Each superheater element is made in two sections and provides a total length of steam path of approximately 200 ft. between the saturated and superheated steam headers. Each complete superheater is divided into two halves, there being two inlets and two outlets for each boiler. To ensure the necessary protection to the superheater elements a reasonably high steam velocity is essential; this was provided for by designing the superheaters for a pressure-drop of 40 lb. per sq. in. at normal evaporation.

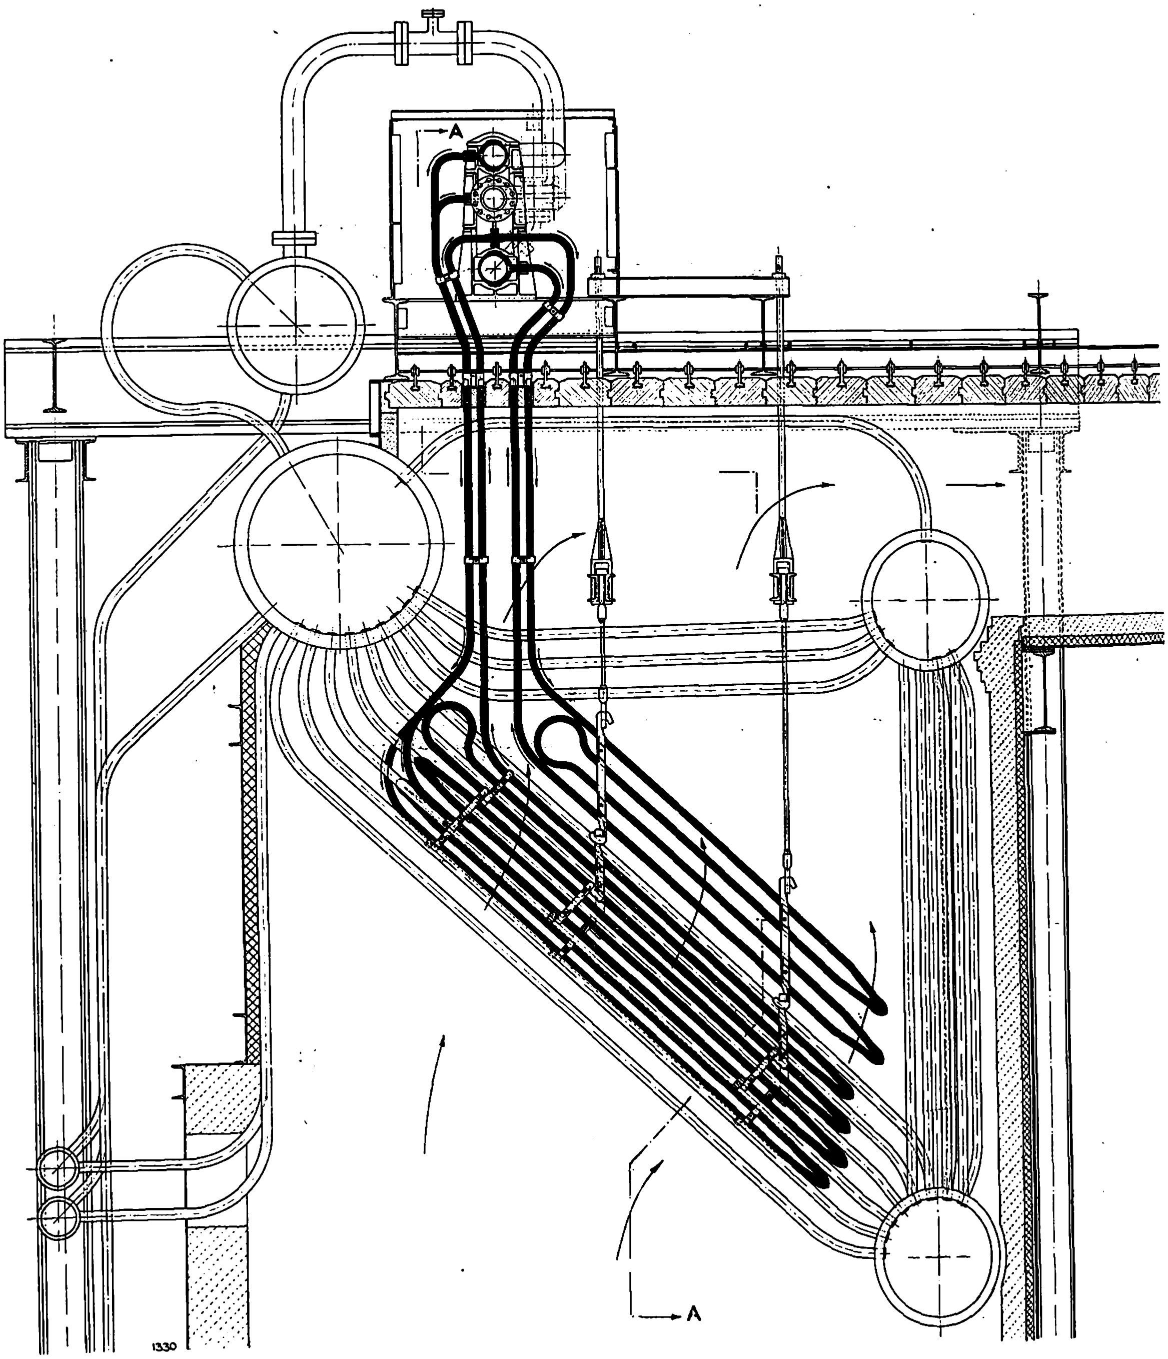

FIG. 15.—Superheater.

Economizers.—A highly interesting feature of the boiler plant is the so-called steaming economizer. The economizers can be seen at the rear of the boilers in Fig. 2. The advantages of steaming over non-steaming economizers are a saving in space and the elimination of baffles in the boiler, with a consequent reduction in draught loss and fan power.

Each economizer has a heating surface of 23 000 sq. ft. and is connected to the boiler by means of a number of bent tubes, a mixture of steam and water entering these tubes at a temperature of 524° F., the feed-water temperature at the economizer inlet being 401° F. The corresponding flue-gas inlet and outlet temperatures are 1 150° F. and 600° F. respectively.

Burners and Air Preheaters.—The horizontal burners, of which there are four to each boiler, are located at the front of the combustion chamber. These burners are of the new short-flame, turbulent type and are each capable of burning more than 4 tons of coal per hour.

FIG. 16.—Diagram showing symmetrical lay-out of pipework.

The air preheaters are of a well-known rotary type and present no special features, except in regard to size. Each preheater has a heating surface of 37 000 sq. ft. and raises the temperature of some 3½ million cub. ft. of air per hour from 60° F. to 500° F.

Control of Boiler Auxiliaries.—The boiler auxiliaries are driven by d.c. motors, the distribution being so arranged that each pair of boilers forms a complete and independent system. The distribution boards in the boiler plant are each fed by two cables in parallel from the d.c. board in the switch house and are interconnected, thus ensuring that the worst possible steam restriction is that due to the opening of the breaker supplying one induced-draught and the forced-draught fan on one boiler, under which condition 75 per cent output of the pair of boilers can be maintained. Two fuel feeders and one primary air fan for each boiler are fed from each distribution board in order to keep half the burners in operation until the interconnecting links can be closed in the event of an interruption of the supply to either board.

Contactor-type startors are installed for each motor, and the remote controls are grouped on a central board in front of each boiler together with the other boiler control instruments and gauges. An interlock is provided to ensure that the forced-draught fans, primary air fans and fuel feeders cannot be run without one of the induced-draught fans being in commission.

The raw-coal handling plant includes two vertical automatic skip hoists and two belt conveyors with travelling trippers.

Visible and audible warning signals are installed on each mill system and on the pulverized-fuel conveyors to draw attention to any departure from the correct sequence of operation or failure of any of the drives concerned.

There are 75 a.c. motors and 92 d.c. motors of the totally enclosed type in the boiler and pulverizer plants, 44 of these motors being equipped with water-cooling on a system specially designed for the purpose by the staff of Synthetic Ammonia and Nitrates, Ltd. The largest motors are the 350-b.h.p. mill motors.

(*b*) *Pipework and Receiver System.*

Lay-out.—In the design of the station the accommodation of about 30 000 ft. of steam and water piping and nearly 2 500 valves of all sorts and sizes presented a problem of no mean order. The unusual feature, therefore, of a separate bay for pipework was decided upon and incorporated in the lay-out.

In order to arrive at a satisfactory arrangement of the maze of pipework resulting from the accommodation of some 50 distinct pipe ranges in a comparatively small space, it was found essential to construct and make frequent use of a scale model. This principle was also applied to the pipework in the feed-heating bay, and eventually the model was extended to include the boiler plant as well as the entire power plant.

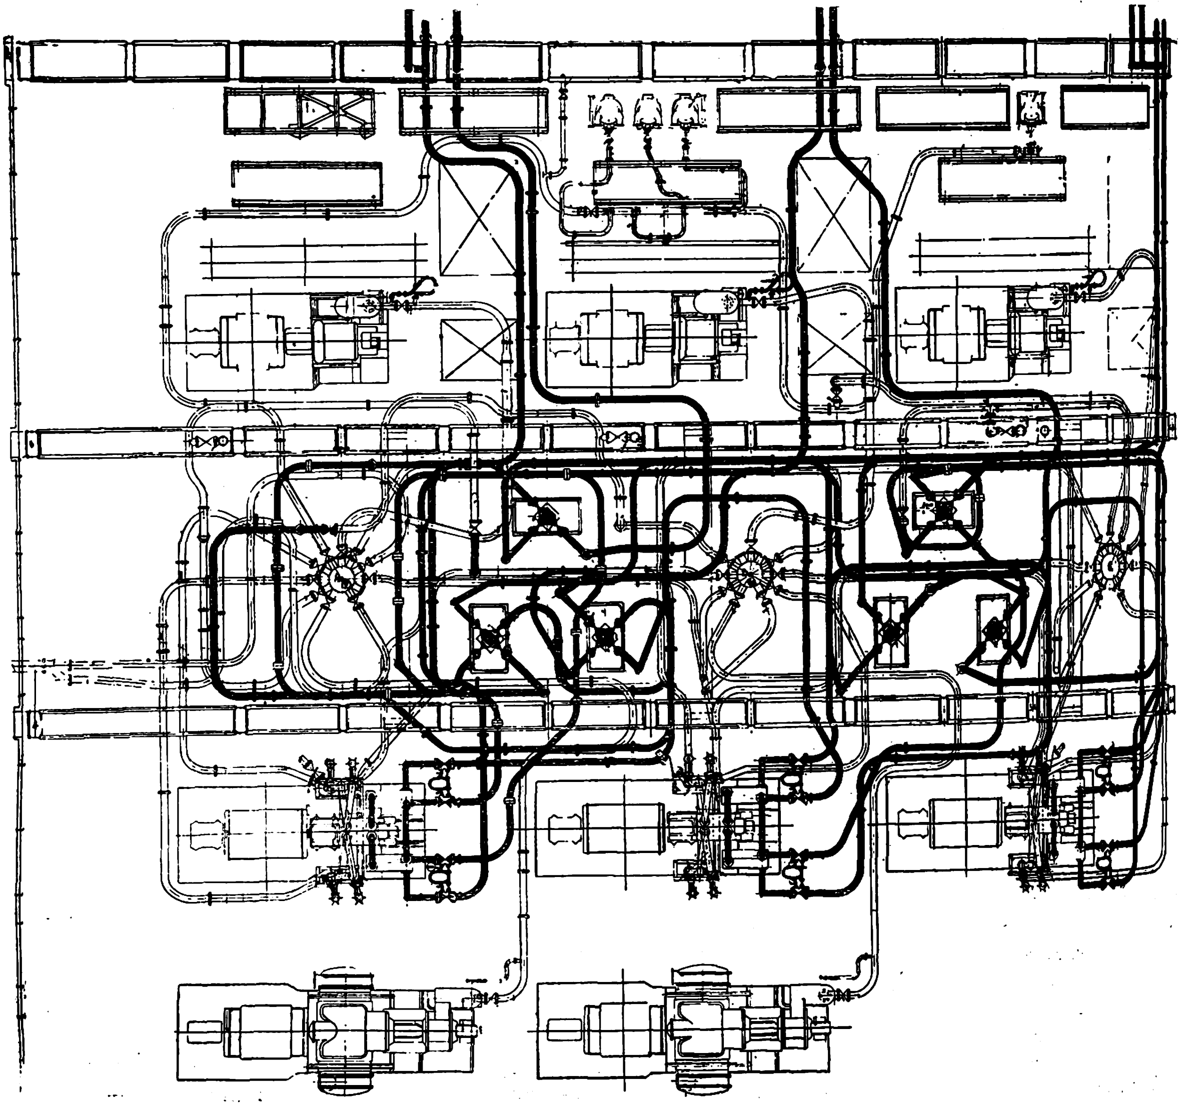

Fig. 17.—Arrangement of steam pipework (high-pressure pipes shown solid).

The pipe bay contains 6 high-pressure receivers and 3 low-pressure receivers or de-superheaters which, with all pipework, are below turbine floor-level. The spindles of all valves are extended up to this level, and consequently on the operating floor are erected three circular valve tables above the de-superheaters, with pressure and temperature gauges mounted above them, the valve wheels on these tables being neatly labelled and the surface of each table bearing a diagram similar to an electrical control diagram. The high-pressure valve wheels are grouped above each high-pressure receiver, forming six symmetrically disposed groups in all. The three electrically operated reducing valves are also situated in this floor.

A plan view of the pipe-bay control floor is shown in Fig. 6, while the general arrangement of the pipework is given in Fig. 17.

Design Conditions.

High-pressure steam pipes and valves, 815 lb./sq. in. and 850° F.

Intermediate-pressure steam pipes and valves, 290 lb./sq. in. and 650° F.

High-pressure feed pipes and valves, 1 150 lb./sq. in. and 400° F.

The same standard of piping, valves and joints, etc., was adopted for both the high-pressure steam piping and the high-pressure feed piping.

Practice Adopted.—After consideration of the various factors involved it was decided to adopt the following practice:—

(1) High-pressure steam and feed pipes not to exceed 10 in. bore.

(2) Intermediate-pressure steam and feed pipes not to exceed 12 in. bore.

(3) All high-pressure pipes to be solid-drawn.
(4) Pipes to be manufactured in as long lengths as possible.
(5) High-pressure steam ranges to be pulled up on erection by an amount equal to the full expansion between the anchorages under working temperature.
(6) High-pressure feed and also intermediate-pressure steam ranges to be pulled up on erection by an amount equal to half the maximum expansion between the anchorages under working temperature.
(7) The maximum thrust of any anchorage not to exceed 7 cwt.
(8) The flexibility of the pipework to be such that the thrust on the steam chests of the primary turbines did not exceed 6 cwt. per pipe line.
(9) The pipes to be run as far as possible from the line between anchorages, in order to minimize thrust thereon and also pipe bending stresses.
(10) To arrange that any boiler could supply any h.p. turbine.
(11) To adopt spring-cushioned pipe hangers with ball sockets, permitting movement in any direction.

TABLE 5.

Particulars of Main Piping.

	Number of ranges	Bore of pipes	Thickness	Location
		in.	in.	
715 lb. per sq. in.	16	7	0·643	Superheater header to main steam line
	6	10	0·850	Boilers to receivers
	12	9	0·770	Receivers to primary turbines
	3	9	0·770	Receivers to reducing valves
	2	10	0·850	Feed to boilers
290 lb. per sq. in.	12	12½	0·5	Primary turbines to de-superheaters
	3	12½	0·5	Reducing valves to de-superheaters
	3	12½	0·5	De-superheaters to F.H. turbines
	2	12½	0·5	De-superheaters to condensing turbines
	6	12½	0·5	De-superheaters to process
	2	12½	0·5	Between de-superheaters

Particulars of Main Piping.—These are given in Table 5.

Type of Joint.—The research department of Synthetic Ammonia and Nitrates, Ltd., conducted extended experiments, as a result of which it was decided to adopt, for the high-pressure pipes, screwed flanges with spot welding on both sides (Fig. 18), and a compressed asbestos fibre joint ring $\frac{1}{32}$ in. thick. Screwed flanges were finally adopted in preference to welded flanges, chiefly because of the impracticability of satisfactorily welding such thick flanges as were required.

Particulars of the flanges are given in Table 6.

The joints were not "followed up" after putting steam on the ranges. The majority of them have now been in use for several months and no trouble has yet been experienced.

Bolts.—These are made of special alloy steel, with a maximum cold yield of 50 tons per sq. in. To obtain uniform bolt stress around the joint, the bolts were tightened up to a definite elongation measured by micrometer, the bolts being pointed for this purpose.

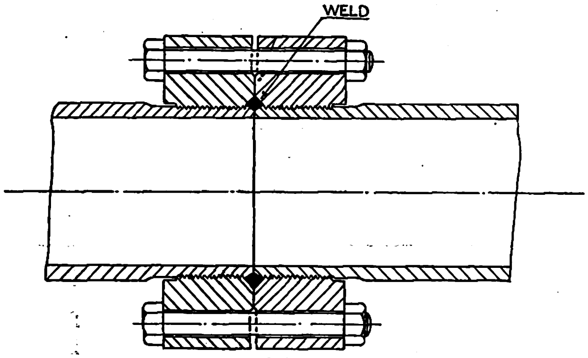

FIG. 18.—Flanged joint for 800 lb. pressure.

These decisions were the result of experiments. The bolt stresses are given in Table 7, the bolts being $9\frac{1}{32}$ in. long and 1½ in. diameter.

TABLE 6.

Flange Particulars.

Duty	Diameter and thickness of flange	Number of bolts
	in.	
10-in. feed pipes	21 in. × 3 in.	16
10-in. steam pipes	21 in. × 6 in.	16
9-in. steam pipes	19 in. × 5¾ in.	14
7-in. steam pipes	15½ in. × 5 in.	12

High-Pressure Receivers.—Six of these vertical receivers are installed, each having one 10-in. inlet connection from the boilers and either two or three 9-in. outlets (see Fig. 16). The receivers are 20½ in. square outside, 18 in. diameter inside and 9·5 ft. high and are hollow steel forgings. A flexible type of vertical plate supports the receivers. The four connections are disposed one on each side and "staggered" in position (see Fig. 19).

Secondary Receivers (De-Superheaters).—Three cylindrical secondary receivers of the vertical type are installed, the dimensions being 4 ft. 2 in. diameter and 19 ft. high (see Fig. 19). Each receiver has four 12-in. inlet branches from its corresponding primary turbines and reducing valve (see Fig. 16), and eight 12-in. bore outlet branches at the top supplying the process plants and the secondary turbines. De-superheater sprays are fitted adjacent to the inlet branches, the water being supplied from the intermediate feed line at 330 lb. per sq. in. and 300° F. These de-superheaters are the largest of their type in existence.

TABLE 7.

Bolt Sizes and Extensions.

Duty	Extension	Stress
	in.	tons/sq. in.
10-in. bore feed pipes	0·008	16
10-in. bore steam pipe	0·010	20
9-in. bore steam pipe	0·009	20
7-in. bore steam pipe	0·007	20

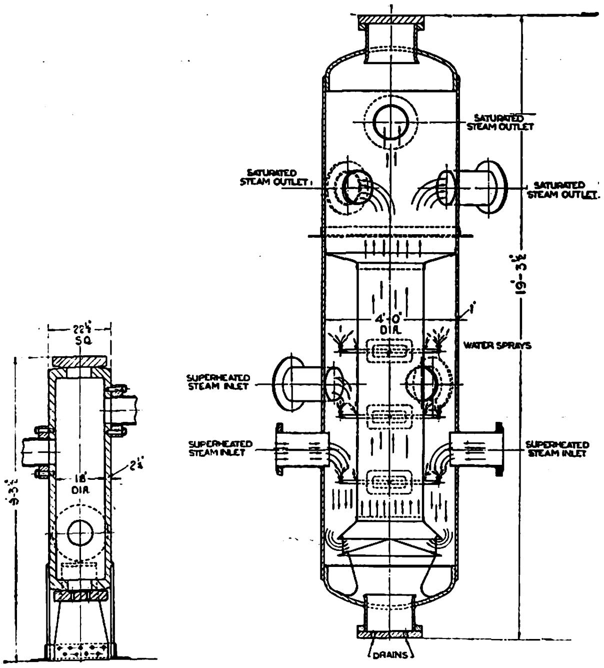

FIG. 19.—Sections of primary and secondary steam receivers.

Valves.—Generally all valves are of the parallel slide type. Up to and including 5-in. bore the valve bodies are of forged steel, and over 5 in. the bodies are of cast steel. As already stated, the spindles of all main stop-valves, valve drains and bypass valves are extended to the operating floor-level. The three electrically-operated reducing valves are of the balanced non-seated type, with 9-in. inlets, 12-in. outlets, 5-in. throats, 3½ in. lift and 2 in. overlap, and are each capable of reducing 437 000 lb. of steam per hour from a maximum pressure of 665 lb. per sq. in. to 290 lb. per sq. in.

Steam-pipe Drainage.—All pipe ranges were designed with a fall of at least 3 in. per 100 ft. towards the receivers. To reduce the cost of traps on the high-pressure steam lines, about four drain-pipes were led to each trap. All traps are provided with strainers and by-passes so that, in the event of a trap sticking, it can be isolated and repaired without shutting down the line.

Lagging.—The economic thickness of high-pressure pipe lagging was determined in the Billingham research department and consists of the following:—

Asbestos	1 in.	Total, 4 in.
Magnesia	2½ in.	
Hard-setting cement ..	½ in.	

Materials and Tests.—The work involved in drafting specifications was immense, especially in the absence of standards for the high pressures and temperatures being considered, and necessitated the closest collaboration with steel-makers and also the various contractors. As a result, the authors desire to stress the urgent need of appropriate British Standard Specifications, owing to the rapid increase in the use of high pressures and temperatures.

The following general information relative to materials and tests will be of interest. The analysis of the high-pressure pipe steel is:—

Carbon, 0·15 to 0·20 max.; silicon, 0·30; manganese, 0·80; sulphur, 0·03; phosphorus, 0·03;

and that of the bolts is:—

Carbon, 0·30; silicon, 0·15; manganese, 0·60; phosphorus, 0·03; sulphur, 0·04; nickel, 2·50; chromium, 0·60; molybdenum, 0·60.

The physical tests are as follows:—

Pipes.—Ultimate tensile stress of 26 to 30 tons per sq. in. with a yield stress of 13 tons per sq. in.; pipe to be flattened cold to one-third outside diameter without cracks, in addition to a temper bend test, and finally each pipe when manufactured to be water-tested to 3 500 lb. per sq. in. abs.

Bolts.—Ultimate tensile stress of 60 to 70 tons per sq. in. with a yield stress of 50 tons per sq. in.; elongation not to exceed 20 per cent and reduction in area 50 per cent. Izod impact value 60 ft.-lb.

In conclusion it may be mentioned that, when delivered, all pipes were "pickled" with a weak nitric acid solution for a few hours, this proving very effective in the removal of scale.

(c) *Turbines.*

High-pressure Turbines.—A sectional view of one of these turbines is given in Fig. 20. They are of the single-cylinder type and have 16 stages. The cylinder and the two steam chests are of forged steel and their manufacture required the exercise of extreme care on the part of the makers.

It is outside the scope of this paper to describe in detail the many specially devised features which had, of necessity, to be incorporated in this unique turbine. It will be of interest, however, to refer briefly to the following outstanding features:—

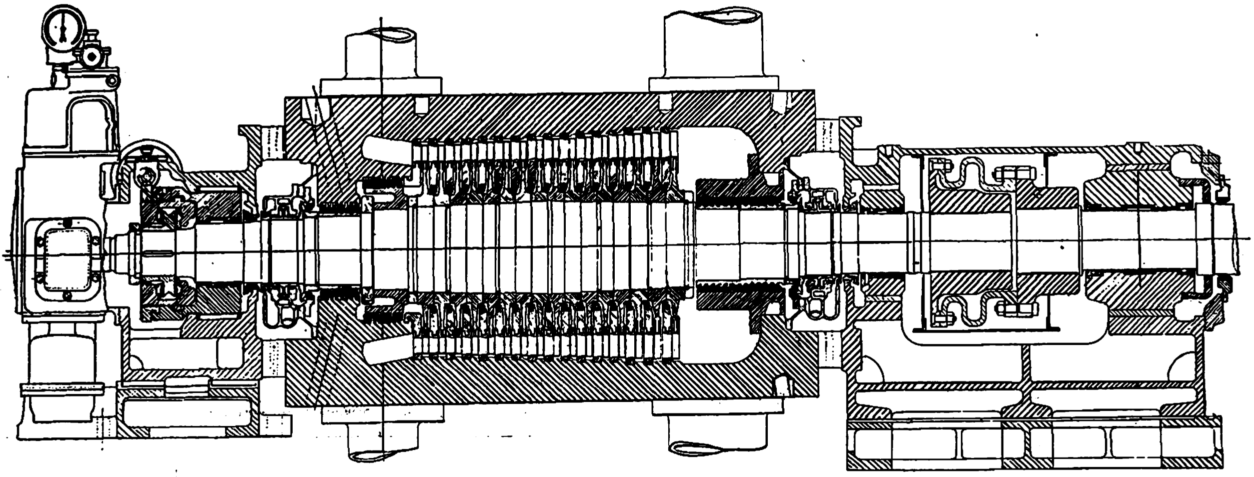

Fig. 20.—Sectional arrangement of high-pressure turbine.

Steam Chests.—The admission of a very large quantity of steam at high pressure and temperature in the case of these turbines necessitated departure from the usual steam-chest practice. Each turbine has two steam chests in parallel, one on each side of the inlet end of the turbine, to which chests the high-pressure steam is supplied via four 9-in. pipes and stop-valves, two per chest. Steam passes from the chests to the turbine admission belt via four 9-in. arched pipes or bends. By this procedure a far greater degree of steam pipe flexibility is obtained than would be possible if one, or even two, connecting pipes of larger diameter were employed. The exhaust end of the turbine is similarly equipped with two steam chests connected to the cylinder by four 12-in. pipes. The arrangement of the various pipes is shown in Figs. 2 and 7, half of them (two inlet and two exhaust) being arched above the turbine, the other half of them being correspondingly arched below the turbine, this arrangement eliminating unbalanced expansion thrusts on the cylinder. The two inlet chests are also interconnected by an arched 8-in. balance pipe. A 12-in. spring-loaded relief valve is attached to one of the exhaust steam chests and is set to operate at about 320 lb. per sq. in.

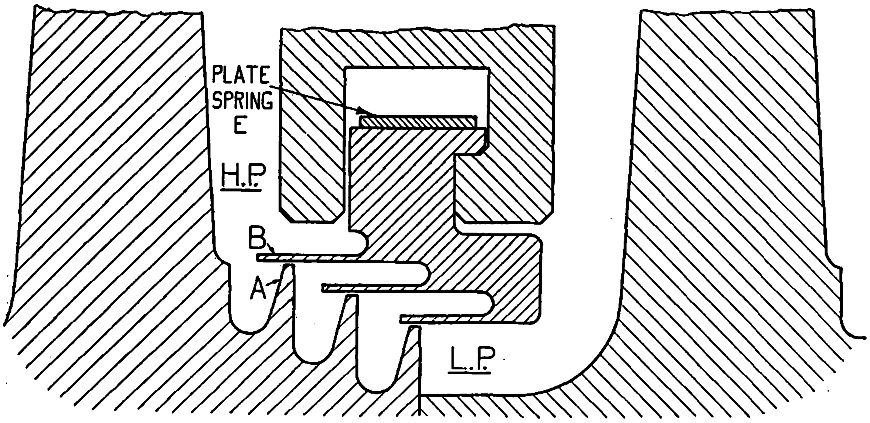

Fig. 20A.—Labyrinth packing.

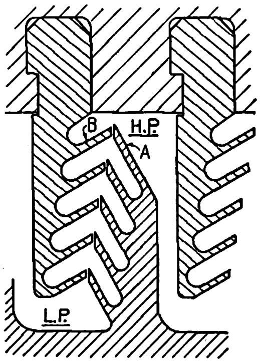

Fig. 20B.—High-pressure gland.

Diaphragms.—The question of expansion throughout these turbines was very exhaustively studied by the makers, and the various devices adopted to allow for such expansions have proved eminently satisfactory. Fig. 20A illustrates the labyrinth packing between the diaphragms. The latter consists of a number of projections " A " cut on the boss of the diaphragms. These projections almost touch a number of projections, " B," on the packing piece " C," which fits into a slot. The clearance space behind " C " is taken up by the spring " E." This device is also one for regulating the clearance and this is accomplished by virtue of the shape taken by the projections during expansion, the diaphragm projections lengthening while the packing-piece projections assume the shape shown in Fig. 20A. The clearance is thus always preserved. One of these packings is placed between each diaphragm, and 8 are placed together at the exhaust end of the turbine.

Glands.—The use of increased steam pressure, particularly in the case of large units, has resulted in radical changes in gland design. The disadvantage of some earlier types of labyrinth glands was that, in the event of rubbing of the faces, the resultant heating, with distortion of the faces, caused wear and decreased the gland efficiency.

The glands employed at both high-pressure and low-pressure ends of the turbines are so designed that, if rubbing should occur, the resultant distortion of the parts in contact causes the clearance to be increased automatically.

The glands at the high-pressure ends are of a special axial clearance type, illustrated in Fig. 20B. The projections "A" were made solid with the sleeve keyed to the main shaft, similar projections being cut on the packing piece "B" fitted into the turbine casing. A clearance is thus always maintained, since the projections on expanding tend to curve outwards from the clearance space, which tends therefore to become larger instead of smaller. This design enables a very large number of throttling joints to be provided in a given gland length, while the fitting of an adjustable thrust block of the Michell type permits the gland clearance to be most accurately adjusted to a working minimum while the set is in operation.

The glands at the low-pressure ends are of the standard radial comb type. External to the labyrinth glands on both h.p. and l.p. ends, water-sealed glands are provided to prevent leakage of steam to the turbine room, these glands also tending to cool the shaft near the bends.

Coupling.—The coupling used in this instance for coupling the turbine to the generator is known as the semi-flexible type. With its use the turbine and generator rotors may be balanced separately and when coupled together the degree of flexibility provided by the coupling allows their perfect individual balance to be maintained in operation. The coupling consists of a solid steel shell of corrugated section provided with flanges at each end for direct coupling to the ends of the turbine and generator shafts.

Steam Consumption.—The steam consumption guarantees of the high-pressure turbines are given in Table 8.

TABLE 8.

Turbine Steam Consumptions.

	Primary	Feed-heating	Condensing
Service rating (kW)	11 900	5 670	8 544
Service rating as a percentage of max. cont. rating	95·2	94·5	68·3
Stop-valve pressure (lb./sq. in. abs.)	644·7	289·7	289·7
Stop-valve temperature (° F.)	833	653	653
Superheat (° F.)	340	243	243
Exhaust pressure (lb./sq. in. abs.)	289·7	12·73	0·526
Exhaust temperature (° F.)	653	205	81·23
Steam flow (tonnes/day)	5 850	1 511	933
Steam flow (lb./hour)	538 000	139 000	86 800
Overall efficiency of turbo-alternator (per cent)	75·0	73·1	75·6
Total steam consumption at unity power factor (lb./kWh) ..	45·07	24·4	10·01

Feed-heating and Condensing Turbines.—These turbines are of standard construction and possess no unusual features. Their steam consumptions are also given in Table 8. The stages at which the former turbines are bled are given in Section 3 (*d*).

Turbine Governors.—The only governors which call for special comment are those controlling the steam admission to the primary turbines. With this class of turbine the inertia of the rotor is small in comparison with the power output, and consequently a heavy duty is imposed on the governor in the event of the alternator suddenly throwing off a heavy load.

For this reason the manufacturers have made these governors much quicker in operation than is usual on the more standard type of turbine; the responsiveness of these governors is about 10 times greater than that of ordinary turbine governors.

It is explained in Section (4) why it was necessary to design the primary governors with a speed regulation of 9 per cent in place of the more usual 3½ per cent. This characteristic necessitated raising the setting of the overspeed device from 10 per cent to 12½ per cent to avoid, as far as possible, the total shutting down of the turbine in the event of the alternator switch opening with the set carrying full load. It was considered that the increased margin of 3½ per cent as against 1 per cent would be sufficient to meet this case, in view of the high speed of operation of the governor itself.

The governor is of the vertical type, and there are no mechanical connections between it and the steam admission valves, the control of the steam admission being effected by means of an oil relay system. A relay valve mounted on the governor spindle controls the admission of oil under pressure to power pistons arranged on the steam admission valves and so controls their opening.

General.—Each alternator is also of standard design, with closed-circuit air-cooling system, and direct-coupled exciter with radial commutator. All turbines have duplicate oil coolers, and the condensing sets have duplicate air-ejector equipments. A complete set of instruments for each machine is grouped in compact systematic formation upon a vertical steel control board adjacent to the governor end of the machine.

(*d*) *Feed-Heating and Distillation Plants.*

(1) *Feed-Heating.*

The 3 single-cylinder 6 000-kW feed-heating turbines are bled after the 6th, 12th and 18th stages, the whole of the remaining steam being used in a lower-stage feed-heater and for the distillation of raw water in the evaporators.

The normal working conditions of these turbines are given in Table 9.

The condition of the steam leaving the turbine at the various stages is given in Table 11 at the end of Appendix 3.

Relief and non-return valves have been installed on all bled-steam connections from the turbine. No pressure regulators, however, have been employed.

Feed-Heaters.—The feed water passes through 7 heaters before entering the economizer. The first two heaters are situated in the distillation bay. The next four heaters are supplied with steam tapped from the feed-heating turbine and are of the vertical type with the tubes expanded into the tube plates at both ends. The last heater in the line (No. 7) is supplied with steam at 290 lb. per sq. in. and 653° F. The temperature of the feed water leaving this heater is 401° F.

Heaters Nos. 3, 4, 5 and 6 are situated as close to the turbines as possible in order to reduce the pressure-drop across the bled-steam pipes, and also to facilitate operation. In the event of the bursting of a tube, any heater can easily be bypassed, and the accumulated water in that case is automatically let down to the condensate tanks.

The heater extraction pumps are arranged on the separate drain-pump system. The steam water from each heater is pumped into the main feed line by its own extraction pump. As already stated, in the event of the bursting of a tube or the failure of the extraction pump or motors, the condensate is returned to the condensate tanks by virtue of the steam pressure in the heater.

The heaters supplied with steam from the turbine have their air vents connected to the preceding turbine bleeder connection. Since the amount of air-venting depends upon the amount of oxygen in the feed water, and as this amounts to only about 0·1 milligramme per litre, the air vents were purposely closed for long periods and then opened, when it was found that under the same steam and water conditions no appreciable temperature-rise across the heaters was to be observed.

Feed-Pumps.—The feed water, after being de-aerated and evaporated, emerges from the distillation plant to the feed-heating bay through No. 3 heater at a pressure of about 50 lb. per sq. in. and 197° F. The water then enters a 2-stage rotary pump " C " which discharges at a pressure of 130 lb. per sq. in. through Nos. 4 and 5 heaters (see Fig. 13). From No. 5 heater the water enters a 5-stage rotary pump " B," the discharge pressure of which is 200 to 450 lb. per sq. in., and the water continues through Nos. 6 and 7 heaters into the suction omnibus-main from which the high-pressure final boiler feed-pumps " A " are supplied. These pumps boost the feed-water pressure up to a normal value of 820 lb. per sq. in. (900 lb. per sq. in. max.). The intermediate feed-pumps (" B " and " C ") are driven by a common 450-b.h.p., 6 600-volt, 1 200-r.p.m., 3-phase motor. The speed of this motor is varied automatically from 400 to 1 200 r.p.m. by a liquid rheostat [see Section 5 (*c*)].

TABLE 9.

Working Conditions of Feed-Heating Turbine.

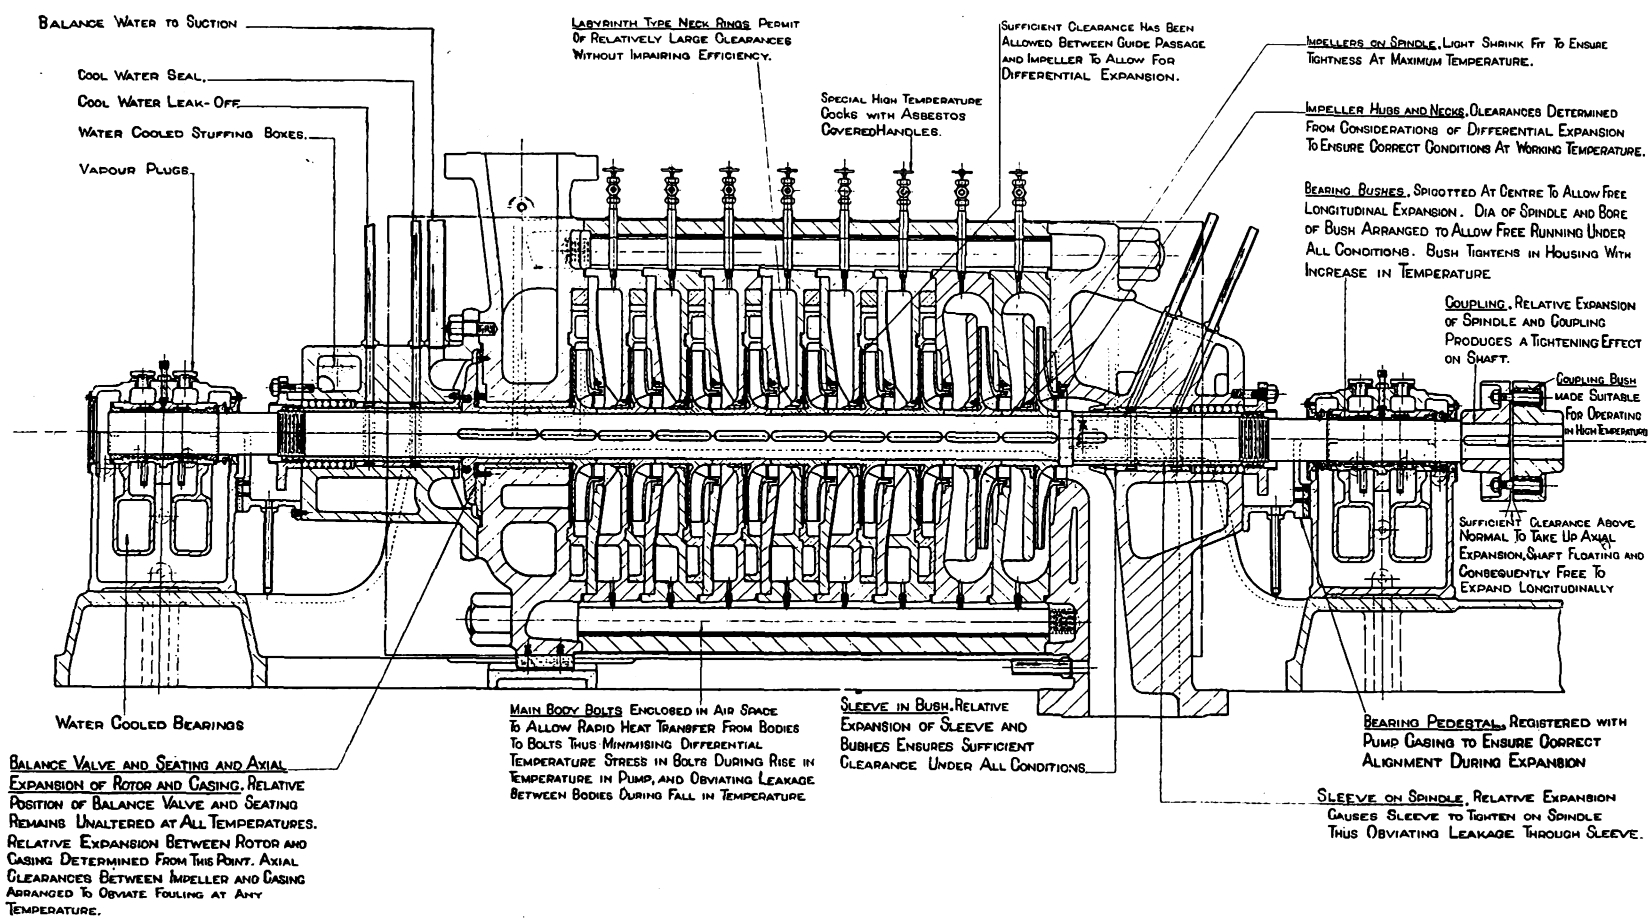
Steam to turbine	Electrical output	Input of raw water	Gained distillate	Condensate input to No. 3 heater	Condensate to boilers	Steam pressure after governor valve	Steam bypassed
tonnes/day 1 310	kW 4 750	tonnes/day 1 256	tonnes/day 1 138	tonnes/day 4 650	tonnes/day 5 950	lb./sq. in. abs. 220	tonnes/day nil

The high-pressure boiler feed-pumps " A " are 8-stage rotary pumps, driven by 900-b.h.p., 6 600-volt, 1 200-r.p.m., 3-phase motors. Each pump is capable of delivering 660 000 lb. of water per hour. As these pumps had to deal with water at 401° F., large clearances were necessary. Differential expansion of the various component parts of the pump was the subject of careful consideration. The cross-section of this pump shown in Fig. 21 reveals details of the means adopted to allow for expansion.

The bearings of the " A," " B " and " C " pumps are of the pedestal type with oiler-rings, all bearings and glands being water-cooled.

Two 6-stage sealing water pumps are installed in the feed-heating bay, each being driven by a 60-b.h.p. motor and having a capacity of 25 tonnes per hour. These pumps supply de-aerated water at 95° F. to the suction and delivery end sleeves and bushes of all feed and extraction pumps, the sealing water being returned to the process condensate tanks in the distillation bay.

Owing to the large amount of feed and ancillary piping in the feed-heating bay, and also because of the desire to place all main feed-pumps on the turbine floor-level, it was necessary to support these pumps by individual steel structures. To mitigate as far as possible all vibration troubles the foundations for these structures were isolated from the concrete basement



Balance Water to Suction
Cool Water Seal.
Cool Water Leak-Off.
Water Cooled Stuffing Boxes.
Vapour Plugs.
Labyrinth Type Neck Rings Permit Of Relatively Large Clearances Without Impairing Efficiency.
Special High Temperature Cocks with Asbestos Covered Handles.
Sufficient Clearance Has Been Allowed Between Guide Passage and Impeller To Allow For Differential Expansion.
Impellers on Spindle. Light Shrink Fit To Ensure Tightness At Maximum Temperature.
Impeller Hubs and Necks. Clearances Determined From Considerations of Differential Expansion To Ensure Correct Conditions At Working Temperature.
Bearing Bushes. Spigotted At Centre To Allow Free Longitudinal Expansion. Dia of Spindle and Bore of Bush Arranged to Allow Free Running Under All Conditions. Bush Tightens in Housing With Increase in Temperature.
Coupling. Relative Expansion of Spindle and Coupling Produces a Tightening Effect on Shaft.
Coupling Bush made Suitable For Operating in High Temperature
Sufficient Clearance Above Normal To Take Up Axial Expansion, Shaft Floating and Consequently Free To Expand Longitudinally
Water Cooled Bearings
Balance Valve and Seating and Axial Expansion of Rotor and Casing. Relative Position of Balance Valve and Seating Remains Unaltered at All Temperatures. Relative Expansion Between Rotor and Casing Determined From This Point. Axial Clearances Between Impeller and Casing Arranged To Obviate Fouling at Any Temperature.
Main Body Bolts Enclosed in Air Space To Allow Rapid Heat Transfer From Bodies To Bolts Thus Minimising Differential Temperature Stress in Bolts During Rise in Temperature in Pump, and Obviating Leakage Between Bodies During Fall in Temperature
Sleeve in Bush. Relative Expansion of Sleeve and Bushes Ensures Sufficient Clearance Under All Conditions.
Bearing Pedestal. Registered with Pump Casing to Ensure Correct Alignment During Expansion
Sleeve on Spindle. Relative Expansion Causes Sleeve to Tighten on Spindle Thus Obviating Leakage Through Sleeve.

FIG. 21.—Section of boiler feed-pump for 1 150 lb. pressure.

floor by an insertion of tar-macadam about 2 in. thick.

The axial thrust on the "A" and "B" pumps is taken by an hydraulically balanced sleeve. The jointing material between the middle bodies and the partition plates of these pumps consists of compressed asbestos fibre 0·008 in. thick.

A plan of the feed-heating bay is given in Fig. 5, this bay, together with the distillation bay, containing a total of 46 pumps.

(2) *Distillation.*

As already stated in the introductory remarks, about two-thirds of the total steam output from the boiler plant is passed out to the chemical plant for process purposes. About 60 per cent of the steam to process is returned to the process condensate tanks, and therefore it is necessary to "make up" the remaining 40 per cent. In order to keep the solids in the feed water down to 3 parts in 100 000 it was necessary to erect a distillation plant capable of evaporating the required amount of "make-up," approximately 3 000 tonnes per day under normal operating conditions. Of this quantity three-quarters is obtained from the quadruple-effect distillation sets, and the remainder from the sextuple-effect distillation sets.

Under conditions of maximum boiler load the output capacity of the entire distillation plant is between 7 000 and 8 000 tonnes per day, a figure which has probably never yet been exceeded in any boiler feed-water distillation plant.

The steam for this purpose is obtained from the feed-heating turbines. The raw water is obtained from a reservoir specially constructed on Billingham Beck, a small tributary of the River Tees. This reservoir is situated about ½ mile from the power plant, and two rotary pumps each capable of pumping 225 tonnes of water per hour, driven by 60-b.h.p. motors, are installed in a pump-house at the reservoir.

Each quadruple-effect distillation plant consists of six evaporators, two evaporators forming the first-effect, two forming the second-effect and the two remaining evaporators constituting the third- and fourth-effects respectively. Exhaust steam from the feed-heating turbine passes into the first-effect, heating the raw water supplied thereto. The vapour produced in this effect passes to the steam space of the next effect, where the process is continued in a similar manner.

Some of the vapour from the second-effect passes to the raw-water heater which heats the raw water before it enters the first- and second-effects. Another portion of the vapour from the second-effect goes to the process condensate (No. 2) heater and raises the temperature of the feed water to a predetermined value. The remainder of the vapour passes to the third-effect where the process is continued.

The vapour from the fourth—and last—effect goes to the raw-water de-aerator and to the process condensate de-aerator where the heat in the vapour is utilized in raising the temperatures of both the raw water supplied to the evaporators and the process condensate, or boiler feed, which passes into the feed-water system.

Each evaporator is fitted with a condensate drain from the steam header, this drainage water being flashed back to either the process condensate heater or de-aerator (see Fig. 13) from two flashing chambers or flash-boxes. A blow-down sludge-box is provided for each two evaporators, the sludge being discharged to waste whilst the vapour is led to the raw-water de-aerator.

The evaporators are of the horizontal-tube type, steam passing on the inside of the copper tubes and raw water on the outside. Large stuffing boxes are provided in one end tube-plate of each evaporator to allow the tubes to be withdrawn for the removal of scale.

The raw-water supply to the distillation plant is stored in two tanks having a combined capacity of 30 tonnes. The raw water flows by gravity through a preliminary heater incorporated in the raw-water de-aerator. When the water reaches the heating surface of the de-aerator it is heated to the boiling point equivalent to the pressure maintained in the water space and is then pumped to the evaporators.

The returned condensate from the factory and from the condensing turbines in the power plant is stored in three tanks having a combined capacity of 135 tonnes, which quantity can maintain the normal feed-water supply for nearly 3 hours. All the condensate is first de-aerated and then passes to No. 2 heater and then via Nos. 3, 4, 5, 6 and 7 heaters and the final feed pumps ("A") to the economizers.

The evaporators, etc., comprising the sextuple-effect distillation plant are similar to those in the quadruple-effect plant. When the first quadruple-effect plants were started up the demands for make-up water for the boiler feed were very heavy, and the plants while in operation were used continuously for prolonged periods. As this occurred in a very dry summer the quality of water supply was such that it was found expedient to change over to the supply from the district water board (Tees Valley) in order to maintain continuous maximum operation.

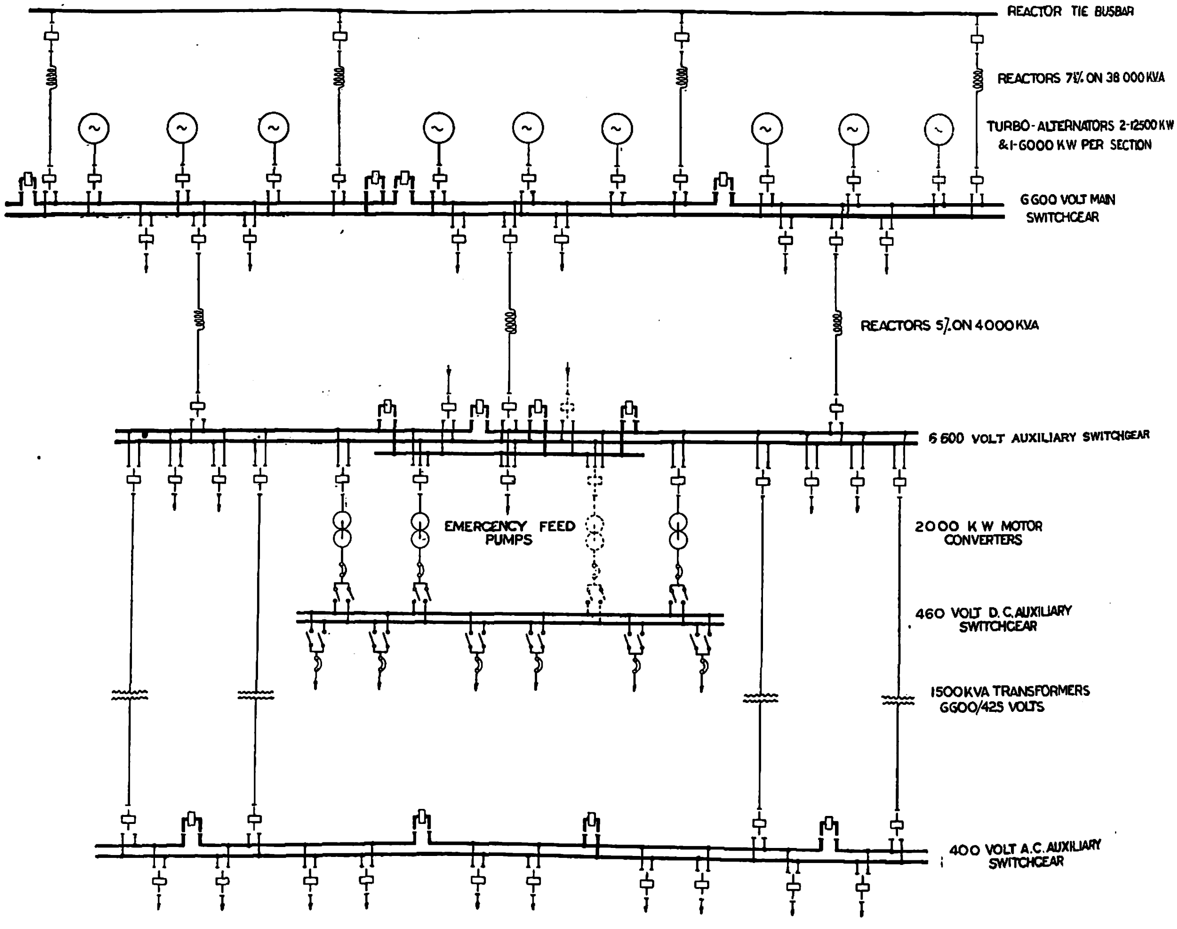
Investigations have been carried out in connection with pre-treatment of the raw water, whilst a method has been tried out, and found to be successful, whereby the plant can be expeditiously cleaned when required. As a result of these investigations it is expected that a return to the use of Billingham Beck water will shortly be made.

(*e*) *Switchgear.*

The arrangement of the main switchgear and reactors, the auxiliary e.h.t. and l.t. switchgear, and the auxiliary d.c. switchgear is depicted in diagrammatic form in Fig. 22.

(1) *Main Switchgear.*

This is situated on the same level as the turbines (Fig. 9) and consists of 56 panels of the metal-clad, compound-filled, double-busbar type, rated at 11 000 volts and remote-controlled electrically from the control room on the floor above. There are at present three sections, erected back to back, with a brick dividing-wall between, two sections being in the outer gallery, and the third section, with space for a fourth, being in the inner gallery. There is ample room between the back of the switchgear and the dividing wall, and the gallery floors slope gently downwards to a gravel-filled duct running along the foot of the outer wall of each gallery for the absorption of accidental oil leakage. The oil-vent bus-pipes terminate outside the building at each end and are also provided with drain cocks at suitable positions. The trifurcating boxes are mounted beneath the floor (i.e. on the roof of the 6-ft. high main cable race, Fig. 2) and are of the right-angle type, thus permitting a direct and very neat lead-away, horizontally, of the large number of heavy feeder cables out through the switch-house wall on to a steel bridge running the entire length of the switch house, at the same level as the emerging cables. All cables and pipes are carried on such bridges throughout the factory, buried cables being impracticable on such a congested site, quite apart from liability to attack by leakage of chemicals into the ground.



REACTOR TIE BUSBAR
REACTORS 7½% ON 38 000 KVA
TURBO-ALTERNATORS 2-12500 KW & 1-6000 KW PER SECTION
6600 VOLT MAIN SWITCHGEAR
REACTORS 5% ON 4000 KVA
6600 VOLT AUXILIARY SWITCHGEAR
EMERGENCY FEED PUMPS
2000 KW MOTOR CONVERTERS
460 VOLT D.C. AUXILIARY SWITCHGEAR
1500 KVA TRANSFORMERS 6600/425 VOLTS
400 VOLT A.C. AUXILIARY SWITCHGEAR

FIG. 22.—Arrangement of main and auxiliary switchgear.

The switchgear galleries extend over the railway running inside one end of the building, thus allowing switchgear to be lifted directly out of the trucks and up through a square opening in the floor of each gallery.

Each of the three sections is supplied by one primary set, one condensing set and one feed-heating set, totalling 31 000 kW at 6 600 volts, 40 cycles. The double-busbar switchgear in each substation is also divided into three sections, and is fed on the radial-feeder system by three feeders, any two of which are amply capable of carrying the full load of the substation continuously.

The main oil circuit-breakers have a rupturing capacity of 500 000 kVA, any fault being limited to this value by reactors between the sections, which are normally indirectly connected via these reactors and a common reactor tie busbar, but which can also be directly connected by section switches, overload-protected, in the event of the failure of a reactor. These main reactors consist of 3 single-phase open-type reactors of value $7\frac{1}{2}$ per cent on 38 000 kVA. They are mounted separately in brick cubicles, adjacent to the tie busbar switchgear, and occupy the whole of the outer gallery on the ground floor, the inner gallery containing the house-feeder reactors, the e.h.t. auxiliary switchgear and the neutral earthing resistance and its switchgear (see Fig. 10).

(2) *Auxiliary E.H.T. Supply* (6 600 *Volts*).

The auxiliary e.h.t. switchgear is also provided with duplicate busbars and is supplied from the main switchgear by three feeders, one on each section, through single-phase reactors, having a value of 5 per cent on 4 000 kVA, and of the same type and make as the main reactors.

The busbars are arranged in two sections with a transfer busbar common to both. In addition a third busbar, also common to both sections, is provided which is supplied direct from the Newcastle-upon-Tyne Electric Supply Co.'s 11 000-volt network through a 11 000/6 600-volt transformer as described in Section 5 (*a*). In this way an alternative supply is always available for the more important auxiliaries in the power station.

The auxiliary e.h.t. switchgear supplies, direct, the 6 600-volt motors driving the main and intermediate feed-pumps; the auxiliary l.t. switchgear through four 1 500-kVA, 6 600/400-volt transformers; and the auxiliary d.c. switchgear through three 2 000-kW 6 600/460-volt motor-convertors. It is situated on the ground floor of the switch house (Fig. 10) and is of the metal-clad, compound-filled, horizontal draw-out type. The oil circuit-breakers have a rupturing capacity of 100 000 kVA and are electrically operated from the control room.

(3) *Auxiliary L.T. Supply* (400 *Volts*).
